We present two MFP-based algorithms that localize multiple, extended scatterers placed in the near field of a receiver array. Furthermore, instead of independently radiating point sources, or sources with predetermined distribution characteristics, the radiators in this paper scatter the incident plane wave, and the physics of the multiple scattering is exactly accounted for using full scattering models. We have also determined geometries for which simpler forward scattering models can be utilized to reduce the computational complexity of the localization algorithm. At the end, we derive and verify the Cramer-Rao performance bounds for multiple, extended, near field objects.

We begin by describing a simple modification of the MUSIC algorithm in which the electromagnetic interactions between targets are ignored, and the problem is approached as if a number of spatially extended objects are independently scattering the incident electromagnetic field. While the resulting method has relatively low computational complexity, there are two issues in need of some analysis to characterize its performance. First, there is a signal coherence issue arising

from our frequency domain formulation of the problem. Second, it is necessary to determine in a quantitative manner conditions under which one may safely ignore the interactions among the scatterers. Both of these issues are addressed in Section 3.2.

In Section 3.3 we describe a second option for localizing multiple objects in which all multiple scattering effects are taken into consideration. While this approach is more computationally costly than the former, by modeling the non-trivial interactions of wavefields among scatterers, we improve our ability to resolve closely spaced scatterers. We demonstrate that this technique can easily localize the targets in geometries where the former approach fails to resolve the target positions.

Finally, we derive the Cramér-Rao bounds on variances of estimation errors for multiple object detection scenario. Our Cramér-Rao bound derivation adapts the results in [15], and accounts for near field observations. Analytical bounds of estimated object coordinates are then validated by running Monte-Carlo experiments for the estimator presented in this paper.

While our long term interests are in application of these ideas to the localization of buried objects (i.e. targets located in a halfspace), in this work, we concentrate on the simpler problem of localization when the objects are embedded in a homogeneous medium. It is our intent that the insight and experience gained from studying the homogeneous medium case will be of use when considering the more complicated half-space problem. Moreover, by considering this simpler physical problem, we are able to make extensive use of the T-matrix method [16–18] both in the localization algorithms as well as in the performance analysis. Indeed, the analytical structure of the T-matrix approach provides for the efficient computation of certain gradient information required for the method of Section 3.3 and for computing the Cramer-Rao bound in Section 4. Given the strong results in this paper, an interesting and non-trivial avenue of future research is the adaptation of the single object, half-space T-matrix approach of [19] to the multi-object

problem of interest here and the use of this forward model in an MFP-type inversion algorithm.

The remainder of the paper is organized as follows. In Section 2, we introduce the problem geometry and describe plane wave MUSIC. Section 3 is devoted to an exposition of the MFP-based algorithms. The Cramér-Rao lower bound is derived in Section 4. Numerical examples are presented in Section 5, and in Section 6, conclusions will be drawn.

2 Background

The measurement scheme depicted in Fig. 1 is considered in this paper. The objects are located in a background for which the constant electrical characteristics (relative permittivity and conductivity) are assumed known. A transverse magnetic (TM) polarized plane wave, $E_i(\mathbf{r})$, impinges on the objects, inducing surface and volume currents which in turn radiate a scattered field, $E_s(\mathbf{r})$ ¹. In this work, we are interested only in the object localization problem, thus material properties, shapes and the number of objects are assumed known.

The scattered electric field from N objects is spatially sampled by a uniformly spaced, linear array with M isotropic receivers, $M > N$. When the multiple scattering effects are taken into consideration, the measured data at the sensor outputs can be written as:

$$\mathbf{y} = \mathbf{A}_{ms}\mathbf{x} + \mathbf{n}, \quad (1)$$

where $\mathbf{A}_{ms} = [\mathbf{E}_{s1}(\mathbf{r}_1, \dots, \mathbf{r}_N) \ \mathbf{E}_{s2}(\mathbf{r}_1, \dots, \mathbf{r}_N) \ \dots \ \mathbf{E}_{sN}(\mathbf{r}_1, \dots, \mathbf{r}_N)]$ and $\mathbf{E}_{si}(\mathbf{r}_1, \dots, \mathbf{r}_N)$ denotes the scattered field observed at the array due to the i th object, in the presence of all other $(N - 1)$ scatterers, $i = 1, 2, \dots, N$. For time domain applications, the vector \mathbf{x} contains the narrow band time variations. Since we do our analysis in the frequency domain and suppress $e^{j\omega t}$, $\mathbf{x} = [1 \ 1 \ \dots \ 1]^T$. The i th column of matrix \mathbf{A}_{ms} depends not only on the position of the i th object, but also that of $(N - 1)$ other objects. Therefore, we may replace $\mathbf{A}_{ms}\mathbf{x}$ in (1) with $M \times 1$ vector

¹All analysis is in the frequency domain, thus the $e^{j\omega t}$ time dependence will be dropped.

$\mathbf{B} = \mathbf{E}_s(\mathbf{r}_1, \mathbf{r}_2 \cdots \mathbf{r}_N) = \mathbf{E}_{s1}(\mathbf{r}_1, \dots, \mathbf{r}_N) + \mathbf{E}_{s2}(\mathbf{r}_1, \dots, \mathbf{r}_N) + \dots + \mathbf{E}_{sN}(\mathbf{r}_1, \dots, \mathbf{r}_N)$, which denotes the total scattered field at the receiver array.

The recursive T matrix algorithm [16–18] is used to calculate the exact scattered field \mathbf{E}_{si} due to the i th object in the presence of other objects. The algorithm reported in [18] is designed for the efficient solution of near field scattering problems with heterogeneous collection of metallic and dielectric objects. In addition, using the recursive T-matrix algorithm the solution to the scattering problem can be written in a closed form. This property is especially useful in obtaining analytical expressions for gradients and derivatives in multi-dimensional parameter search in Section 3.3 and in Cramér-Rao bound analysis in Section 4.

Electromagnetic interactions between the objects may be ignored in favor of reducing the computational complexity of the localization process. For the method presented in Section 3.2, we use the same data model as in (1), except that the matrix \mathbf{A}_{ms} is replaced by

$$\mathbf{A}_{ss} = [\mathbf{E}_s(\mathbf{r}_1) \ \mathbf{E}_s(\mathbf{r}_2) \cdots \mathbf{E}_s(\mathbf{r}_N)]. \quad (2)$$

The $M \times 1$ vector $\mathbf{E}_s(\mathbf{r}_i)$ denotes the scattered field due to a single object located at \mathbf{r}_i , $i = 1, 2, \dots, N$, and it is calculated using the Mie series [20]. Therefore, each column of \mathbf{A}_{ss} contains the scattered field that is a function of position of only one particular object. In fact, in this definition of matrix \mathbf{A}_{ss} , each column is equivalent to those of \mathbf{A}_{ms} in (1) when all other scatterers are infinitely far away. The vector \mathbf{x} is the same as before, $\mathbf{x} = [1 \ 1 \cdots 1]^T$.

2.1 Review of Plane wave MUSIC

For plane wave MUSIC, the data model is in the following form:

$$\mathbf{y} = \mathbf{A}_{pw}\mathbf{x} + \mathbf{n}, \quad (3)$$

where $\mathbf{A}_{pw} = [\mathbf{a}(\theta_1) \ \mathbf{a}(\theta_2) \ \cdots \ \mathbf{a}(\theta_N)]$, and $\mathbf{a}(\theta_i) = [1 \ e^{jkd \cos \theta_i} \ e^{j2kd \cos \theta_i} \ \cdots \ e^{j(M-1)kd \cos \theta_i}]^T$.

Here $\mathbf{a}(\theta_i)$ is known as the direction vector, θ_i is the direction of arrival (DOA) of the i th plane

wave, k is the wave number in the medium of propagation, and d is the distance between two sensors. The experiment as represented by the data model in (3) is repeated many times in order to determine the statistics of \mathbf{y} . In particular, if L experiments are performed, then the maximum likelihood estimate of the spatial autocovariance matrix $\mathbf{R} = E\{\mathbf{y}\mathbf{y}^H\}$ is given by [4]:

$$\hat{\mathbf{R}} = \frac{1}{L} \sum_{l=1}^L \mathbf{y}_l \mathbf{y}_l^H \quad (4)$$

where \mathbf{y}_l is the data measured at the l th experiment, and superscript H denotes the complex conjugate transpose. The sample covariance matrix $\hat{\mathbf{R}}$ is used in MUSIC algorithm to separate signal and noise subspaces through the eigenspace decomposition [4]:

$$\hat{\mathbf{R}} = \hat{\mathbf{U}}_s \hat{\Lambda}_s \hat{\mathbf{U}}_s^H + \hat{\mathbf{U}}_n [\hat{\sigma}^2 \mathbf{I}] \hat{\mathbf{U}}_n^H \quad (5)$$

where $\hat{\mathbf{U}}_s$ is the estimated signal subspace matrix and contains the N signal eigenvectors, and $\hat{\mathbf{U}}_n$ is the estimated noise subspace matrix and contains $M - N$ noise eigenvectors of multiple noise eigenvalue $\hat{\sigma}^2$. The projection operator onto the noise subspace is defined as [4]:

$$\hat{\Pi}_n = \hat{\mathbf{U}}_n \hat{\mathbf{U}}_n^H. \quad (6)$$

The basic idea behind the planewave MUSIC algorithm is that the reciprocal of the “distance” between the estimated noise subspace and the true noise subspace has sharp peaks around the DOAs. Thus, if one plots this quantity versus all possible angles, estimates of DOAs can be determined by the maxima of the angular spectrum. The spatial spectrum of the MUSIC algorithm is given by [4]:

$$P_{MUSIC}(\theta) = \frac{\mathbf{a}(\theta)^H \mathbf{a}(\theta)}{\mathbf{a}(\theta)^H \hat{\Pi}_n \mathbf{a}(\theta)} \quad (7)$$

where $\mathbf{a}(\theta) = [1 \quad e^{jkd \cos \theta} \quad e^{j2kd \cos \theta} \dots e^{j(M-1)kd \cos \theta}]^T$ is the direction vector that accounts for a plane wave impinging on the array from the direction θ .

It is important to realize that the formulation of the array processing problem presented in this section implicitly assumes that the radiator is infinitely distant so that the scattered field has planar wavefronts at the sensor array. Thus, the elements of the direction vector $\mathbf{a}(\theta)$ are complex

exponentials indicative of plane wave signals. However in many applications, including near field object detection, the receivers are in the near-field region of the radiating sources, resulting in non-planar wavefronts. The target localization problem, therefore, not only requires the DOA relative to the array but also the range of the target from a point on the array.

3 Matched Field Processing for Object Localization

As mentioned in the introduction, matched field processing [6] uses the spatial complexities of the fields to localize sources in underwater acoustics. In a similar manner, plane wave MUSIC outlined in Section 2 can be modified so that the direction vector is filled with the type of the wavefront impinging on the array [2, 3, 8–10]. We divided this section into three parts. In the first part we will describe the single object localization. Even though single object localization is a subset of multiple object localization, we present it separately in order to explain the multiple object case clearly. The second part will deal with multiple objects, but the electromagnetic interaction between objects will be ignored. In the last part, we will treat multiple object detection problem when the multiple scattering effects are taken into account.

3.1 Single Object Localization

By using the spatial distribution of the scattered field, we can fill the direction vector in plane wave MUSIC with non-planar scattered fields to locate the near field objects. By modifying the spatial MUSIC spectrum in (7), we form the following spectrum:

$$P_{MUSIC}(r, \theta) = \frac{\mathbf{E}_s(r, \theta)^H \mathbf{E}_s(r, \theta)}{\mathbf{E}_s(r, \theta)^H \hat{\Pi}_n \mathbf{E}_s(r, \theta)} \quad (8)$$

where the new “direction” vector (actually, the *locus vector* in r and θ space) $\mathbf{E}_s(r, \theta)$ is now filled with the scattered field observed for an object located at $\mathbf{r} = (r, \theta)$. Then, the location $(\hat{r}, \hat{\theta})$ maximizing the MUSIC spectrum in (8) is selected as the estimated object center.

Because a two dimensional search requires that the exact scattered field be calculated at each point of the parameter mesh, this technique is in general computationally intensive. When the objects to be detected are modeled as simple shapes, computing the exact scattered field can be relatively simple. Here we consider the case of infinitely long cylinders so that the scattered field due to a plane wave can be calculated using the Mie series:

$$E_s(\rho, \phi) = \sum_{n=-\infty}^{\infty} c_n H_n^{(2)}(k\rho) e^{jn(\phi + \pi - \phi_{inc})} \quad (9)$$

where $H_n^{(2)}(.)$ is the Hankel function of the second kind of order n representing cylindrical outgoing waves, k is the wavenumber in the homogeneous, possibly lossy, background, and ϕ_{inc} is the incidence angle of the plane wave. The coefficients c_n are determined from the boundary conditions when ρ is equal to the radius of the cylinder. For computer implementations, the infinite sum in (9) is truncated at a finite value beyond which the coefficients c_n are below machine precision. Here ρ and ϕ denote the coordinates of the receivers since (9) assumes that the center of the cylinder is located at the origin. In implementing (8), translations from object-to-receiver coordinate system (ρ, ϕ) to array-to-object-position coordinate system (r, θ) are required. These translations do not significantly alter the computational load or functional form implied by (9).

Fig. 2(b) shows the MUSIC spectrum for a localization scenario when a small metallic object in 7.5 cm diameter is placed 15 cm below the array as depicted in Fig. 2(a). The 33-element linear, uniform receiver array spans an aperture of 1.5 meters. All sensors are assumed to be ideal, isotropic receivers. The operating frequency is 1.0 GHz and the plane wave is incident with 90 degrees. The lossy, homogeneous background has the same electrical characteristics of 5% moist San Antonio clay loam or 10% moist Puerto Rico clay loam ($\epsilon_b = 6\epsilon_0$, $\sigma_b = 5 \times 10^{-2} S/m$) at around 1.0 GHz [21]. The signal to noise ratio (SNR) is fixed at 0 decibels. As Fig. 2(b) depicts, the location of the object ($r = 15cm$, $\theta = 90^\circ$) is indicated with a very sharp peak. We note that

the prominent peak structure of the spectrum in this example is representative of a wide range of other cases for which the background electrical properties, target electrical characteristics and the signal to noise ratios are varied [2].

3.2 Multiple Object Localization: No Interaction

In this section, we describe multiple object localization assuming that the objects are located sufficiently far apart, so that the interactions among them can be ignored. For this case, multiple object localization is equivalent to having a superposition of cylindrical waves of the form in (9) incident on the array. Since the interactions are ignored, the scattered field due to one object is independent of the positions of the other objects, and thus we can use the single object localization approach described in previous section to search for multiple peaks in MUSIC spectrum given in (8) to determine positions of multiple objects. As in Section 3.1, the scattered field due to a single scatterer is calculated using the Mie series in (9), and a two-dimensional search is carried out to find N peaks corresponding to estimated target locations $(\hat{r}_1, \hat{\theta}_1), (\hat{r}_2, \hat{\theta}_2), \dots, (\hat{r}_N, \hat{\theta}_N)$.

The use of MUSIC in this manner raises two issues which are considered in the following paragraphs. First, because we are operating in the frequency domain, there are signal coherence difficulties which we address through the use of frequency diversity. The second issue is the need to develop a quantitative means of understanding the circumstances under which the no-interaction approximation is valid. In analyzing both of these issues, we present closed form analytical results valid for near field objects of infinitesimal radius and verify through numerical calculation that the insight provided by these expressions carries over for objects of finite size.

Because of the structure of \mathbf{x} in (1), the rank of $\mathbf{P} = E\{\mathbf{x}\mathbf{x}^H\}$, is one and so is the rank of \mathbf{R} . Thus, the signals impinging on the array are coherent. To increase the rank of \mathbf{R} (i.e. to decorrelate the signals) we repeat the scattering experiment as represented by (1) at N different frequencies

where N is the number of objects whose locations are to be determined. Thus (4) becomes:

$$\hat{\mathbf{R}}_i = \frac{1}{L} \sum_{l=1}^L \mathbf{y}_{li} \mathbf{y}_{li}^H \quad (10)$$

where \mathbf{y}_{li} is the l th data vector observed at the i th operating frequency, f_i , and $\hat{\mathbf{R}}_i$ is the spatial autocovariance matrix at f_i , $i = 1, 2, \dots, N$. Then, the rank enhanced autocovariance matrix $\hat{\mathbf{R}}_d$ is obtained by

$$\hat{\mathbf{R}}_d = \frac{1}{N} \sum_{i=1}^N \hat{\mathbf{R}}_i. \quad (11)$$

In Appendix A, we prove for $N = 2$ that in the limiting case of infinitesimal object radius, frequency diversity does, in fact, increase the rank of the autocovariance matrix $\hat{\mathbf{R}}_d$ to two. In addition, for objects with finite radii, we can computationally demonstrate that using frequency diversity we obtain a full rank autocovariance matrix. Having decorrelated the signals, the projector onto the noise subspace, $\hat{\Pi}_n$ in (8), is found from eigendecomposition of $\hat{\mathbf{R}}_d$.

While neglecting the interactions reduces the computational demand of localization considerably, it may introduce large estimation errors if the interactions are in fact sizeable. To analyze this issue we consider a scenario in which two objects are located a fixed distance beneath a receiver array and separated by a distance d .² We define the following normalized interaction term to measure the relative import of the multiple scattering between the two objects

$$\delta(d) = \frac{\|\mathbf{E}_{s1}^{(2)} - \mathbf{E}_{s1}\|_2^2}{\max_{d \in [d_{min}, d_{max}]} \|\mathbf{E}_{s1}^{(2)} - \mathbf{E}_{s1}\|_2^2} \quad (12)$$

where $\mathbf{E}_{s1}^{(2)}$ is the scattered field vector observed at the array due to the first object in the presence of the second object, \mathbf{E}_{s1} is the scattered field from the first object when there are no other scatterers, and d_{min} and d_{max} are limits over which we want to perform the analysis as dictated by the nature of the underlying application. In Appendix B we provide a closed form expression for δ in the case of two infinitesimally thin scatterers and show in Section 5.1, that (a) the δ for filamentary

²While not the most general setup, this configuration is representative of the types of application of interest in this paper (eg. mine detection) in which at most a couple of objects are in the array's field of view at about the same depth. Moreover, this simplified problem provides insight which may well be of use in more complex situations.

objects bounds those for the extended objects for a wide range of distances and (b) the error in the localization procedure tracks closely the value of δ . Thus, the expression in Appendix B can be used to determine the degree of interaction between two scatterers in terms of spacing and electrical properties of medium of propagation. By selecting a desired interaction level, we may calculate the minimum distance between scatterers that satisfy this a priori level. If for a given scenario we suspect that the actual distance is smaller than the minimum distance, then we should not ignore the interactions, and use the technique in Section 3.3 to localize the objects.

3.3 Multiple Object Localization: With Interaction

In this section, we describe multiple object localization using MUSIC when the electromagnetic interactions between objects are completely taken into consideration. In a sense, this is the multi-dimensional equivalent of single object detection where we aggregate all scatterers into one, large scatterer whose electrical characteristics are defined by the $2N$ co-ordinates of the individual objects. For object localization, then, we form the following MUSIC spectrum:

$$P_{MUSIC}(r_1, \theta_1, r_2, \theta_2, \dots, r_N, \theta_N) = \frac{\mathbf{E}_s(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N)^H \mathbf{E}_s(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N)}{\mathbf{E}_s(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N)^H \hat{\Pi}_n \mathbf{E}_s(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N)} \quad (13)$$

where $\mathbf{E}_s(\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_N)$ denotes the total scattered field due to objects located at $\mathbf{r}_i, i = 1, 2, \dots, N$ and is filled using the recursive T-matrix algorithm [16–18]. In order to find the positions of the objects, then, we perform a $2N$ -dimensional search in location space of all objects, $(r_1, \theta_1), (r_2, \theta_2), \dots, (r_N, \theta_N)$. The coordinates $(\hat{r}_1, \hat{\theta}_1), (\hat{r}_2, \hat{\theta}_2), \dots, (\hat{r}_N, \hat{\theta}_N)$ at which the spectrum (13) reaches maximum give us the estimated target locations. Finally we note that since there is only a single signal vector defined by the position of all the objects, we have no signal coherence issue here.

The computational complexity of this approach is considerably larger than the no interaction case for two inter-related reasons: the repeated use of the forward scattering model many times for the $2N$ -dimensional search, and the extra cost of taking electromagnetic interactions into account

in the exact forward model. To keep the computational load at reasonable levels, we used the recursive T-matrix algorithm given in [18] to calculate the scattered fields due to multiple objects. This variant of T matrix algorithm is specifically designed for the efficient solution of near field scattering problems involving heterogeneous collections of metallic and dielectric objects. Finally, to further reduce the computational load, we employ a variable step-size steepest ascent approach to maximize (13) which, for the problems of interest here typically converges to the neighborhood of the maximum in 7-10 iterations after which point we use a less costly simplex search [22] to locate the exact maximum. Explicit, closed form expressions for the gradient of the MUSIC spectrum with respect to the target coordinates are provided through the use of the T matrix forward model. The associated long and tedious formulae are provided in [23].

4 Cramér-Rao Performance Bounds on Object Localization

The Cramer-Rao Bound (CRB) provides very valuable information about the lower limit for the variance of any unbiased estimator. In order to find CRB, however, one should have a closed form expression of the log-likelihood function. In this section, we will extend the results in [15] to find the Cramér-Rao bounds for the near field, multiple object detection geometries. Since the additive noise in (1) is white and Gaussian, the log-likelihood function can be written as [15]:

$$\ln \mathcal{L} = \text{constant} - 2ML \ln \sigma - \frac{1}{\sigma^2} \sum_{l=1}^L [\mathbf{y} - \mathbf{A}_{ms} \mathbf{x}]^H [\mathbf{y} - \mathbf{A}_{ms} \mathbf{x}] \quad (14)$$

where σ^2 is the noise variance, M is the number of receivers and L is the number of data vectors used for estimating the covariance matrix $\hat{\mathbf{R}}$ in (4).

Given the log-likelihood function, the Fisher Information Matrix (FIM) can be written as:

$$\mathbf{J} = E\{\psi\psi^T\} \quad (15)$$

where $\psi = [\frac{\partial \ln \mathcal{L}}{\partial r_1} \frac{\partial \ln \mathcal{L}}{\partial \theta_1} \dots \frac{\partial \ln \mathcal{L}}{\partial r_N} \frac{\partial \ln \mathcal{L}}{\partial \theta_N}]^T$. The FIM is then expressed in matrix form as:

$$J = \begin{bmatrix} \Gamma_{r_1 r_1} & \Gamma_{r_1 \theta_1} & \cdots & \Gamma_{r_1 r_N} & \Gamma_{r_1 \theta_N} \\ \Gamma_{\theta_1 r_1} & \Gamma_{\theta_1 \theta_1} & \cdots & \Gamma_{\theta_1 r_N} & \Gamma_{\theta_1 \theta_N} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \Gamma_{r_N r_1} & \Gamma_{r_N \theta_1} & \cdots & \Gamma_{r_N r_N} & \Gamma_{r_N \theta_N} \\ \Gamma_{\theta_N r_1} & \Gamma_{\theta_N \theta_1} & \cdots & \Gamma_{\theta_N r_N} & \Gamma_{\theta_N \theta_N} \end{bmatrix} \quad (16)$$

where $\Gamma_{pq} = E[\frac{\partial^2 \ln \mathcal{L}}{\partial p \partial q}]$, $\{p, q\} = \{r_1, \theta_1, r_2, \theta_2 \dots r_N, \theta_N\}$. The entries of FIM are [15]:

$$\Gamma_{pq} = \frac{2}{\sigma^2} \sum_{l=1}^L \text{Re}\{\mathbf{x}^H \mathbf{D}_p^H \mathbf{D}_q \mathbf{x}\}, \quad (17)$$

where $\mathbf{D}_p = \frac{\partial \mathbf{A}_{ms}}{\partial p}$ and $\mathbf{D}_q = \frac{\partial \mathbf{A}_{ms}}{\partial q}$. The columns of matrix \mathbf{A}_{ms} contain the scattered fields as defined in (1), and since the scattered fields are calculated using the recursive T-matrix algorithm, derivatives of \mathbf{A} with respect to object positions, \mathbf{D}_p and \mathbf{D}_q , can be easily obtained [23]. Since \mathbf{x} is constant over L experiments, (17) can be further reduced to:

$$\Gamma_{pq} = \frac{2L}{\sigma^2} \text{Re}\{\mathbf{x}^H \mathbf{D}_p^H \mathbf{D}_q \mathbf{x}\}. \quad (18)$$

The Cramér-Rao bound by definition is, then, the inverse of the FIM:

$$\text{CRB}(r_1, \theta_1, \dots, r_N, \theta_N) = J^{-1}. \quad (19)$$

The i th diagonal entry in the Cramér-Rao bound expression in (19) gives the Cramér-Rao lower bound for the i th variable in the parameter set $\{r_1, \theta_1, r_2, \theta_2 \dots r_N, \theta_N\}$. In Section 5, we will verify the analytical expressions given by (19) with the Monte-Carlo simulated error variances.

5 Examples

In this section, we present numerical examples on localization of multiple objects and verification of Cramér-Rao lower bounds with Monte-Carlo simulations. In order to simplify the scattering phenomenon associated with the detection problem, the targets are modeled as simple, circular objects with diameters of 7.5 cm. The system parameters are kept constant throughout the examples to allow meaningful comparisons. The scattered field due to an incident plane wave is observed

along a 33-element, uniform, linear receiver array which spans an aperture of 1.5 m. The sensors are assumed to be ideal, isotropic receivers. Unless otherwise noted, the operating frequency is set to 1.0 GHz. The objects are placed in a lossy, homogeneous background which has the same electrical characteristics of 5% moist San Antonio clay loam ($\epsilon_b = 6\epsilon_0$, $\sigma_b = 5 \times 10^{-2} \text{S/m}$) at around 1.0 GHz [21]. In all examples the scattering simulations are repeated 250 times to estimate the autocovariance matrices, i.e. $L = 250$ in (4) and (10).

In order to show the performance of the algorithms, we consider two objects geometries. In the first case (Fig. 3(a)), the objects are located quite far from each other. For this object geometry, due to the lossy background, the interactions between the targets are very weak. In the second case (Fig. 3(b)), the objects are located closely, and the electromagnetic interactions between the objects are considerably stronger.

For the simulations, the definition of signal to noise ratio (SNR) is not obvious. In practical problems, SNR is imposed by the nature of the system noise. However, in computer simulations we want to reference the noise power to a fixed quantity that does not change as the positions of the objects change. For this purpose SNR is referenced to the scattered field strength of a single, cylindrical, metallic object placed at the same depth as the objects, in the same lossy medium. The radius of the reference scatterer is the same as the radii of the targets. With this definition, the noise power is always proportional to the power of reference scattered field.

5.1 Multiple Object Localization: No Interaction

As described in Section 3.2, all scatterers are assumed to be scattering the incident plane wave independently. Therefore, we used the Mie series to generate the MUSIC spectrum in (8). The issue of signal coherence is solved by using two operating frequencies, 1.0 and 1.2 GHz. The autocovariance matrix at each frequency is estimated using (10), and the full rank autocovariance

matrix is calculated using (11). For a wide range of target locations, we have verified that the autocovariance matrix $\hat{\mathbf{R}}_d$ has two distinct signal eigenvalues that are quite different from the noise eigenvalues. The order of magnitude difference, of course, depends on the signal-to-noise ratio. At the 20 dB SNR level used in this example, the smallest signal eigenvalue is approximately two orders of magnitude larger than the largest noise eigenvalue.

In Fig. 4, we plot the MUSIC spectrum in (8) for the case of well separated objects. As the figure depicts, the target locations are indicated by two peaks that are easy to distinguish from the background. The spectrum for the closely packed object case is shown in Fig. 5. It is clear from the figure that the no-interaction approach fails for this case. This is expected, since the no interaction model ignores the multiscattering effects that are very strong for closely spaced scatterers.

Since ignoring electromagnetic interactions may result in estimation errors, or even prevent resolution of targets as in Fig. 5, we investigated the interaction between two extended objects and compared the results with filamentary objects. Consider a problem where two objects are located 15 cm below the array. The position of one is kept fixed at (125, -15) cm (i.e. about 1/4 of the way from the right edge of the array) while the second is moved from left to right such that the inter-object distance, d , varies from eight centimeters to one meter. The interaction term given by (12) for both extended objects (computed using the T matrix method) and the filamentary objects (obtained from (28)) are shown as a function of d in Fig. 6(a). It is clear from this figure that for both extended and infinitesimally thin objects, the interaction terms decay very similarly.

The link between estimation error and object separation is shown in Fig. 6(b). A comparison of Figs. 6(a) and (b) reveals the expected result that both estimation errors and interaction terms decay as the objects are located farther apart. Figs. 6(c) and (d) show the same comparisons in (a) and (b) when the objects are located 25 cm below the array, further indicating that the

simple interaction term of Appendix B clearly provides a good measure of the level of interaction between extended objects, and one may use this simple interaction criterion to decide whether the no-interaction case would result in acceptable estimation errors. In fact, we can use Figs. 6(a) and (b) to estimate how the no-interaction case would perform for geometries given in Fig. 3. When the objects are 1 meter apart, Fig. 6 indicates that the interaction term is insignificant, so is the estimation error. As seen from Fig. 4, for this case the object centers are clearly defined by two peaks around the true center coordinates. When the objects are separated by 10 cm, however, there is a considerable electromagnetic coupling between objects, and the estimation errors are so large that the objects centers cannot be resolved as verified in Fig. 5.

5.2 Multiple Object Localization: With Interaction

We have applied the algorithm given in Section 3.3 to localize the targets for the two geometries: well separated and closely spaced objects. The signal to noise ratio is fixed at 20 dB and the autocovariance matrix, and the projection operator onto the noise subspace is calculated.

To determine the positions of the two targets, we searched for the maximum of the spectrum $P_{MUSIC}(r_1, \theta_1, r_2, \theta_2)$ given by (13) in $(r_1, \theta_1, r_2, \theta_2)$ space. To find this maximum we use the steepest descend algorithm described in Section 3.3. Fig. 7 shows the intermediate object positions at each iteration during the multi-dimensional search. The objects are located 1 meter apart, and the initial guesses are denoted with *'s³. Large circles indicate the support of the objects. Although not clear from this figure, as the number of iterations increase, the location estimates get closer to the true estimates at (25, -15) and (125, -15) cm. Fig. 8 shows the object positions at each iteration during the multi-dimensional search when the objects are closely spaced. The

³Here we have initialized the search method by hand to illustrate the manner in which the search process functions. As described below, to verify the Cramer-Rao bound analysis, we employ an automatic method for initializing the nonlinear optimization.

distance between the targets for this case is 10 cm. Again the initial guesses are indicated with *'s, and as the number of iterations increase, the location estimates get closer to the true estimates at $(70, -15)$ and $(80, -15)$ cm. For both cases, we observed that this approach quickly converges to the general maximum area in 7-10 iterations using the steepest decent algorithm. After the initial quick convergence, we switch to a simplex search [22] to locate the precise maximum.

5.3 Verification of Cramér-Rao bounds

In this section, we will compare the analytical Cramér-Rao bound results obtained in Section 4 with the Monte-Carlo simulated error variances. For this purpose, the algorithms described in Sections 3.1 and 3.3 are repeated 500 times at different signal to noise ratios. For each Monte-Carlo simulation, the multi-dimensional search routine requires initial values for the positions of the targets. Thus, to supply the algorithm with an initial value, we used the subarray processing method described in [1]. This approach can efficiently provide rough estimates of the object locations. Once we initialize the object positions with subarray processing, we perform the multi-dimensional search described in the previous section. The position vector maximizing the spectrum is declared as the position estimates and the error variances are calculated from the estimates.

Fig. 9 shows the comparison of analytical CRB calculated for single object geometry of Fig. 2 using (19) with 500 Monte-Carlo simulations of the algorithm described in Section 3.1. The solid line is the CRB for the radial position of the object and measured in squared meters. The dashed line denotes the CRB for the angular position and measured in squared radians. The radial and angular positions are referenced to the center point of the array. Monte-Carlo simulated error variances for range and bearing variables are shown on the same plot with \circ and \diamond symbols, respectively.

Fig. 10 compares the Cramér-Rao bounds with simulated error variances for multiple object geometries of Fig. 3 using the algorithm of Section 3.3. Fig. 10(a) shows the comparison for two

objects located one meter from each other, and Fig. 10(b) show the comparison when the objects are 10 centimeters apart. Again, the solid and dashed lines are the CRBs for radial and angular positions of the objects, respectively. The range variables have the unit of squared meters, and the bearing variables have the unit of squared radians. As before, both coordinate variables are defined with respect to the center point of the array. The symbols \circ and \diamond show the Monte-Carlo simulated error variances for the range and bearing variables, respectively. For this case, since there are two targets present in the region, there are two symbols at each SNR value. The problem geometry is symmetric, thus, one would expect that the error variances should be the same. Indeed, for analytical Cramér-Rao bounds calculated from (19), the bounds for coordinates of both objects are the same. For the simulated error variances, however, we can notice the different values for the range variables in Fig. 10(a) and for the bearing variables in Fig. 10(b). The difference in simulated variances pronounced for low signal to noise ratios, which, we believe, implies that more Monte-Carlo simulations are needed at those SNR values.

In both Fig. 9 and Fig. 10, we observe that the simulated error variances approach the lower limit provided by the Cramér-Rao bounds as the signal to noise ratio increases. This is expected by the results reported in [15] which states that MUSIC is an efficient estimator for large SNR values. The results presented here, therefore, reveal that at high signal to noise ratios MUSIC is an efficient estimator for near field object localization problems, too.

6 Conclusions

In this paper we presented a matched field based high resolution array processing technique for localization of near field targets. The algorithm is presented in three parts: single object localization, multiple object localization ignoring the interactions between objects, and multiple object localization taking multiple scattering into account. When the interactions are ignored,

the computational load is alleviated since the electromagnetic model is a simple Mie series, and a two-dimensional search in parameter space suffices to localize all objects. The drawbacks, on the other hand, are the necessity to take care of the coherent signal issue, and the failure to resolve and localize closely spaced targets. When the electromagnetic interactions are accounted for, these drawbacks are remedied, but the computational load due to multi-dimensional search, and complex, multiple scattering forward model increases.

We have also calculated the analytical Cramér-Rao bound expressions for coordinates of multiple objects when the interactions are taken into consideration. These lower bounds are then verified with Monte-Carlo simulated error variances. We have shown that as the signal to noise ratio increases, simulated error variances approach the lower limit set by the Cramér-Rao bounds.

In terms of future work, our primary interest is the extension of this method to three dimensional buried objects for problems in which the halfspace between the air and the earth is explicitly modeled. This will require the generalization of the single object, half-space T matrix method of Kristensson and Strom [19] to the multi-object case as well as the development of MFP-type methods which are built around this new forward model.

Appendices

A Frequency Diversity

In this appendix, we will show that under simplifying assumptions the frequency diversity described by (10) and (11) increases the rank of the autocovariance matrix. Consider the data model $\mathbf{y}_i = \mathbf{s}_i + \mathbf{n}_i$ where \mathbf{s}_i is the noise-free scattered field due to a scatterer at frequency f_i , \mathbf{n}_i is the white, Gaussian noise as before, and \mathbf{y}_i is the observed data vector at frequency f_i , $i = 1, 2, \dots, N$. To simplify the problem, we will assume that the number of scatterers is limited

to two ($N = 2$), and the scatterers are infinitesimally thin.

The exact expression for the rank enhanced autocovariance matrix, \mathbf{R}_d is:

$$\mathbf{R}_d = \frac{1}{2} \mathbb{E} \{ \mathbf{y}_1 \mathbf{y}_1^H + \mathbf{y}_2 \mathbf{y}_2^H \} = \frac{1}{2} [\mathbf{s}_1 \mathbf{s}_1^H + \mathbf{s}_2 \mathbf{s}_2^H + 2\sigma^2 \mathbf{I}]. \quad (20)$$

For two scatterers, the frequency diversity should ensure that the signal subspace of \mathbf{R}_d is two dimensional. To see the conditions for which the signal subspace of \mathbf{R}_d is two dimensional, we rewrite (20) as:

$$\mathbf{R}_d = \underbrace{\frac{1}{2} [\mathbf{s}_1 \mathbf{s}_2] \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \mathbf{s}_1^H \\ \mathbf{s}_2^H \end{bmatrix}}_{\mathbf{S}} + \sigma^2 \mathbf{I}. \quad (21)$$

For the signal subspace of \mathbf{R}_d to be two dimensional, the matrix \mathbf{S} should have rank two which is possible if vectors \mathbf{s}_1 and \mathbf{s}_2 are linearly independent. Since the maximum likelihood estimate of the rank enhanced autocovariance matrix $\hat{\mathbf{R}}_d$ in (11) is asymptotically equal to \mathbf{R}_d , the proof for \mathbf{R}_d is valid for $\hat{\mathbf{R}}_d$ for large snapshots, i.e. $L \rightarrow \infty$. In the rest of the appendix, we show that \mathbf{R}_d has a two dimensional signal subspace, by proving that \mathbf{s}_1 and \mathbf{s}_2 are independent.

For this purpose, we show that the scattered fields due to the filament scatterers observed at two points, A and B , in space at two distinct frequencies, f_1 and f_2 , are independent. Thus, the data vectors measured over an array at more than two points will also be independent. The general Mie scattering series given in (9), is reduced to the following expressions for filament scatterers:

$$\begin{aligned} E_{s1}^A &= c_0 H_0^{(2)}(k_1 r_A) & E_{s2}^A &= d_0 H_0^{(2)}(k_1 r_A) \\ E_{s1}^B &= c_0 H_0^{(2)}(k_1 r_B) & E_{s2}^B &= d_0 H_0^{(2)}(k_2 r_B) \end{aligned} \quad (22)$$

where r_A and r_B denote the observation points, coefficients c_0 and d_0 are dependent on the frequency and object properties, $H_0^{(2)}(.)$ is the zeroth order outgoing Hankel function, and k_i is the wavenumber at f_i , $i = 1, 2$. We will show that the vectors

$$\mathbf{s}_1 = \begin{bmatrix} E_{s1}^A \\ E_{s1}^B \end{bmatrix} \quad \text{and} \quad \mathbf{s}_2 = \begin{bmatrix} E_{s2}^A \\ E_{s2}^B \end{bmatrix} \quad (23)$$

are independent, i.e. equations

$$E_{s1}^A = \alpha E_{s2}^A \quad \text{and} \quad E_{s1}^B = \alpha E_{s2}^B \quad (24)$$

cannot be satisfied as long as $f_1 \neq f_2$.

Equations (22) and (24) imply that:

$$c_0 H_0^{(2)}(k_1 r_A) = \alpha d_0 H_0^{(2)}(k_2 r_A) \quad \text{and} \quad c_0 H_0^{(2)}(k_1 r_B) = \alpha d_0 H_0^{(2)}(k_2 r_B) \quad (25)$$

which can be written as

$$\gamma = \frac{\alpha d_0}{c_0} = \frac{H_0^{(2)}(k_1 r_A)}{H_0^{(2)}(k_2 r_A)} = \frac{H_0^{(2)}(k_1 r_B)}{H_0^{(2)}(k_2 r_B)}. \quad (26)$$

Properties of Hankel functions require that $|H_0^{(2)}(k_1 r)|$ and $|H_0^{(2)}(k_2 r)|$ are monotonically decreasing, and do not intersect at any r . These two properties and the fact that $H_0^{(2)}(k_1 r)/H_0^{(2)}(k_2 r)$ is not a constant imply that if we choose a γ such that $H_0^{(2)}(k_1 r_A) = \gamma H_0^{(2)}(k_2 r_A)$, then there would be no r_B which satisfies $H_0^{(2)}(k_1 r_B) = \gamma H_0^{(2)}(k_2 r_B)$ unless $k_1 = k_2$ and $\gamma = 1$. Therefore, the vectors in (23) are mutually dependent only when $k_1 = k_2$, i.e. $f_1 = f_2$.

B Bound on Electromagnetic Interactions

In this appendix, we derive the interaction terms between two infinitesimally thin scatterers. Using the definition of the interaction term in (12), we calculate the electromagnetic interactions between two infinitesimal scatterers here, and then compare these simple interaction terms with those of extended objects in Section 5.1.

First we derive the scattered field from two filamentary objects separated by a distance d , when they are excited with a plane wave, $e^{j\mathbf{k} \cdot \mathbf{r}}$. With a simple approach, schematically shown in Fig. 11, we account for the multiple scattering between these objects iteratively. The field scattered from the first object due to the plane wave is obtained by setting $n = 0$ in (9) and is $\mathbf{E}_{s1} = c_0 H_0^{(2)}(k|\mathbf{r}|)$ where c_0 depends on the object radius, and $|\mathbf{r}|$ is the distance between the scatterer and the receivers

in the array. Thus, the value of $\mathbf{E}_{\mathbf{s1}}$ at the location of the second object is $c_0 H_0^{(2)}(kd)$, where d is the distance between the two objects.

Still assuming no interaction, we use $c_0 H_0^{(2)}(kd)$ as incident field on the second object, and find the scattered field due to the wave scattered from the first object as: $\mathbf{E}_{\mathbf{s12}} = d_0 H_0^{(2)}(k|\mathbf{r}|)$ where $d_0 = c_0 [c_0 H_0^{(2)}(kd)]$. When this field arrives at the location of the first object, it becomes $d_0 H_0^{(2)}(kd)$. Using this as the incident field on the first object, we calculate the third term in our scattering series as $\mathbf{E}_{\mathbf{s121}} = e_0 H_0^{(2)}(k|\mathbf{r}|)$ with $e_0 = c_0 [d_0 H_0^{(2)}(kd)]$. By carrying no-interaction scattered fields between scatterers in this manner, the scattered field due to the first object, in the presence of the second is given in the form of an infinite sum:

$$\begin{aligned} \mathbf{E}_{\mathbf{s1}}^{(2)} &= \mathbf{E}_{\mathbf{s1}} + \mathbf{E}_{\mathbf{s12}} + \mathbf{E}_{\mathbf{s121}} + \mathbf{E}_{\mathbf{s1212}} + \dots \\ &= c_0 \left\{ 1 + c_0 H_0^{(2)}(kd) + [c_0 H_0^{(2)}(kd)]^2 + [c_0 H_0^{(2)}(kd)]^3 + \dots \right\} H_0^{(2)}(k|\mathbf{r}|). \end{aligned} \quad (27)$$

The difference between with-interaction and no-interaction fields can now be expressed as:

$$\mathbf{E}_{\mathbf{s1}}^{(2)} - \mathbf{E}_{\mathbf{s1}} = c_0 \{ c_0 H_0^{(2)}(kd) + [c_0 H_0^{(2)}(kd)]^2 + [c_0 H_0^{(2)}(kd)]^3 + \dots \} H_0^{(2)}(k|\mathbf{r}|),$$

which can be written concisely as:

$$\mathbf{E}_{\mathbf{s1}}^{(2)} - \mathbf{E}_{\mathbf{s1}} = \frac{c_0^2 H_0^{(2)}(kd)}{1 - c_0 H_0^{(2)}(kd)} H_0^{(2)}(k|\mathbf{r}|). \quad (28)$$

Expression in (28) is warranted since $|c_0 H_0^{(2)}(kd)| < 1$, where $c_0 = \frac{J_0(ka)}{H_0^{(2)}(ka)}$ and a is the radius of the object, $a < d$. Evaluation of (28) for \mathbf{r} equal to the positions of the receivers then provides the means of determining $\delta(d)$ in (12).

ABSTRACT

We consider the problem of detecting and localizing buried landmines from a ground penetrating radar (GPR) array. A simplified, ray-optics-based physical model for time domain GPR returns is presented. Under this model in the absence of an object from the field of view of the array, there exist well defined symmetries in the structure of the radar returns. In particular, for a bistatic system composed of one length M transmit array and a second length M array of receivers, we identify M subsets of signals from the M^2 total transmitter/receiver pairs such that the mean value of the signals within each subset should be the same when no object is present. This relationship then forms the basis for a modified Hotelling's T^2 -test to detect the presence of objects when there is noise in the signal. Simulation results demonstrate the validity of these methods.

1. INTRODUCTION

Mines kill or maim hundreds of people every week, mostly innocent and defenseless civilians. Among the various demining methods developed in recent years, ground penetrating radar (GPR) holds substantial promise because of its sensitivity to non-metallic, plastic objects which traditional metal detectors are largely incapable of finding. Nevertheless, using GPR to detect and localize mines is both difficult and complex. One key problem is the rejection of interference caused by the signal arising from scatter off the air-earth interface. Both the magnitude of the ground bounce and its timing are such that they can easily swamp the relatively small signal arising from the interaction of the transmitted GPR waveform with the buried mine. To help overcome this difficulty, we consider the use of a GPR array to provide a richer and more diverse set of data thereby making accurate detection and localization possible in circumstances where a single GPR is unable to perform well.

In this paper we discuss a method to detect mines which exploits both the physics of the problem as well as the geometry of the array system. We assume that the GPR array is deployed as shown in Fig. 3 with one linear array of transmitters and a second array of receivers both traveling down a track. As described in Section 3, the geometric symmetry inherent in this configuration introduces a “statistical symmetry” in the received signals. In particular, this symmetry is preserved precisely when there is no mine. On the other hand, the presence of a mine will break this symmetry and therefore provide information as to the existence of an object. Based on this relationship, we develop a statistical test of homogeneity to ascertain the presence of an object in the field of view of the array.

The organization of this paper is as follows. Section 2 introduces the physical model of GPR signals and the configuration of the GPR array. In Section 3 we present the detection algorithm, using a modified

form of Hotelling's T^2 -test. Examples are given in Section 4 to demonstrate validity of the algorithm. Section 5 summarizes present work and points out future research direction.

2. PHYSICAL MODEL AND PROBLEM FORMULATION

2.1. A Single GPR System

To detect and localize mines, a ground penetrating radar array is implemented. Fig. 1 shows a typical single GPR system with the signals it generates.¹ In this paper we assume a simplified model where the signal seen by the receiver is composed of at most two components. The first signal is the reflected signal from the ground and is always present in the data. The second component (if it exists) is the reflected contribution from an object in the field of view of the array.

Figure 1. Schematic drawing of a single GPR, transmitter and receiver.

The received signal, $\phi(t)$, is taken to be the sum of delayed and attenuated versions of two “template” signals indicating the nominal behavior of the ground bounce signal and the nominal behavior of a signal arising from scattering from a mine. Mathematically we have

$$\phi(t) = a\psi_g(t - \tau_g) + b\psi_m(t - \tau_m) \quad (1)$$

where ψ_g and ψ_m are the nominal ground bounce and mine reflected signal, a and b are attenuation factors, τ_g is the delay of the ground reflection, and τ_m is the delay of the mine signal. Note that if no mine is present, ϕ is just equal to the first term of (1).

To find the delays and the attenuation factors we assume that the propagation of the signal from the transmitter to the receiver can be described using a ray-optics-type model shown in Fig. 1. That is, the ground bounce is composed of signal reflected from the interface at the specular point midway between the transmitter and receiver while the four-part path of the mine component of the signal can be determined via the judicious use of Snell's law.

To begin, the τ_g and τ_m are determined by the travel time of two-way paths and can be calculated as

$$\text{Delay} = \frac{\text{2-way path length}}{\text{velocity of the wave}}. \quad (2)$$

To find τ_g and τ_m , we need to locate reflecting point and refracting point shown in Fig. 2. Let media 1 be air and media 2 be soil, with electric permittivity ϵ_0 and ϵ_1 , respectively, Fig. 2.(a), the reflecting point on the boundary between two points (x_1, y_1) and (x_2, y_1) in media 1 is simply the mid-point $(x_4, 0)$, where $x_4 = \frac{x_1 + x_2}{2}$.

Figure 2. Geometries for determining (a) the reflecting point and (b) the refracting point, $\epsilon_1 > \epsilon_0$.

For the refracting point, according to Snell's law, for a source located at (x_1, y_1) in media 1 and target at (x_3, y_3) in media 2, the refracted ray from source to target must intersect the boundary at a point $(x_5, 0)$, Fig. 2.(b), such that²

$$\frac{Re\{\epsilon_1\}}{\epsilon_0} = \frac{\frac{(x_1 - x_5)^2}{(x_1 - x_5)^2 + y_1^2}}{\frac{(x_3 - x_5)^2}{(x_3 - x_5)^2 + y_3^2}}. \quad (3)$$

Solution of this quartic equation has four roots. By Fermat's principle, which states that of all possible paths joining two given points on a wave path, the wave path has actual least travel time, we can discard three physically impossible roots and retain the true refracting point. Once the reflecting point and the refracting point are established, the delay τ_g and τ_m can be found as,

$$\tau_g = 2 \frac{\sqrt{(x_1 - x_4)^2 + y_1^2}}{c} \quad (4)$$

$$\tau_m = 2 \frac{\sqrt{(x_1 - x_5)^2 + y_1^2}}{c} + 2 \frac{\sqrt{(x_3 - x_5)^2 + y_3^2}}{c/Re\sqrt{\epsilon_1}} \quad (5)$$

where c is the speed of light in air and $\frac{c}{Re\{\sqrt{\epsilon_1}\}}$ is the speed of the wave in soil.

In addition to the time delays, the received signal $\phi(t)$ has an amplitude reduction caused by propagation through the soil as well as geometric spreading as it traverses both the air and the earth. In soil, the wave attenuates exponentially with the distance it travels, $e^{-\alpha_s d}$. The quantity α_s is the attenuation constant of the soil which is related to the conductivity and permittivity of the medium³ while d is the distance the wave travels in the earth. We assume geometric spreading results in an inverse path length amplitude reduction. Referring to the setup of Fig. 2, then we have the overall amplitude reduction factors given by

$$a = \frac{1}{2\sqrt{(x_1 - x_4)^2 + y_1^2}} \quad \text{and} \quad b = \left(\frac{e^{-\alpha_s \sqrt{(x_3 - x_5)^2 + y_3^2}}}{\sqrt{(x_1 - x_5)^2 + y_1^2} + \sqrt{(x_3 - x_5)^2 + y_3^2}} \right)^2.$$

2.2. GPR Array

In this work, the GPR array is assumed to consist of M pairs of transmitters and receivers. Data are collected by the GPR array as it travels step by step down track, Fig. 3. At each stop of the array, M^2 signals (time-traces) are collected; one for each transmitter/receiver pair.

Figure 3. Array of GPR, moves in x-direction(down-track).

Using the model developed in the previous section and assuming that the GPR array is at its k -th stop, the signal seen at receiver j due to input from transmitter i is written as

$$\phi_{ij}^k(t) = a_{ij}\psi_g(t - \tau_{g,ij}) + b_{ij}^k\psi_m(t - \tau_{m,ij}^k), \quad i, j = 1, \dots, M, \quad k = 1, \dots, K. \quad (6)$$

Note that a and τ_g do not depend on k , the down-track GPR array position. This is easy to understand because the ground-reflected signal only depends on the relative position of transmitter and receiver*. To simplify matters, in the future we use the following shorthand

$$g_{ij}(t) = a_{ij}\psi_g(t - \tau_{g,ij}) \quad s_{ij}^k(t) = b_{ij}^k\psi_m(t - \tau_{m,ij}^k).$$

Each $\phi_{ij}(t)$ is densely sampled P times over a time interval. The interval is chosen to be long enough to embrace both ground bounce and mine signal. When no ambiguity will arise, we refer to the vector of samples, $\underline{\phi}_{ij}^k$, rather than the temporal signal, $\phi_{ij}^k(t)$ with a similar interpretation holding for \underline{g}_{ij} and \underline{s}_{ij}^k . Note $\underline{\phi}_{ij}^k$, \underline{g}_{ij} , and \underline{s}_{ij}^k are column vectors of size P .

For a given location of the GPR array, to detect mines, we carry out a binary hypothesis test. Under the null hypothesis, H_0 , the received signal $\underline{\phi}_{ij}^k$ is comprised of ground bounce \underline{g}_{ij} plus measurement noise, which is assumed to be a white Gaussian vector, $\underline{w} \sim N(0, \sigma^2 \mathbf{I})$. Under the alternate hypothesis, H_1 , $\underline{\phi}_{ij}^k$ consists of ground bounce, noise, and mine signal, \underline{s}_{ij}^k . Mathematically we have

$$\begin{aligned} H_0^k : \quad & \underline{\phi}_{ij}^k = \underline{g}_{ij} + \underline{w} \\ H_1^k : \quad & \underline{\phi}_{ij}^k = \underline{g}_{ij} + \underline{s}_{ij}^k + \underline{w}. \end{aligned} \quad (7)$$

Our processing method is based on the observation that under H_0 , the M^2 received signal should display certain symmetries, as illustrated by Fig. 4. For example if no mine is present then $\underline{\phi}_{12}$ should be “statistically equal” to $\underline{\phi}_{21}$, $\underline{\phi}_{23}$, $\underline{\phi}_{32}$, $\underline{\phi}_{34}$, and $\underline{\phi}_{43}$ because the ground bounce in each case depends only on the relative spacing of the sensors which is identical for these six pairs. Similarly, $\underline{\phi}_{13}$ should be statistically equal to $\underline{\phi}_{31}$, and so on. By “statistically equal” we mean that any variations in these signal are caused by random sensor noise. In other words, signals from these sets will, on average, possess the same means with some variability (variance) caused by the noise. Thus statistical tests designed to determine homogeneity of a population (i.e. equality of mean vectors) can be used to test whether an object is present (lack of homogeneity) or absent (all the data vectors are about the same). Finally, for the M^2 received signals it is not hard to show that there are only M sets of statistically different signals because of this symmetry. Note the M sets of signals are not of equal size, some sets consist of more signals than the others.

*Here we are assuming that the ground is locally flat over the extent of the sensing system. Extension of the results in this work to smoothly changing ground is an area of current work.

Figure 4. Symmetry of GPR signals, 4 different path lengths are shown in solid line, dashed line, dashed-dot line, and dot line.

3. INFORMATION EXTRACTION ALGORITHM

From the above discussion, we know that if a mine is present, the symmetry of received signals will be disrupted. Therefore, to detect mines, we can look for asymmetry of received signals. Basically, our approach is to sequentially detect any changes in the means of the received signals. For the purpose of illustration, we use $M = 4$ pairs of transmitter and receiver. At each stop k of the GPR array, we then have 4 sets of statistically different signals, $S_1 = \{\phi_{11}^k, \phi_{22}^k, \phi_{33}^k, \phi_{44}^k\}$, $S_2 = \{\phi_{12}^k, \phi_{21}^k, \phi_{23}^k, \phi_{32}^k, \phi_{34}^k, \phi_{43}^k\}$, $S_3 = \{\phi_{13}^k, \phi_{31}^k, \phi_{24}^k, \phi_{42}^k\}$, and $S_4 = \{\phi_{14}^k, \phi_{41}^k\}$.

3.1. Homogeneity Test of Single Set

Here we discuss the homogeneity test of a single set, say $S_1 = \{\phi_{11}^k, \phi_{22}^k, \phi_{33}^k, \phi_{44}^k\}$. We consider the acceptance test of the hypothesis

$$H_0: \underline{\phi}_{ii}^k \text{ in the set are from same multivariate Gaussian distribution, with equal and known covariance matrices, and identical, unknown means, } i = 1, \dots, 4.$$

Because the test is identically the same at each stop k for the remainder of this subsection we drop the k notation.

As the problem currently stands, we do not assume that the ground bounce signals are known. In fact, a simple transformation of the data allows us to perform the test without ever having to know the ground bounces or estimate them. To see this, we begin by forming the collection of all pairwise differences of the signals within the set under consideration. For S_1 we get the set D_1 defined as

$$D_1 = \left\{ \phi_{11} - \phi_{22}, \phi_{11} - \phi_{33}, \phi_{11} - \phi_{44}, \phi_{22} - \phi_{33}, \phi_{22} - \phi_{44}, \phi_{33} - \phi_{44} \right\} \equiv \{\underline{\delta}_1, \underline{\delta}_2, \underline{\delta}_3, \underline{\delta}_4, \underline{\delta}_5, \underline{\delta}_6\}.$$

Testing H_0 using the original set of $\underline{\phi}_{ii}$ signals then is equivalent to testing the following hypothesis using the $\underline{\delta}_n$ vectors:

$$H'_0: \underline{\delta}_n \text{ in the set are from same multivariate Gaussian distribution, with equal and known covariance matrices and means equal to zero}$$

To test this equality of means, we carry out a Hotelling's T^2 -test.⁴ As described more fully in [5], this test amounts to the following comparison

$$\xi_1 = \sum_{n=1}^6 \frac{1}{2} \underline{\delta}_n^T \mathbf{R}^{-1} \underline{\delta}_n \leqslant threshold \quad (8)$$

with $\mathbf{R}(= \sigma^2 \mathbf{I})$ is the covariance matrix of the measurement noise and *threshold* is chosen to ensure an *a priori* specified probability of false acceptance. The hypothesis is accepted if the left hand side is less than or equal to *threshold* and rejected otherwise. Noting that \mathbf{R} is diagonal, we write ξ_1 as

$$\xi_1 = \frac{1}{2\sigma^2} \Phi_1^T \mathbf{A}_1 \Phi_1 = \frac{1}{2\sigma^2} \begin{bmatrix} \underline{\phi}_1^T & \underline{\phi}_2^T & \underline{\phi}_3^T & \underline{\phi}_4^T \end{bmatrix} \begin{bmatrix} 3\mathbf{I} & -\mathbf{I} & -\mathbf{I} & -\mathbf{I} \\ -\mathbf{I} & 3\mathbf{I} & -\mathbf{I} & -\mathbf{I} \\ -\mathbf{I} & -\mathbf{I} & 3\mathbf{I} & -\mathbf{I} \\ -\mathbf{I} & -\mathbf{I} & -\mathbf{I} & 3\mathbf{I} \end{bmatrix} \begin{bmatrix} \underline{\phi}_1 \\ \underline{\phi}_2 \\ \underline{\phi}_3 \\ \underline{\phi}_4 \end{bmatrix}. \quad (9)$$

For a set S_i of size N_i , it is easy to show that \mathbf{A}_i is an $N_i \times N_i$ block matrix. Its block diagonal elements are $(N_i - 1)\mathbf{I}_{P \times P}$ and the off diagonal elements are $-\mathbf{I}_{P \times P}$.

3.2. Homogeneity Test of Multiple Sets

For the application of interest in this paper, we have multiple sets (four for our sample system) for which we wish to test homogeneity. Here we adopt a simple, generalized form of the T^2 test in which the four ξ_i 's are weighted and added to yield one final test statistic,

$$\xi = \xi_1 \eta_1 + \xi_2 \eta_2 + \xi_3 \eta_3 + \xi_4 \eta_4. \quad (10)$$

The η_i are weight factors, defined by

$$\eta_i = \frac{1}{l_i} \left(\sum_{j=1}^4 l_j^{-1} \right)^{-1} \quad (11)$$

where l_j are the path lengths of ground bounces for set S_j . More will be said about this weight factor in Section 3.3. Stacking all the 16 signals ϕ_{ij} to form a long column vector, we obtain a new vector

$$\Phi^T = [\Phi_1^T \ \Phi_2^T \ \Phi_3^T \ \Phi_4^T]$$

and

$$\xi = \frac{1}{2\sigma^2} \Phi^T \mathbf{A} \Phi = \frac{1}{2\sigma^2} \begin{bmatrix} \Phi_1^T & \Phi_2^T & \Phi_3^T & \Phi_4^T \end{bmatrix} \begin{bmatrix} \mathbf{A}_1 \eta_1 & 0 & 0 & 0 \\ 0 & \mathbf{A}_2 \eta_2 & 0 & 0 \\ 0 & 0 & \mathbf{A}_3 \eta_3 & 0 \\ 0 & 0 & 0 & \mathbf{A}_4 \eta_4 \end{bmatrix} \begin{bmatrix} \Phi_1 \\ \Phi_2 \\ \Phi_3 \\ \Phi_4 \end{bmatrix}. \quad (12)$$

Matrix \mathbf{A} is a block diagonal matrix. Obviously, \mathbf{A} is symmetric. Note \mathbf{A} is positive semidefinite by its buildup. According to Mathai,⁶ the first two moments of ξ are given by,

$$\begin{aligned} \mu_\xi &= (6\eta_1 + 15\eta_2 + 6\eta_3 + \eta_4)P \\ \sigma_\xi^2 &= (24\eta_1^2 + 90\eta_2^2 + 24\eta_3^2 + 2\eta_4^2)P.^\dagger \end{aligned} \quad (13)$$

It has been shown that ξ asymptotically has a Gaussian distribution⁶ for large NP , i.e., $\xi \sim N(\mu_\xi, \sigma_\xi^2)$. The generalized T^2 -test amounts to $\xi \leq \alpha$ where α is the threshold chosen to ensure an *a priori* specified probability P_{fa} of false acceptance. The α is determined by

$$P_{fa} = \int_{\alpha}^{\infty} \frac{1}{\sqrt{2\pi\sigma_\xi^2}} e^{-\frac{(\xi-\mu_\xi)^2}{2\sigma_\xi^2}} d\xi. \quad (14)$$

3.3. Sequential Detection

Now we consider the actual GPR array operation as the array moves down-track. At each stop k , we calculate a corresponding ξ^k . When there is no mine in the field of view of the array, we record ξ^k only. That is, $\nu^k = \xi^k$ under hypothesis H_0 . When there is a mine, the mine signal \underline{s}_{ij}^k adds to the ground bounce. Passing \underline{s}_{ij}^k to the generalized Hotelling's T^2 -test produces an output signal, denoted by ζ^k . So the problem is to detect signal ζ^k , given the observed signal sequence ν^k and known "noise" ξ^k , using the additive noise model $\nu^k = \xi^k + \zeta^k$ under the alternate hypothesis H_1 . Though ζ^k is unknown and changes with k , it is always *positive* because of the very nature of quadratic form of the generalized T^2 -test. Fig. 5 shows separate ξ_i^k and $\xi_i^k + \zeta_i^k$. Signals on the left side of Fig. 5 are typical "noise" sequences, taken from four different sets of transmitter-receiver combinations. Signals on the right side are "noise" and mine signals, corresponding to the respective sets of transmitter-receiver combinations. It is seen that ζ_i^k are much weaker in set S_3 and S_4 . This observation can be explained by the increased attenuation associated with the longer distances the mine signals in sets S_3 and S_4 travel. For this reason, we introduced the weight factors in Eq. 11.

When the mine is buried deep, the mine signal attenuates exponentially as explained in Section 2.1. Detecting this unknown low power signal can be aided quite a bit using sequential detection methods which retain information from previous scans to improve the SNR. We therefore employ a sequential detector as the GPR array moves down track. At each stop k , the detector makes one of two decisions⁷: (1) Hypothesis H_0 is true, no mine signal is present, (2) Reject H_0 . Because ζ^k causes a positive displacement of the mean of ν^k , we choose a running average of ν^k as a statistical test^{8,9}

$$g^k = \frac{1}{N} \sum_{j=k-N+1}^k \nu^j, \quad k = N, N+1, \dots, K \quad (15)$$

and make a decision by checking $g^k \leq \beta$ where β is a threshold. At each stop k , g^k is compared to the threshold to make a declaration of mine presence. Fig. 6 illustrates relationship between threshold settings and declaration of mine presence as the GPR arrays move down-track. Each filled dot indicates a location of the array where we say that a mine is present. Such a declaration is made when g^k is above the threshold for consecutive 5 stops of k . A lower threshold allows us to make early declaration of mine. The disadvantage is a high false-acceptance rate. The false-acceptance probability P_{fa} equals the probability under hypothesis H_0 that the g^k crosses the threshold. The detection probability P_d equals to $1 - P_{fa}$. By virtue of the generalized T^2 -test, ν^k are statistically independent. Hence, g^k has the Gaussian distribution, $N(\mu_\xi, \frac{1}{N}\sigma_\xi^2)$. Thus, in principle, for a given P_{fa} , β can be determined similarly as in Eq. 14.

[†]See appendix

Figure 5. First row of figures corresponds to the T^2 statistic for set S_1 , the left figure is “noise” only, the right figure has both “noise” and mine reflected signal, second row of figures corresponds to set S_2 , third row of figures corresponds to set S_3 , and, fourth row of figures corresponds to set S_4 .

Figure 6. Detection results versus prescribed false alarm probability, P_{fa} . Note that lower P_{fa} results in slower detection while a higher allowable false alarm rate allows for detection prior to the array passing over the mine.

4. EXAMPLES

In this section we consider some examples of the above procedure. Monte-Carlo runs were used to determine the probability of detection and probability of false-alarm for various noise levels and depth of buried mines. In this work, the signal to interference plus noise ratio is defined as

$$\text{SINR} = 10 \log_{10} \frac{\underline{s}^T \underline{s}}{\underline{g}^T \underline{g} + P\sigma^2}. \quad (16)$$

In all cases, we generate synthetic data with an object located around the 50th stops of the GPR array and buried 10 cm underground. The GPR array is composed of four pairs of transmitters and receivers evenly spaced along a baseline width of 80 cm. A transmitter and its corresponding receiver (e.g. transmitter 1 and receiver 1) are 20 cm apart. The GPR array is 40 cm above the ground. For simplicity we assume that the nominal ground bounce and mine-bounce signal take the form of a second derivative of a Gaussian shown in Fig. 7(a). Current work in our group is aimed at developing more sophisticated models for these signals. Fig. 7(b) and (c) show the received signals of two pairs of T/R combinations. Because of the domination of the ground bounce, it is difficult to see any mine signature. Even after pairwise subtraction, the mine signal can hardly be observed in Fig. 7(d). But the generalized T^2 -test can pick up this difference and declare a mine.

Fig. 8(a) shows the receiver operating characteristics of detecting a mine buried 10 cm underground. Fig. 8(b) shows two ROC's for mines buried at different depth under the same noise power. Because of the fast attenuation in soil, the deeper buried mine has a significantly smaller SINR thereby leading to the degradation in performance.

5. CONCLUSIONS AND FUTURE WORK

In this paper, we discuss a statistical approach to detect mines using a GPR array. Exploiting the geometric symmetry of GPR array setting, we have looked into tests for statistical homogeneity of GPR returns as a tool for performing detection. Basically, by treating the received signal as a multivariate Gaussian distribution we test its statistical homogeneity using a generalized, sequential Hotelling's T^2 -test.

Future work will take into consideration of rough ground-air interface and time-delay estimation to actually localize detected mines. An assumption of this work is that the soil conditions are known. Sensitivity analysis involving mismatch in soil parameters will be valuable to apply this method to realistic scenario. Moreover, the additive white Gaussian noise mode will be lifted as we explore issues associated with the modeling of clutter, the incorporation of these models into our processing, and the development of test which are robust (or invariant) to uncertainty in these models.

6. APPENDIX

From Mathai's⁶ work, for $\mathbf{X} \sim \mathbf{N}(\mu, \Sigma)$, the first two moments of quadratic $\mathbf{X}^T \mathbf{A} \mathbf{X}$ can be found by

$$\begin{aligned} E[\xi] &= \text{tr}(\mathbf{A}\Sigma) + \underline{\mu}^T \mathbf{A} \underline{\mu} \\ \text{Var}[\xi] &= 2\text{tr}(\mathbf{A}\Sigma)^2 + 4\underline{\mu}^T \mathbf{A} \Sigma \mathbf{A} \underline{\mu}. \end{aligned} \quad (17)$$

For the generalized T^2 -test, we have

$$\underline{\mu}^T = \left[\underline{\mu}_{11}^T, \dots, \underline{\mu}_{44}^T, \underline{\mu}_{12}^T, \dots, \underline{\mu}_{34}^T, \underline{\mu}_{13}^T, \dots, \underline{\mu}_{24}^T, \underline{\mu}_{14}^T, \underline{\mu}_{41}^T \right] \quad (18)$$

(a) Received signal, the second order derivative of a Gaussian.

(b) Time trace of ϕ_{11}

(c) Time trace of ϕ_{22}

(d) Difference of time traces, $\phi_{11} - \phi_{22}$,
SINR = -11 dB.

Figure 7. Received signal and time traces.

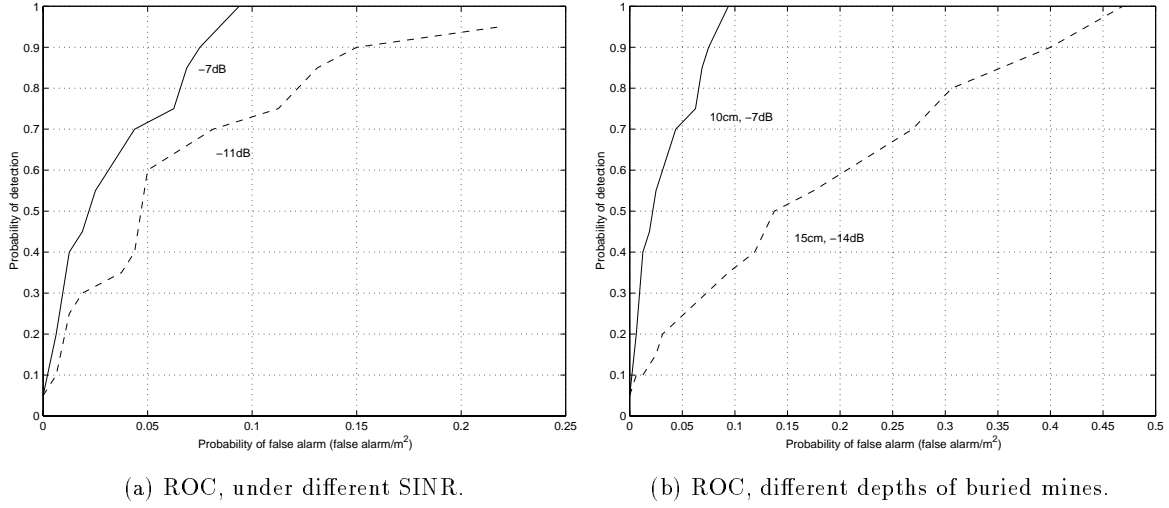

Figure 8. Receiver operating characteristics.

where

$$\begin{aligned}
 \underline{\mu}_{11} = \dots = \underline{\mu}_{44} &\equiv \underline{\mu}^{(1)} & \underline{\mu}_{12} = \dots = \underline{\mu}_{34} &\equiv \underline{\mu}^{(2)} \\
 \underline{\mu}_{13} = \dots = \underline{\mu}_{24} &\equiv \underline{\mu}^{(3)} & \underline{\mu}_{14} = \underline{\mu}_{41} &\equiv \underline{\mu}^{(3)}.
 \end{aligned} \tag{19}$$

Next, we note that $4\underline{\mu}^T \mathbf{A} \Sigma \mathbf{A} \underline{\mu} = 0$ under the condition of Eq. 19,

$$4\underline{\mu}^T \mathbf{A} \Sigma \mathbf{A} \underline{\mu} = 4 \sum_{i=1}^4 \underbrace{\begin{bmatrix} \underline{\mu}^{(i)T} & \dots & \underline{\mu}^{(i)T} \end{bmatrix}}_{N_i} \mathbf{A}_i \Sigma \mathbf{A}_i \begin{bmatrix} \underline{\mu}^{(i)} \\ \vdots \\ \underline{\mu}^{(i)} \end{bmatrix} \tag{20}$$

where

$$\begin{bmatrix} \underline{\mu}^{(i)T} & \dots & \underline{\mu}^{(i)T} \end{bmatrix} \mathbf{A}_i = 0 \tag{21}$$

because of the semidefiniteness of \mathbf{A}_i . Similarly, $\underline{\mu}^T \mathbf{A} \underline{\mu} = 0$. The mean of ξ is then given by $\frac{1}{2\sigma^2} [tr(\mathbf{A} \Sigma)]$. For $\mathbf{A} = \text{block diag} \{ \mathbf{A}_1 \eta_1, \mathbf{A}_2 \eta_2, \mathbf{A}_3 \eta_3, \mathbf{A}_4 \eta_4 \}$ we have

$$E[\xi] = \frac{1}{2\sigma^2} tr(\mathbf{A} \Sigma) = \frac{1}{2} \sum_{i=1}^4 N_i (N_i - 1) P \eta_i. \tag{22}$$

Additionally $\mathbf{A} \mathbf{A} = \text{block diag} \{ \mathbf{A}_1 \mathbf{A}_1 \eta_1^2, \mathbf{A}_2 \mathbf{A}_2 \eta_2^2, \mathbf{A}_3 \mathbf{A}_3 \eta_3^2, \mathbf{A}_4 \mathbf{A}_4 \eta_4^2 \}$ where

$$\mathbf{A}_i \mathbf{A}_i = \begin{bmatrix} (N_i^2 - N_i) \mathbf{I} & -N_i \mathbf{I} & \dots & -N_i \mathbf{I} \\ -N_i \mathbf{I} & (N_i^2 - N_i) \mathbf{I} & \dots & -N_i \mathbf{I} \\ \dots & \dots & \ddots & \dots \\ -N_i \mathbf{I} & -N_i \mathbf{I} & \dots & (N_i^2 - N_i) \mathbf{I} \end{bmatrix}. \tag{23}$$

Here \mathbf{I} is of size $P \times P$ and \mathbf{A}_i is of size $N_i P \times N_i P$. We then have

$$tr(\mathbf{A}_i)^2 = (N_i^2 - N_i)N_i P \quad tr(\mathbf{A})^2 = \sum_{i=1}^4 tr(\mathbf{A}_i)\eta_i^2 = \sum_{i=1}^4 (N_i^2 - N_i)N_i P \eta_i^2.$$

so that $Var[\xi] = \frac{1}{4\sigma^4} 2tr(\mathbf{A}\Sigma)^2 = \frac{1}{2} \sum_{i=1}^4 (N_i^2 - N_i)N_i P \eta_i^2$.

Nonlinear inverse scattering methods for thermal wave slice tomography

by Eric Miller¹, Lena Nicolaides² and Andreas Mandelis²

¹Dept. Electrical and Computer Engineering, Northeastern University, Boston, MA 02215, USA; ²Photothermal and Optoelectronic Diagnostics Laboratories Dept. of Mechanical Engineering, Univ. of Toronto, Toronto M5S 3G8, CANADA

Abstract

A wavelet domain, non-linear inverse scattering approach is presented for imaging sub-surface defects in a material sample based on observations of scattered thermal waves. We use newly developed wavelet-based regularization methods to resolve better the edge structures of defects relative to reconstructions obtained with smoothness-type regularizers. A non-linear approximation to the exact forward scattering model is introduced to simplify the inversion with little loss in accuracy. We demonstrate this approach on cross-section imaging problems using synthetically generated scattering data from transmission and backprojection geometries.

Keywords: Thermal wave slice tomography, inverse scattering, wavelet transform, edge preserving regularization

1. Introduction

Thermal wave slice tomography (TWST) has evolved in recent years as a useful tool for non-invasively imaging and detecting defects in the bulk properties of a material sample [1, 2]. This non-destructive evaluation (NDE) technique makes use of a modulated laser source illuminating an external surface of the material under test to induce internal thermal waves. Interaction of the thermal wave field with material inhomogeneities gives rise to scattered fields which propagate and are ultimately measured at the surface of the material. The problem of interest in this paper is, given knowledge of the applied thermal wave field and the observed scattered fields, to produce a reconstruction of the internal structure which reproduces as faithfully as possible features of interest such as defects.

The techniques we use to solve this inverse problem are based on the results of Mandelis who has shown that the thermal wavefield obeys a scalar Helmholtz equation with a complex valued, space varying propagation constant [3]. The spatial structure of this constant is related to the thermal diffusivity of the material. Because defects are reflected in changes in the thermal diffusivity, a reconstruction of the propagation constant, or a normalized form known as the object function [1], yields quantitative information about the material's bulk structure.

In this work, we extend the use of linearized wavefield inversion methods initially developed in [1, 2] for the TWST problem in a number of ways. First, a full, non-linear inverse scattering approach is used to generate the reconstruction. The resulting inversion method is iterative in nature and may allow for the more accurate reconstruction of defects whose structure falls outside of the bounds where the Born approximation is valid. We also build on our previous efforts in wavelet-based non-linear inverse scattering techniques [4, 5]. First, the TWST inverse problem is highly ill-posed in the sense discussed in [6]. That is, small perturbations in the data, as would come from noise, can result in reconstructions with high amplitude, oscillatory structure. We introduce and demonstrate the utility of a class of wavelet regularization schemes which are appropriate for the reconstruction of objects (defects) with sharply defined boundaries. Tikhonov type regularizers typically are designed to produce smooth, low-pass reconstruc-

tions which blur important features such as edges in the image [6]. Using certain mathematical results stating that wavelets are bases for a wide range of function spaces including spaces containing “edgy” objects [7], we develop a new scale-space regularization method which produces significantly sharper reconstructions.

Additionally, we employ wavelet methods to lower the computational burden of the inversion procedure. The wavelet transform is known to make sparse the matrix representations of many integral operators including those arising in the TWST scattering problem [8]. Thus, a transform domain formulation can build on this sparsity to reduce the computational burden of generating a reconstruction. We also develop a wavelet-based, reduced complexity approximation to the forward TWST problem. At each stage of the iterative solution method we must compute explicitly the inverse of a large, dense matrix, a computationally intensive task. This matrix is related to the solution of the thermal-wave forward scattering problem for an object function equal to the reconstruction obtained at the previous iteration plus a small correction. By linearizing the expression for this matrix about this correction we obtain a recursive formula in which the inverse matrix at the current iteration is equal to the one from the last iteration plus an easily-constructed increment due to the change in the material properties.

The remainder of this paper is organized as follows. In Section 2. the mathematical model for the TWST problem is defined. Section 3. is devoted to the application of the wavelet transform to the TWST problem. The non-linear inverse scattering algorithm is developed in Section 4. with examples of its application to synthetic problems provided in Section 5.. In Section 6., conclusions are discussed.

2. Physical Model for TWST

As illustrated in *Fig. 1*, we consider TWST problems in which a modulated laser illuminates a point at the top of the material sample inducing thermal waves in the bulk. Upon scattering from inhomogeneities, whose spatial structure is defined by the real-valued object function the field is measured along an array of points either at the top (backpropagation geometry) or the bottom (transmission mode). The inversion routines are based on K such scattering experiments. The data for the i th experiment form the vector of in-phase and quadrature components of the scattered thermal-wave field measurements obtained along one of the arrays due to illumination by the laser at a given point on the top surface.

As discussed in [1], the object function is related to the measured data non-linearly through a pair of coupled integral equations. Our algorithms are based on discrete representations of these equations obtained using the method of moments [9] with a pulse basis and Dirac testing functions. Upon discretization the model takes the form

$$\mathbf{y}_i = \mathbf{L}_i \mathcal{D}(\mathbf{T}_i) \mathbf{g} + \mathbf{n}_i \quad (1)$$

$$\mathbf{T}_i = \bar{\mathbf{T}}_i + \mathbf{G} \mathcal{D}(\mathbf{g}) \mathbf{T}_i \quad (2)$$

where \mathbf{y}_i is the vector of observations along the array for the i th experiment, \mathbf{g} and \mathbf{T}_i are vectors containing the lexicographically ordered pulse basis expansion coefficients for the object function and the thermal fields internal to the medium respectively, $\bar{\mathbf{T}}_i$ is the discrete representation of the thermal field in the absence of defects, $\mathcal{D}(\mathbf{x})$ is a diagonal matrix whose entries are the elements of the vector \mathbf{x} , and \mathbf{L}_i and \mathbf{G} are the matrices obtained by discretizing the integral kernels in the underlying continuous model. \mathbf{n}_i are taken to be mutually uncorrelated, zero mean, white Gaussian noise vectors. By solving for \mathbf{T}_i in (2), and substituting the result into (1), the data are related to the object function via the non-linear model

$$\mathbf{y}_i = \mathbf{h}_i(\mathbf{g}) + \mathbf{n}_i \quad \text{with} \quad \mathbf{h}_i(\mathbf{g}) = \mathbf{L}_i \mathcal{D} [(\mathbf{I} - \mathbf{G} \mathcal{D}(\mathbf{g}))^{-1} \bar{\mathbf{T}}_i] \mathbf{g}. \quad (3)$$

Figure 1: *Experimental setup for thermal wave slice tomography.*

Given the model in (3), the TWST problem is to determine g based on the data, y_i from K scattering experiments.

3. Wavelet Domain Model

Here we employ discrete, orthonormal wavelet transforms to take the inverse problem from physical to scale space. As described more fully in [10], given a signal or image \mathbf{a} , we obtain its wavelet transform, denoted α via multiplication by a unitary wavelet transform matrix, \mathbf{W}_a . That is, $\alpha = \mathbf{W}_a^T \mathbf{a}$ and $\mathbf{a} = \mathbf{W}_a^T \alpha$. The transform of \mathbf{a} is composed of wavelet coefficients over the scales and dyadic shifts of interest in the particular problem under investigation. We subscript the matrix \mathbf{W}_a to make explicit that this is the transform for \mathbf{a} . We will use different wavelet transforms for the different variables.

We use the discrete wavelet transform to take (1) and (2) from physical space to scale space. Defining \mathbf{W}_g as the 2D transform for g and \mathbf{W}_i for $i = 1, 2, \dots, K$ as the 1D transforms for y_i yields:

$$\begin{aligned} \mathbf{W}_i \mathbf{y}_i &= [\mathbf{W}_i \mathbf{L}_i \mathbf{W}_g^T] [\mathbf{W}_g \mathcal{D}(\mathbf{T}_i) \mathbf{W}_g^T] (\mathbf{W}_g \mathbf{g}) + \mathbf{W}_i \mathbf{n}_i \\ \mathbf{W}_i \mathbf{T}_i &= \mathbf{W}_i \bar{\mathbf{T}}_i + [\mathbf{W}_i \mathbf{G} \mathbf{W}_g^T] [\mathbf{W}_g \mathcal{D}(\mathbf{g}) \mathbf{W}_g^T] (\mathbf{W}_i \mathbf{T}_i) \end{aligned}$$

which, upon making the obvious definitions become

$$\eta_i = \Lambda_i \Delta(\theta_i) \gamma + \nu_i \quad (4)$$

$$\theta_i = \bar{\theta}_i + \Gamma \Delta(\gamma) \theta_i \quad (5)$$

where, $\Delta(\gamma)$ is a function of γ since $\Delta(\gamma) = \mathbf{W}_g \mathcal{D}(\mathbf{W}_g^T \gamma) \mathbf{W}_g^T$. From (4) and (5), the complete model relating the transform of the object to those of the data is

$$\eta_i = \Upsilon_i(\gamma) + \nu_i \quad \text{with} \quad \Upsilon_i(\gamma) = \Lambda_i \Delta \left[(\mathbf{I} - \Gamma \Delta(\gamma))^{-1} \bar{\theta}_i \right] \gamma. \quad (6)$$

Finally, we aggregate the η_i into a single data vector and define the stacked system $\eta = \Upsilon(\gamma) + \nu$ with $\eta = [\eta_1^T \dots \eta_K^T]$ and $\Upsilon(\gamma)$ and ν defined accordingly. Thus, the TWST inverse problem is the recovery of γ , the DWT of g , from measurements η , knowledge of Υ , and the statistics of ν .

4. Inversion Algorithm

In this paper, the reconstruction of γ , denoted by $\hat{\gamma}$, given the data, η , is defined to be the solution to the following non-linear least squares type of optimization problem

$$\hat{\gamma} = \arg \min_{\gamma} \mathcal{C}(\gamma) \quad (7)$$

$$\mathcal{C}(\gamma) = \frac{1}{2} \|\eta - \Upsilon(\gamma)\|_{\mathcal{R}^{-1}}^2 + \lambda^2 \rho^T(\gamma) \rho(\gamma) \quad (8)$$

where $\|\mathbf{x}\|_{\mathbf{A}} \equiv \mathbf{x}^T \mathbf{A} \mathbf{x}$, \mathcal{R} is a diagonal weighting matrix whose entries reflect the noise levels in the data, $\rho^T(\gamma) \rho(\gamma)$ is used to regularize the problem, and λ^2 is the regularization parameter. We employ a form of the Levenberg-Marquardt algorithm (LMA) for finding $\hat{\gamma}$. This iterative technique defines a sequence of reconstructions, $\hat{\gamma}_n$, whose costs as measured by (8) are steadily decreasing. Starting from an initial guess, $\hat{\gamma}_0$, the form of the LMA used here is

$$\begin{aligned} \hat{\gamma}_{n+1} &= \hat{\gamma}_n + \mathbf{s}_n \\ \mathbf{s}_n &= \arg \min_{\sigma^2} \mathcal{C}(\hat{\gamma}_n + \mathbf{s}) \end{aligned} \quad (9)$$

$$\mathbf{s} = [\mathcal{J}^T(\hat{\gamma}_n) \mathcal{R}^{-1} \mathcal{J}^T(\hat{\gamma}_n) + \sigma^2 \mathcal{L}^T(\hat{\gamma}_n) \mathcal{L}(\hat{\gamma}_n)]^{-1} \times \mathcal{J}^T(\hat{\gamma}_n) \mathcal{R}^{-1} [\eta - \Upsilon(\hat{\gamma}_n)] - \mathcal{L}^T(\hat{\gamma}_n) \mathcal{L}(\hat{\gamma}_n). \quad (10)$$

In (10), $\mathcal{J}(\hat{\gamma}_n)$ (resp. $\mathcal{L}(\hat{\gamma}_n)$) is the Jacobian matrix of Υ (resp. ρ) evaluated at the vector $\hat{\gamma}_n$ and σ is a regularization parameter whose value is determined adaptively at each iteration of the algorithm.

4.1. Edge Preserving Wavelet Regularization

In our previous work [4, 5], we have concentrated on the use of wavelet domain regularizers with $\rho(\gamma) = \mathbf{D}\gamma$ where the matrix \mathbf{D} was diagonal with

$$[\mathbf{D}]_{ii} \equiv d_i = 2^{-(\alpha_x j_{x,i} + \alpha_y j_{y,i})}. \quad (11)$$

In (11) $j_{x,i}$ and $j_{y,i}$ are the horizontal and vertical scale indices for the i th wavelet coefficient and α_x and α_y are constants. For this regularization approach, $\rho^T(\hat{\gamma}_n) \rho(\hat{\gamma}_n)$ is a weighted two-norm of $\hat{\gamma}_n$ and functions in much the same way as traditional smoothness type regularizers [4, 5]. One consequence of this choice is that edges tend to be blurred in the reconstruction.

Recently, there has been considerable work performed in the area of “edge-preserving” regularizers [11]. The idea is to construct a physical-space regularization scheme which results in reconstructions whose discontinuities are better preserved as compared to a Tikhonov approach [12]. One way of implementing this regularization technique is to choose an expression for $\rho^T \rho$ which is a norm in a function space containing “edgy” objects. Adding this as the second term in (8) produces an object which lies in such a space and therefore retains the desired edge-like structure.

It is the case that, in addition to spanning the space of square integrable functions, orthonormal wavelets are also bases for these more exotic function spaces [7]. Here we make use of the fact that the norm in such a space may be computed in terms of the wavelet coefficients via $\sum_i d_i |\gamma_i|^p$ with $1 \leq p \leq 2$ and d_i as in (12). With this motivation, we make the following choice for $\rho(\gamma)$

$$\rho^T(\gamma) = \left[d_1^{1/2} |\gamma_1|^{p/2} \quad d_2^{1/2} |\gamma_2|^{p/2} \quad \dots \quad d_N^{1/2} |\gamma_N|^{p/2} \right]. \quad (12)$$

4.2. Approximate Physical Model

A large computational burden associated with the LMA is the need to invert the matrix $\mathbf{I} - \Gamma\Delta(\hat{\gamma}_n)$ for numerous $\hat{\gamma}_n$. This operation amounts to explicitly inverting the generally large and dense system matrix for the forward scattering problem. To bypass this operation we note that at the beginning of stage $n + 1$ of the LMA, we require

$$\Xi_{n+1} \equiv [\mathbf{I} - \Gamma\Delta(\hat{\gamma}_{n+1})]^{-1} = [\mathbf{I} - \Gamma\Delta(\hat{\gamma}_n + \mathbf{s}_n)]^{-1}.$$

Making use of the fact that Δ is a linear operator [5],

$$\Xi_{n+1} = [\mathbf{I} - \Gamma\Delta(\hat{\gamma}_n + \mathbf{s}_n)]^{-1} = [\mathbf{I} - \Gamma\Delta(\hat{\gamma}_n) - \Gamma\Delta(\mathbf{s}_n)]^{-1} = \Xi_n [\mathbf{I} - \Gamma\Delta(\mathbf{s}_n)\Xi_n]^{-1} \quad (13)$$

$$\approx \Xi_n + \Xi_n \Gamma\Delta(\mathbf{s}_n)\Xi_n \quad (14)$$

where (14) follows from (13) under the assumption that $\Gamma\Delta(\mathbf{s}_n)\Xi_n$ is “small” relative to \mathbf{I} . We note that, unlike the Born approximation, this is not a linearization of the physics about the current estimate of the object function. Additionally, our approximation provides a recursive method for updating Ξ_n from one iteration of the LMA to the next.

5. Example of Thermal-Wave Tomographic Imaging

To illustrate the inversion algorithm developed in the previous sections, we consider the imaging of a square hole centered near the top of a 3 mm by 3 mm block of aluminum (thermal diffusivity of $0.82 \text{ cm}^2\text{s}^{-1}$). The object function for this case is shown in *Fig. 2(a)* is of amplitude $(\alpha_{\text{Al}}/\alpha_{\text{air}}) - 1 \approx 3$ [3] and the SNR is 50dB. The reconstruction obtained under the Born approximation is displayed in *Fig. 2(b)*. For this case, the Born approximation yields coarse-scale localization of the defect. That is, the reconstruction is non-zero over a region of space which includes the area of the true defect. However, the amplitude of the reconstruction is at best a third of the true amplitude and the shape of the reconstructed defect is in fact larger than that of the true structure.

The final results of the LMA using $p = 2$ (which corresponds to a traditional Tikhonov smoothness regularization scheme) and $p = 1.2$ (an edge preserving case) are shown in *Figs. 2, (c), and (d)* respectively. In *Fig. 2(e)*, the value of $\|\hat{\gamma}_n - \gamma\|_2$ is plotted for both regularization schemes as a function of iteration. It is evident that both regularization schemes produce reconstructions which are better localized with more accurate amplitude information than the Born inversion. The $p = 1.2$ case is a slightly better than the $p = 2$ reconstruction both from a quantitative and qualitative perspective. Quantitatively, the error in the $p = 1.2$ estimate is somewhat lower than that of the $p = 2$ case after 10 iterations. This improvement is due to the fact that the $p = 2$ case overestimates the amplitudes in a couple of pixels, while the amplitude of the $p = 1.2$ version is quite accurate. Visually, as we expect, the edges on the $p = 1.2$ reconstruction are sharper and the overall reconstruction looks much more like a box than a smoothed blob as in *Fig. 2(c)*.

6. Conclusions

We have presented a new approach to image formation from scattered thermal waves based on the use of non-linear inverse scattering methods and wavelet-domain techniques. We build our inversion routine on the full wavefield physics developed by Mandelis in [3] resulting in a highly non-linear relationship between the data on which a reconstruction is to be based and the desired image of the object function. The reconstruction problem was formulated as a solution to a non-linear least-squares optimization problem in the wavelet transform domain. We chose to work in a multiscale setting for a number of reasons. First, the matrices comprising the physical model are sparse in this domain thereby lowering the

computational cost of generating a reconstruction. Second, we were able to make use of a new class of edge-preserving regularization methods which are easily specified and implemented in the wavelet transform domain. Finally, the computational burden was further reduced by employing the methods of [5] for rapidly solving non-linear inverse scattering problems in a multiscale domain.

ABSTRACT

The problem of mine detection and localization from array-based electromagnetic induction data is addressed. An efficient forward scattering model based on the Born approximation is employed. Using insight obtained from this model, a clutter model in the form of a state space system is developed which describes the correlation of the noise both across the sensing array and from one position of the array to the next as the measurement device proceeds down track. A multiple-model detection scheme based on the whitening properties of the Kalman filter is employed to perform the actual mine detection. This approach allows for the detection and localization of buried objects well before the array physically moves over mines. Examples are provided for mines buried directly in front and off to one side of the array.

Keywords: Mine detection, EMI arrays, Kalman filter

1. INTRODUCTION

The problem of detecting and localizing buried landmines from indirect observations of scattered electromagnetic radiation has received considerable attention in recent years. Of interest in this paper is the development of statistical signal processing methods for solving such problems based on data collected using an array of very low frequency electromagnetic induction sensors. From a signal processing perspective, the physics of this problem represents an unusual challenge. The majority of array processing algorithms are based on the assumption that the observed waves are propagating in free space and the unknown sources are in the far field. The resulting planewave model for the radiation incident on the sensors serves as the basis for all beamforming and high-resolution localization methods. For the applications of interest here, the objects are in the nearfield of the array and while the sensors are in freespace, the targets are located in a lossy halfspace. The typical array approaches are therefore not applicable.

In addition to the basic physics describing these problems, the data are typically obtained by sweeping the array in a fixed direction over a region of interest, as illustrated in Figure 1. The result is an “image” acquired over time whose number of rows is equal to the number of sensors in the array and whose number of columns is determined by the number of stops the array makes as it sweeps over the area. This implied temporal structure is the second unique image processing element present in this problem. In particular, it is imperative to detect the mine *before* the sensor array actually passes over its location. This requirement implies that any algorithm must process the image data in a real-time, column-by-column manner, continuously updating its decision as to mine presence and its estimate concerning the object’s location as new data are obtained by the scanning procedure.

The final challenging characteristic of this problem is the need to process data contaminated by “clutter.” Physically, such clutter can arise from a variety of inhomogeneities present in the soil including a random distribution of rocks and other discrete structures as well as the continuous, natural changes in the electromagnetic characteristics of the earth. From a signal processing perspective, we regard clutter as a correlated noise source present in the data. The correlation is evident first along the array from one sensor to the next and second along the collection track from one array position to the next. To adequately detect mines whose signals are obscured by such noise requires both careful modeling of the clutter and the development of processing methods explicitly based on these models.

Figure 1. Data Acquisition Method for Subsurface Detection Problem

In this paper, we consider statistical signal processing methods for solving the mine detection problem outlined in the previous paragraphs. Our focus is on shallowly buried metallic anti-personal mines arising in the case of humanitarian demining. In Section 2, we describe a physical model relating the characteristics of the buried mine to the observations obtained over an array. We next use this physical model as the basis for a simple, analytical, stochastic model describing the distribution of clutter. In particular, the clutter model takes the form of a so-called “state-space” system. This system accounts both for the inter-element and inter-array correlation of the noise. In Section 4, we take advantage of the fact that the Kalman filter can be used to decorrelate (or whiten) such noise processes to obtain a method for detecting mines. At each stop of the array, we perform a series of hypothesis tests. Under the null hypothesis for each test, no mine is present. Under the alternative, there is a mine located at one of a number of positions over a coarse scale grid. The whitening properties significantly simplify the formulation of the tests while retaining the optimality property of the procedure. We stop the array and declare the presence of a mine when the sequence of tests for a mine at a hypothesized location are “sufficiently convincing.” We show in the examples in Section 5 that this process is capable of detecting mines reliably (a) up to 20cm before the array actually passes over the mine and (b) under low clutter conditions, when the mine is located up to 30 cm from one side or another of the array. Finally, conclusions and future work are described in Section 6.

2. FORWARD MODEL

To fix notation, we assume that the array is situated in the $x - y$ plane and proceeds from $x = 0$ to $x = x_{max}$ stopping at N_s equally spaced locations to obtain data. The array is composed of a single

transmitter at $y = 0$ and N_r receivers equally spaced on either side of the array. All transducers are taken to be small current loops of radii r_p located z_p above the air-earth interface carrying I A of current with an $e^{-i\omega t}$ time dependence. We define $d_{m,n}$ to be the field measured by the m th element of the array at the n th stop between $x = 0$ and $x = x_{max}$. In this paper, we assume that the mine represents a small perturbation of constant conductivity σ S/m in the electromagnetic properties of the earth so that the first Born approximation¹ can be used to obtain a tractable physical model. For the case of a single mine, it can be shown that the relationship between the physical properties of the mine and y_{mn} is given by¹

$$d_{nm} = -\frac{\sigma(\omega\mu I r_p)^2}{4} \int_V A(\mathbf{r} - \mathbf{r}_0 + \mathbf{r}_n) A(\mathbf{r} - \mathbf{r}_0 + \mathbf{r}_m) d\mathbf{r} \quad (1)$$

where the quantity A represents the Green's function for the problem of a loop over a half-space, $\mathbf{r} = [x \ y \ z]^T$ is a point in three space represented in either Cartesian or polar coordinates, \mathbf{r}_0 is the position of the center of the mine, \mathbf{r}_n (\mathbf{r}_m) is the position of the transmitter (receiver), μ is the magnetic permeability and the integral is taken over the volume, V , of the prototypical mine centered at the origin. In [1], it is shown that the Green's function A can be well approximated as

$$A(\mathbf{r}) = \frac{2}{\pi k(\mathbf{r}) \sqrt{r r_p}} \left[\left(1 - \frac{1}{2} k(\mathbf{r})^2 \right) K(k(\mathbf{r})) - E(k(\mathbf{r})) \right] \quad (2)$$

$$k(\mathbf{r}) = \frac{4 r r_p}{(z + z_p)^2 + (r + r_p)^2} \quad (3)$$

where $r = \|\mathbf{r}\|$ is the distance to the physical point, $K(x)$ is the complete elliptic integral of the first kind, $E(x)$ is the complete elliptic integral of the second kind and the parameter $k(\mathbf{r})$ is in the range 0 to 1.

For the problem of interest in this paper, we have found by direct evaluation that $k(\mathbf{r}) \in [0, 0.6]$. Under this restriction, we have developed the following highly accurate, yet simple approximation to (2):

$$A(\mathbf{r}) = \frac{2}{\pi k(\mathbf{r}) \sqrt{r r_p}} \left(\beta_4 k^4(\mathbf{r}) + \beta_6 k^6(\mathbf{r}) \right) \quad (4)$$

with $\beta_4 = 0.0882$, $\beta_6 = 0.1321$ and $k(\mathbf{r})$ as in (3). The particular values of the β parameters are obtained by a least squares fit and the use of the fourth and sixth powers of k is motivated by the Taylor series expansion for the right hand side of (2). A semilogarithmic comparison of the right hand sides of (2) and (4) is shown in Figure 2. The solid line represents the exact combination of elliptic integrals while the dashed line is the polynomial approximation. It is clear that the approximation is, for all intents and purposes, the same as the exact expression. From a computational perspective however, (4) offers definite advantages over (2) in terms of speed of evaluation and ease of manipulation.

Given this model, the goals of the processing in this paper are the detection of the presence of a mine from noisy observations of d_{ij} and determination of \mathbf{r}_0 once a detection has been declared.

3. CLUTTER MODEL

Typically, white Gaussian noise is used as the clutter model for mine detection problems due to its tractability. Unfortunately, this simplified assumption leads to a degradation in detection performance. In this work we instead explicitly model the clutter or background process, leading to more robust performance. In particular, we develop a tractable yet realistic stochastic model describing the distribution of the data obtained over our receiver in the absence of a target. This statistical model then forms the basis for a decision-theoretic procedure for the localization of buried mines discussed in the remainder of this paper.

Figure 2. Comparison of exact and polynomial approximation to forward scattering model

The motivation for the mathematical form of our clutter model is actually provided by the nature of the signal observed over the array due only to a mine buried some distance away. The wavefield over the aperture of the array is rather smooth when a mine does in fact exist near the array. In Fig. 3, noiseless simulated data is shown for the case of a $.05 \times .05 \times .05$ m³ mine located at $\mathbf{r}_0 = \{x_0, y_0, z_0\} = \{2, .1, -.05\}$ m where an 8 element array of length .6m is positioned at $x \in \{0, .5, 1, 1.5\}$ m. These plots indicate the more general feature that the data over the array can be well modeled by a low order polynomial in y_i , the y position of the i th sensor in the array. In other words we can write

$$d_{m,n} = \sum_{j=0}^J \alpha_{j,n} y_m^j. \quad (5)$$

By defining the vectors $\mathbf{d}^T(n) = [d_{1,n} \ d_{2,n} \ \dots \ d_{N_r,n}]$ and $\boldsymbol{\alpha}^T(n) = [\alpha_{0,n} \ \alpha_{1,n} \ \dots \ \alpha_{J,n}]$, (5) is rewritten as

$$\mathbf{d}(n) = \mathbf{C}\boldsymbol{\alpha}(n). \quad (6)$$

where the (m, j) th element of \mathbf{C} is y_m^j .

The clutter model we employ in this work is based on the assumption that the random signal over the array in the absence of a mine is the sum of two components. The first portion is an additive zero mean, white Gaussian component of variance γ^2 representing sensor noise. The second component is intended to capture the effects due to the statistical distribution of the environmental factors not of primary interest in the detection problem. Here we assume that this signal will display the same basic smoothness as that seen in Fig. 3. That is it will be described by a low order polynomial. In the case of a mine, the coefficients of the polynomial are deterministically related to the position of the object relative to the array. For clutter however, these coefficients are taken to be random quantities. That is, $\boldsymbol{\alpha}(n)$ is a random vector. Such a model arises if we assume that the clutter represents the average effect on the sensor array of a random distribution of small scatterers. If each such scatterer results in a smooth signal over the array then so too will their sum. We note here that this choice of model certainly satisfies the criteria set forth in the Introduction that clutter essentially represents noise which is correlated from one array element to the next.

The second criteria is that the clutter should be correlated from one position of the array to the next. For example, a clutter vector at position n should be correlated to that at position $n + 1$. This implies

Figure 3. Data vectors, \mathbf{d}_j , obtained as array proceeds toward buried mine. Note the scale change in the plots.

the need to specify a dynamic model describing the evolution of $\boldsymbol{\alpha}(n)$. Toward this end, we employ the following model of the spatial evolution of $\boldsymbol{\alpha}(n)$:

$$\boldsymbol{\alpha}(n+1) = \boldsymbol{\alpha}(n) + \mathbf{B}(n)\mathbf{w}(n) \quad (7)$$

where $\mathbf{B} = \nu \text{diag}[\delta^{J/2}, \delta^{(J-1)/2}, \dots, 1]$, $\nu > 0$, $\delta \in (0, 1)$, and $\mathbf{w}(n)$ is a zero mean, unit variance, uncorrelated vector of Gaussian random variables. Finally, $\boldsymbol{\alpha}(0)$ is taken to be a zero mean Gaussian random vector with covariance matrix given by $\mathbf{B}^T \mathbf{B}$. Eq. (7) represents a random walk model for the vector $\boldsymbol{\alpha}(n)$. The matrix \mathbf{B} is such that variance of the additive noise is greatest for the higher order coefficients in (5) and decreases for the lower order α 's representing lower frequency components. The constant ν controls the overall power in the process and δ determines the relative variances among the coefficients.

To summarize, in the absence of a mine, the overall signal model we use for the remainder of the work is described by the following state-space model with $\boldsymbol{\alpha}(n)$ representing the state of the system:

$$\boldsymbol{\alpha}(n+1) = \boldsymbol{\alpha}(n) + \mathbf{B}\mathbf{w}(n) \quad (8)$$

$$\mathbf{d}(n) = \mathbf{C}\boldsymbol{\alpha}(n) + \mathbf{v}(n) \quad (9)$$

where $\mathbf{v}(n) \sim N(0, \gamma^2 \mathbf{I})$ is the additive white, sensor noise.

Sample paths of these clutter models are shown in Figs. 5(a) and 7(a) for an array consisting of 20 receiver elements for parameter choices described in greater depth in Section 5. In both cases, the variance of the $\mathbf{w}(n)$ is greater than that of $\mathbf{v}(n)$ so that the background “clutter to noise” ratio is assumed to be relatively large. These images indicate that our model of clutter possesses the desired features. As functions of y , they are quite smooth. As x (and hence n) increases, they display gradual changes except at a few points where the random walk model results in a sharp alteration of the “shape” of the profile.

In closing this section, we wish to emphasize that the clutter model described above is neither the only nor even necessarily the best such model for the processing of real data. Rather the precise model based on the underlying polynomial regression is intended more as a vehicle for demonstrating the efficacy of the detection algorithm described and tested in subsequent sections. Indeed, our approach towards detection is based only on the reasonable and generally unrestrictive assumption that one can describe the clutter using *some* state space model to capture the temporal correlation of the process. Any valid state space model will work and the problem of fitting field data to such a modeling structure represents an interesting and very worthwhile piece of future research.

4. DETECTION ALGORITHM

In this section, we develop our approach to the detection of buried mines from progressively obtained array EMI data. We begin by solving a simpler problem in which we assume that the mine can exist only at a known point in space and want only to determine whether the mine is present. The solution to this problem then allows for the solution to the problem where we lift the assumption of known location.

4.1. Case I: Known mine location

Assuming that the mine may only be located at position \mathbf{r}_0 , the first problem of interest is to determine whether the data we observe as the array proceeds down the track is just clutter or is comprised of clutter plus mine. From a statistical signal processing perspective, this amounts to a binary hypothesis test. Under the null hypothesis, H_0 , the data $\mathbf{d}(n)$ is comprised only of clutter and is therefore modeled using (8) and (9). Under the alternate hypothesis, the data are described by combining (8) and a modified observation equation:

$$\mathbf{d}(n) = \mathbf{s}_0(n) + \mathbf{C}\boldsymbol{\alpha}(n) + \mathbf{v}(n) \quad (10)$$

where $\mathbf{s}_0(n)$ is the signal over the array at time n arising from the mine at position \mathbf{r}_0 which can be computed using the model of Section 2.

A key difficulty in solving this binary decision problem is that the clutter is correlated. To overcome this problem, we employ a Kalman filter to “whiten” the data. In most cases, the Kalman filter is used to track the state of a stochastically evolving system. It is well known however that a bi-product of the minimum mean square error property of the filter is that it may be interpreted as a means of de-correlating a non-white noise sequence. Specifically, the Kalman filter takes as input the sequence $\mathbf{d}(n)$ and produces as output a new sequence $\mathbf{q}(n)$ termed the innovations. When there is no mine present, $\mathbf{q}(n)$ is a zero mean, unit variance, white Gaussian noise sequence. In the event that a mine is present, $\mathbf{q}(n)$ is again unit variance, white, and Gaussian, but now there is an added mean vector, $\boldsymbol{\rho}(n)$ (also known as a signature), which can be computed directly from $\mathbf{s}(n)$ and the matrices in the state space model for the noise.² Mathematically we have:

$$\text{Under } H_0 \quad \mathbf{q}(n) \sim N(0, \mathbf{I}) \quad (11)$$

$$\text{Under } H_1 \quad \mathbf{q}(n) \sim N(\boldsymbol{\rho}(n), \mathbf{I}) \quad (12)$$

That is, the detection problem now is one of determining whether or not there exists a known mean in a sequence of independent, unit covariance Gaussian random vectors.

In the case where the two hypotheses are to be distinguished based on a batch of data obtained between $n = 0$ and $n = N$, the problem stated in the previous paragraph has a well known solution given in the form of a likelihood ratio test. First, the following likelihood statistic is computed

$$l(N) = \sum_{j=0}^N \boldsymbol{\rho}^T(j)\mathbf{q}(j) - 0.5\boldsymbol{\rho}^T(j)\boldsymbol{\rho}(j). \quad (13)$$

Next, we compare $l(N)$ with a threshold $\tau(N)$. If $l(N) > \tau(N)$ we say that the mine is present otherwise, we continue to collect data. Typically, $\tau(N)$ is chosen such that the probability of false alarm P_{fa} (that is the probability of rejecting H_0 when H_0 is in fact true) is less than or equal to a predefined threshold.³ Under our Gaussian assumptions on the innovations, this threshold is³

$$\tau(N) = d(N) \operatorname{erfc}_*^{-1}(P_{fa}) - d^2(N)/2 \quad (14)$$

with

$$\operatorname{erfc}_*(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty e^{-x^2/2} dx \quad \text{and} \quad d^2(N) = \sum_{j=0}^N \boldsymbol{\rho}^T(j) \boldsymbol{\rho}(j)$$

For the demining application, we want the ability to declare the presence of a mine before the array actually passes the object. That is, we want to solve a sequential detection problem wherein at each n we decide whether to declare a mine, declare no mine, or move the array and collect more data. While well known methods exist for optimally solving this problem when $\boldsymbol{\rho}$ is independent of n , the solution to the problem for a time varying mean is less well studied. The algorithm in this paper represents a first attempt to solve this problem for the demining application.

Since we know where the mine is located, we can, in principle, take data up to but not including the time the sensor passes the mine. Thus, at each n we compute $l(n)$ as in (13) and for a fixed P_{fa} , perform the comparison to $\tau(n)$. We do not stop taking data until that point, n_0 , when the x coordinate of the array is such that at step $n_0 + 1$ the array would pass the mine. At that time we look at the sequence of decisions made for all previous n . If H_1 has been accepted more than Q times (in this paper $Q = 3$, that hypothesis is declared to be true.

We observe that we could have chosen the simpler approach of collecting data until time n_0 and then solving the fixed size binary hypothesis test. The methods described in the previous paragraph though are more easily generalized and provide greater insight into the more complex problem where we cannot wait until n_0 but must make the mine/no mine decision as rapidly as possible.

4.2. Case II: Unknown mine location

In the more realistic event that we know neither whether a mine is in a region of interest nor where it may be, we employ a “multiple model”² approach to the detection problem. As illustrated in Fig. 4, we hypothesize the existence of mines over a coarse grid extending in front of the moving array. Associated with the i th such mine location is a separate signature sequence $\boldsymbol{\rho}_i(n)$. At each n , we perform a separate binary likelihood ratio test for each location in the grid. When the array is set to pass those possible mine locations with a given x coordinate, we look to see if any of the hypotheses in that collection have been chosen more than M times. If none satisfies this criteria, we continue moving the array. If one location passes, we declare a mine. If more than one has been passed more than M times, we take as the actual mine detection that hypotheses which has exceeded its threshold by the widest margin at any time during the scan. Essentially, we take the most likely target if there are multiple possibilities.

The implementation of this procedure can be made quite efficient. Rather than keeping track of a large number of mine locations extending over the entire track of the array, we perform this procedure using a sliding window of hypothesized target positions. Let Δx be the distance the array moves from n to $n + 1$. We choose as the coarse grid of possible mine locations the points at the center of the squares on a grid of size $M\Delta x$. That is, it takes the array M steps to proceed through one column of the coarse scale grid. As shown in Fig. 4, assuming the array has been moving for a sufficiently long time so that the Kalman filter is operating in the steady state, there is a certain shift invariance to the detection problem. In particular, the mathematical forms of the hypotheses generated when the array is in column 1 and the mines in column

Figure 4. Relationship of moving array to coarse grid of possible mine locations. Rectangles represent positions of the array as it moves down the track. Circles represent hypothesized mine locations. There are $M = 4$ array positions per coarse grid cell.

2 (represented by the open boxes and circles) are identical to those obtained when the array is in column 2 and the mines are postulated to lie in column 3 (the darkened rectangles and circles). Clearly this holds for any array/mine combinations with identical relative spacings in the along-track direction.

We use this observation in the following manner. We begin by postulating mines over a $P \times P$ coarse grid in front of the array where P is chosen such that the response of the array when it is $PM\Delta x$ meters away is negligible. This grid (i.e. these hypotheses) are retained for the first M steps of the array. At the $M + 1$ st step, when the array is entering the second column, the grid looks very similar as in step 1 except the columns need to be renumbered. The first column, of the grid is removed since the array is leaving it. Each of the remaining columns are shifted to the left by one and a new column of hypotheses is added to the rightmost edge of the grid so that the overall array is still $P \times P$ only now looking further down track than was the case before. This procedure is repeated every M moves of the array.

This sliding window testing process is advantageous because it requires the storage of a fixed and relatively small number of signature vectors. Rather than having to maintain a $\rho(n)$ sequence for every conceivable combination of array locations and mine positions, we need only compute and store P^2M such sequences. For the EMI problems of interest here, excellent results are obtained in Section 5 for $P = 10$ and $M = 4$. The computation, storage, and manipulation of only 400 $\rho(n)$ sequences is relatively easy making this processing methodology quite amenable to real time implementation.

5. EXAMPLES

In this section, the performance of the detection approach is demonstrated and analyzed under a variety of noise conditions and mine placements. In all cases, the array is composed of a single transmitter located at $x = 0$ and 20 receivers with half equally spaced between $y = 5$ cm and $y = 50$ cm and the other half spaced between $y = -5$ cm and $y = -50$ cm. Thus, the overall length of the array is 1 meter. The transmitters and receivers are modeled as small circular loops of radius 2 cm located 10 cm above the air-earth interface and operating at 3 kHz. The array starts at $x = 0$ meters and proceeds in 75 equally spaced steps to $x = 3.7$ meters. The rolling grid of coarse scale hypothesized mine locations is composed of a 10 by 10

array of square cells stretching from about -90 cm to 90 cm in the y direction and extending about 2 meters in front of the array in the x direction. Finally, the mine-like target used in these simulations is modeled as a $5 \times 5 \times 5 \text{ cm}^3$ parallelepiped of contrast 1 S/m above the surrounding soil. Further, it is assumed that the burial depth of the mine is known *a priori*. Thus, the signature vectors are generated using this information. In practice, this assumption is not overly restrictive as range of burial depths is generally quite limited for a given demining application. Our scenario is meant to model the case of a shallowly buried anti-personnel mine, of interest for humanitarian demining.

For the low-frequency, Born-based inductive model discussed in Sec. 2, the electrical conductivity of the soil is approximated as zero. Moreover, the frequency and conductivity contrast of the mine enter the model only as multiplicative constants scaling the amplitude of the data. At higher frequencies and when an exact scattering model is employed, these various parameters will indeed play a larger role on the performance of the algorithm. For the work in this paper, however the key determination of performance is the relative strengths of the noise, clutter and target signatures. The measure used here is the signal to clutter plus noise ratio (SCNR) taken to be 20 times the base 10 logarithm of the ratio of the signal power to the noise plus clutter power taken over the entire data set obtained from $x = 0$ to $x = 3.7\text{m}$.

As a first example, we consider the detection of a mine located at $(x, y, z) = (2.2, -0.22, -0.05)$ m under a variety of SCNR. In Fig. 5(a) we display a sample data set. The mine, located in the image at $(x, y) = (2.2, -0.22)$ m, is barely discernible at this SCNR. In Fig. 5(b) the detection performance as a function of SCNR is shown. Each point represents the fraction of times the mine was detected in 100 runs of the algorithm using independent realizations of the clutter and noise processes for each run. The SCNR was changed by setting the variance of $\mathbf{v}(n)$ in (9) to 0.01 and increasing the variance of $\mathbf{w}(n)$ in (7) from 0.01 to 0.25 in steps of 0.02. It is clear, that strong performance is seen down to a SCNR of about -20 dB with a gradual decline in detection as the SCNR further degrades. At an SCNR of -15 dB the mine is detected essentially 100% of the time. Finally, since the mine was not located at one of the coarse scale grid points, a detection was declared if the estimated mine location was one of the four neighbors nearest the true mine location on the hypothesis grid.

In Fig. 6, we display the average value of the likelihood statistic less the threshold (i.e. $l - \tau$ from (13) and (14)) as a function of the position of the sensing array as the array proceeds toward the mine. The average is taken over all noise realizations and all experiments where the mine was in fact detected according to the criterion described previously. The SCNR for this problem was about 2.6 dB and the x coordinate of the mine is again 2.2 m. The plot does not reach 2.2 m because of the coarse scale gridding of the mine hypotheses, which for this problem tests for mines located at $x = 2.1$ m and $x = 2.3$ m. Fig. 6 clearly shows that the relevant decision statistic rises to a significant level above the detection threshold of zero well before the array actually passes over the buried object. In particular, these statistics become substantial when the array is located at $x = 1.95$ m which is over 25 cm from the location of the buried mine.

As a second example, we consider the problem of detecting a mine at $(x, y, z) = (2.2, -0.7, -0.05)$. This placement of the mine is interesting because, unlike the first case, the mine is located outside of the direct field of view of the EMI array. In particular, the array extends to $y = -50$ cm; however the mine is located at $y = -70$ cm. A sample data set at an SCNR of about 1.8 dB is shown in Fig. 7(a) and the detection results are given in Fig. 7(b). As in the first problem, the signature of the mine, which should be evident at around $x = 2.2$ m and $y \in (-.3, -.5)$ m, is obscured by the clutter; however the detection rate is quite high even to an SCNR of about -20dB. In Fig. 8, the plot of average likelihood statistics less threshold are shown for this problem at an SCNR of about 1. These plots show that even when the mine is located significantly off the axis of the array, we still retain a strong degree of forward looking, predictive capability. In particular, non-negligible test statistics are reliably observed for this scenario when the array is located at $x = 1.9$ m which is about 30 cm from the mine.

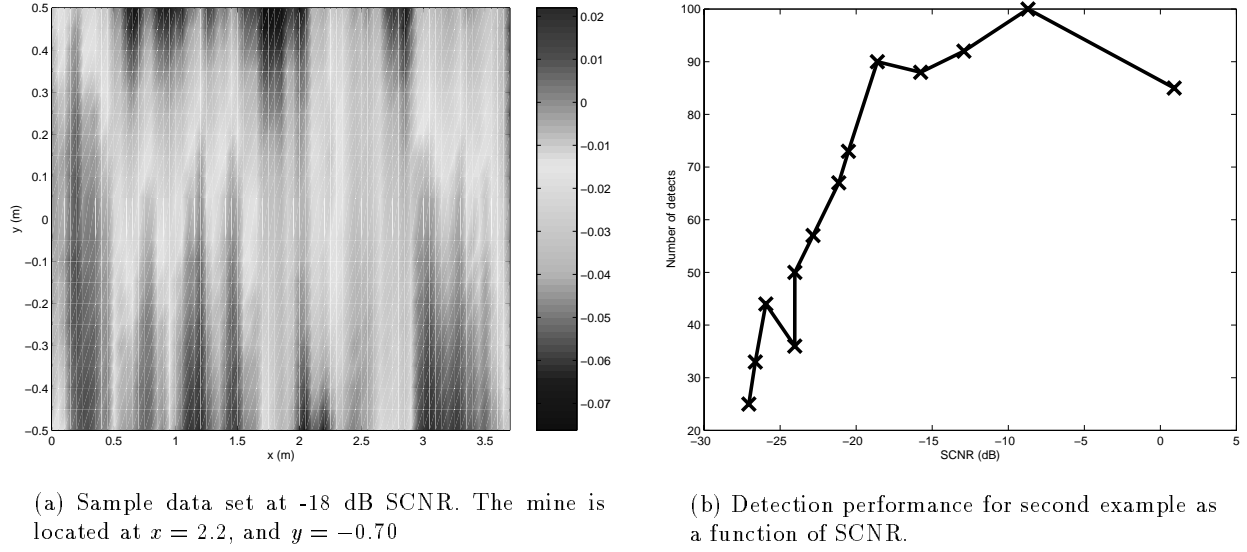

Figure 7. Sample data set and detection results for second example

Figure 8. Average value of likelihood statistic in excess of threshold as array approaches mine location for second problem. Detection requires this value to exceed zero. The dashed line indicates the x coordinate of the mine.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we have presented an approach for the detection and localization of buried landmines from EMI sensor data. Our statistical signal processing approach is tailored both to the sensor (an array of EMI transducers) and the data collection method (progressive acquisition as the array proceeds down track). The approach we have taken casts the detection problem in the form of a statistical hypothesis test. Using a novel state-space model for the clutter, we employ a Kalman filter to whiten the data and use a rolling window, multiple-model approach to ascertain the location of a mine. Preliminary simulations indicate that this approach can provide significant forward and side looking capability thereby increasing the area over which an EMI sensor can reliably detect buried mines.

While the work in this paper has been directed towards an EMI sensing device, the general detection methodology can be extended and applied to *any* scheme in which an array of sensors collects data in a progressive manner. All that is required is a forward model to generate the rather modest sized library of target signatures and a state-space or other recursive model for the clutter. With this in mind, future research efforts stemming from this project include the following:

1. Development of an estimation-based methods to better localize the detected object. Here we are interested in developing a non-linear least squares method which takes the coarse grid estimates generated by the algorithm in this paper and provides a more accurate determination of the mine's true position.
2. Development of methods for “discounting” detected mines from the data set. After the mine has been detected, we want to remove its effects from the data thereby allowing the array to continue down track looking for other buried objects. Failure to perform such discounting generally degrades subsequent performance.
3. Development of a full EMI scattering model for use in generation of target signatures.
4. Identification of state space type model for EMI array from real field data.
5. Extension and adaptation of these methods to ground penetrating radar (GPR) sensor.
6. Use of Kalman filtering ideas for fusion of GPR and EMI sensor data.

Abstract

The problem of near field object detection from array-based electromagnetic induction data is addressed. A forward scattering model based on the Born approximation is employed. Using insight obtained from this model, a clutter model in the form of a state space system is developed which describes the correlation of the noise both across the sensing array and from one position of the array to the next as the measurement device proceeds down track. A multiple-model detection scheme based on the whitening properties of the Kalman filter is employed to perform the actual object detection. This approach is applied to the detection and localization of buried objects. Examples are provided for land mines buried directly in front and off to one side of the array.

1 Introduction

The problem of detecting and localizing highly obscured objects from indirect observations of scattered electromagnetic (EM) radiation has received considerable attention in recent years. In environmental remediation, one is often wants to determine the existence and positions of metallic drums filled with hazardous waste materials. There has been a great deal of attention paid to the problem of finding and removing buried unexploded ordinance using EM sensing technologies. On a smaller scale, the non-destructive testing problem of flaw detection using eddy current sensors possesses essentially the same structure (and physics) as the waste and mine removal applications.

From a signal processing perspective, the physics of these problems represents an unusual challenge to de-

tection and localization tasks. The vast majority of array processing algorithms are based on the assumption that the observed waves are propagating in free space and the unknown sources are in the far field. The resulting planewave model for the radiation incident on the sensors serves as the basis for all beamforming and high-resolution localization methods. For the applications of interest here, the objects are in the nearfield of the array and while the sensors are in freespace, the targets are located in a lossy halfspace. The typical array approaches are therefore not applicable. The problem of information extraction from such data then requires careful modeling of the physics coupled with judicious approximations required for computational efficiency. In this paper we will focus on the problem of detecting buried objects from such array data.

The data for these problems are typically obtained by sweeping an array of transducers in a fixed direction over a region of interest, as illustrated in Figure 1. The result is an “image” whose number of rows is equal to the number of sensors in the array and whose number of columns is determined by the number of stops the array makes. This implied temporal structure is the second unique “image processing” element present in this problem. In applications such as buried landmine detection it is imperative to detect the object (i.e. the mine) *before* the sensor array actually passes over the its location. More generally, there is often a desire in these problem to process the data in a “real time” manner (i.e. as the data is being acquired). This requirement implies that any algorithm must process the image data in a column-by-column manner.

The final challenging characteristic of this problem is the need to process data contaminated by “clutter.” Physically, such clutter can arise from a variety

*This work was supported by the Army Research Office Demining MURI under Grant DAAG55-97-1-0013 and the Air Force Office of Scientific Research under Grant F49620-96-1-0028

of inhomogeneities and man-made non-target discrete structures present in the observed medium as well as the continuous, natural changes in its electromagnetic characteristics. From a signal processing perspective, we regard clutter as a correlated noise source present in the data. The correlation is evident first along the array from one sensor to the next and second along the collection track from one array position to the next.

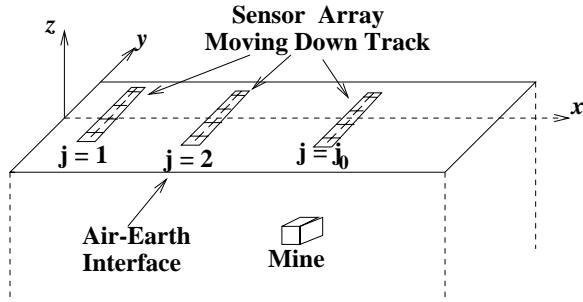

Figure 1: Data Acquisition Method for Subsurface Detection Problem

We consider statistical signal processing methods for solving the object detection problem outlined in the previous paragraphs. In §2, we describe a physical model relating the characteristics of the buried object to the observations obtained over an array. We next use this physical model as the basis for a simple, analytical, stochastic model describing the distribution of clutter. This model takes the form of a state-space system accounting both for the inter-element and inter-array correlation of the noise. In §4, we take advantage of the fact that the Kalman filter can be used to decorrelate (or whiten) such noise processes to obtain a method for detecting objects. We show in the examples in §5 that this process is capable of detecting shallowly buried mine-like objects reliably (a) up to 20cm before the array actually passes over the mine and (b) under low clutter conditions, when the mine is located up to 30 cm from one side or another of the array. Finally, conclusions are described in §6.

2 Forward Model

We assume that the array is situated in the $x - y$ plane and proceeds from $x = 0$ to $x = x_{max}$ stopping at N_s equally spaced locations to obtain data. The array is composed of a single transmitter at $y = 0$ and N_r receivers equally spaced on either side of the array. All transducers are taken to be small current loops of radii r_p located z_p above the air-earth interface carrying I A of current with an $e^{-i\omega t}$ time dependence. We define $d_{m,n}$ to be the field measured by the m th element of the array at the n th stop between $x = 0$ and

$x = x_{max}$. In this paper, we assume that the object represents a small perturbation of constant conductivity σ S/m in the electromagnetic properties of the earth so that the first Born approximation [2] can be used to obtain the following, tractable physical model

$$d_{nm} = -\frac{\sigma(\omega\mu I r_p)^2}{4} \times \int_V A(\mathbf{r} - \mathbf{r}_0 + \mathbf{r}_n) A(\mathbf{r} - \mathbf{r}_0 + \mathbf{r}_m) d\mathbf{r} \quad (1)$$

where the quantity A represents the Green's function for the problem of a loop over a half-space [2], $\mathbf{r} = [x \ y \ z]^T$ is a point in three space represented in either Cartesian or polar coordinates, \mathbf{r}_0 is the position of the center of the object, \mathbf{r}_n (\mathbf{r}_m) is the position of the transmitter (receiver), μ is the magnetic permeability and the integral is taken over the volume, V , of the prototypical object centered at the origin. Given this model, the goals of the processing in this paper are the detection and localization of the presence of an object from noisy observations of d_{ij} .

3 Clutter Model

The motivation for the mathematical form of the clutter model is provided by the nature of the signal observed over the array due only to an object buried some distance away. For the problems of interest here, the wavefield over the aperture of the array is rather smooth when an object does in fact exist near the array and can be well modeled by a low order polynomial in y_m , the y position of the m th sensor in the array [3]. In other words we can write

$$d_{m,n} = \sum_{j=0}^J \alpha_{j,n} y_m^j. \quad (2)$$

By defining the vectors $\mathbf{d}^T(n) = [d_{1,n} \ d_{2,n} \ \dots \ d_{N_r,n}]$ and $\boldsymbol{\alpha}^T(n) = [\alpha_{0,n} \ \alpha_{1,n} \ \dots \ \alpha_{J,n}]$, (2) is rewritten as

$$\mathbf{d}(n) = \mathbf{C}\boldsymbol{\alpha}(n). \quad (3)$$

where the (m, j) th element of \mathbf{C} is y_m^j .

The clutter model we employ in this work is based on the assumption that the random signal over the array in the absence of an object is the sum of two components. The first portion is an additive zero mean, white Gaussian component of variance γ^2 representing sensor noise. The second component is intended to capture the effects due to the statistical distribution of the environmental factors not of interest in the detection problem. Here we assume that this signal can also be described by a model of the form (3). In the case of an object, the coefficients of the polynomial

are deterministically related to the position of the object relative to the array. For clutter however, these coefficients are taken to be random quantities. That is, $\alpha(n)$ is a random vector. Such a model arises if we assume that the clutter represents the average effect on the sensor array of a random distribution of small scatterers.

To account for the fact that the clutter seen at position n of the array should be correlated to that at position $n + 1$, we employ the following model of the spatial evolution of $\alpha(n)$:

$$\alpha(n+1) = \alpha(n) + \mathbf{B}(n)\mathbf{w}(n) \quad (4)$$

where $\mathbf{B} = \nu \text{diag} [\delta^{J/2}, \delta^{(J-1)/2}, \dots, 1]$, $\nu > 0$, $\delta \in (0, 1)$, and $\mathbf{w}(n)$ is a zero mean, unit variance, uncorrelated vector of Gaussian random variables. Finally, $\alpha(0)$ is taken to be a zero mean Gaussian random vector with covariance matrix given by $\mathbf{B}^T \mathbf{B}$. Eq. (4) represents a random walk model for the vector $\alpha(n)$. The matrix \mathbf{B} is such that variance of the additive noise is greatest for the higher order coefficients in (2) and decreases for the lower order α 's representing lower frequency components. The constant ν controls the overall power in the process and δ determines the relative variances among the coefficients.

To summarize, in the absence of an object, the overall signal model we use for the remainder of the work is described by the following state-space model with $\alpha(n)$ representing the state of the system:

$$\alpha(n+1) = \alpha(n) + \mathbf{B}\mathbf{w}(n) \quad (5)$$

$$\mathbf{d}(n) = \mathbf{C}\alpha(n) + \mathbf{v}(n) \quad (6)$$

where $\mathbf{v}(n) \sim N(0, \gamma^2 \mathbf{I})$ is the white sensor noise.

4 Detection algorithm

We begin by assuming that the object may only be located at position \mathbf{r}_0 so that the first problem of interest is to determine whether the data we observe as the array proceeds down the track are just clutter or are comprised of clutter plus object. From a statistical signal processing perspective, this amounts to a binary hypothesis test. Under the null hypothesis, H_0 , the data $\mathbf{d}(n)$ are comprised only of clutter and is therefore modeled using (5) and (6). Under the hypothesis that a mine is present, the data are described by:

$$\alpha(n+1) = \alpha(n) + \mathbf{B}\mathbf{w}(n) \quad (7)$$

$$\mathbf{d}(n) = \mathbf{s}_0(n) + \mathbf{C}\alpha(n) + \mathbf{v}(n) \quad (8)$$

where $\mathbf{s}_0(n)$ is the signal over the array at time n arising from the object at position \mathbf{r}_0 which can be computed using the model of §2.

A key difficulty in solving this binary decision problem is that the clutter is correlated. To overcome this problem, we employ a Kalman filter to “whiten” the data. Specifically, the Kalman filter takes as input the sequence $\mathbf{d}(n)$ and produces as output a new sequence $\mathbf{q}(n)$ termed the innovations [1]. When there is no object present, $\mathbf{q}(n)$ is a zero mean, unit variance, white Gaussian noise sequence. In the event that an object is present, $\mathbf{q}(n)$ is again unit variance, white, and Gaussian, but now there is an added mean vector, $\rho(n)$ (also known as a signature), which can be computed directly from $\mathbf{s}(n)$ and the matrices in the state space model for the noise [1]. Thus, the detection problem now is one of determining whether or not there exists a known mean in a sequence of independent, unit covariance Gaussian random vectors.

In the case where the two hypotheses are to be distinguished based on a batch of data obtained between $n = 0$ and $n = N$, the problem stated in the previous paragraph has a well known solution given in the form of a likelihood ratio test. First, the following likelihood statistic is computed

$$l(N) = \sum_{j=0}^N \rho^T(j) \mathbf{q}(j) - 0.5 \rho^T(j) \rho(j). \quad (9)$$

Next, we compare $l(N)$ with a threshold $\tau(N)$. If $l(N) > \tau(N)$ we say that the object is present otherwise, we continue to collect data. Typically, $\tau(N)$ is chosen such that the probability of false alarm P_{fa} is less than or equal to a predefined threshold [4]. For the application here, we want the ability to declare the presence of an object before the array actually passes the object. That is, we want to solve a sequential detection problem wherein at each n we decide whether to declare an object, declare no object, or move the array and collect more data. While well known methods exist for optimally solving this problem when ρ is independent of n , the solution to the problem for a time varying mean is less well studied. The algorithm here represents a first attempt to solve this problem for our object detection application.

Since we know the object location, we can, in principle, take data up to but not including the time the sensor passes the object. Thus, at each n we compute $l(n)$ as in (9) and for a fixed P_{fa} , perform the comparison to $\tau(n)$. We do not stop taking data until that point, n_0 , when the x coordinate of the array is such that at step $n_0 + 1$ the array would pass the object. At that time we look at the sequence of decisions made for $n \leq n_0$. If H_1 has been accepted more than Q times (here $Q = 3$), that hypothesis is declared to be true.

In the more realistic event that we know neither whether an object is in a region of interest nor where it may be, we employ a “multiple model” [1] approach to the detection problem. We hypothesize the existence of objects over a coarse grid extending in front of the moving array. Associated with the i th such object location is a separate signature sequence $\rho_i(n)$. At each n , we perform a separate binary likelihood ratio test for each location in the grid. When the array is set to pass those possible object locations with a given x coordinate, we look to see if any of the hypotheses in that collection have been chosen more than M times. If none satisfies this criteria, we continue moving the array. If one location passes, we declare an object. If more than one has been passed more than M times, we take as the actual object detection that hypotheses which has exceeded its threshold by the widest margin at any time during the scan. Essentially, we take the most likely target if there are multiple possibilities.

As we discuss in the talk accompanying this paper, this sliding window testing process is advantageous because it requires the storage of a fixed and relatively small number of signature vectors. In particular, excellent results are obtained in §5 for using a target signature library of only 400 $\rho(n)$ sequences the computation, storage, and manipulation of which is relatively easy making this processing methodology quite amenable to real time implementation.

5 Examples

For the following examples, the array is composed of a single transmitter located at $x = 0$ and 20 receivers with half equally spaced between $y = 5$ cm and $y = 50$ cm and the other half spaced between $y = -5$ cm and $y = -50$ cm. The array starts at $x = 0$ m and proceeds in 75 equally spaced steps to $x = 3.7$ m. The target is modeled as a $5 \times 5 \times 5$ cm³ parallelepiped of contrast 1 S/m above the surrounding soil and it is assumed that the burial depth of the object is known *a priori*. Thus, the signature vectors are generated using this information. In practice, this assumption is not overly restrictive as the range of burial depths is generally quite limited for a given demining application. Our scenario is meant to model the case of a shallowly buried anti-personnel mine, of interest for humanitarian demining. The noise measure used here is the signal to clutter plus noise ratio (SCNR) taken to be 20 times the base 10 logarithm of the ratio of the signal power to the noise plus clutter power taken over the entire data set.

We first consider the detection of an object located at $(x, y, z) = (2.2, -0.22, -0.05)$ m under a variety of SCNR. In Fig. 2(a) we display a sample data set. The

(b) Detection performance for first example.

(c) Average value of likelihood statistic in excess of threshold. The dashed line indicates the x coordinate of the object.

Figure 2: Results for first example

object, located in the image at $(x, y) = (2.2, -0.22)$ m, is barely discernible at this SCNR. In Fig. 2(b) the detection performance as a function of SCNR is shown. Each point represents the fraction of times the object was detected in 100 runs of the algorithm using independent realizations of the clutter and noise processes for each run. Strong performance is seen down to a SCNR of about -20 dB with a gradual decline in detection as the SCNR further degrades. At -15 dB the object is detected essentially 100% of the time.

In Fig. 2(c), we display the average value of the likelihood statistic less the threshold (i.e. $l - \tau$) as a function of the position of the sensing array as the array proceeds toward the object. The average is taken over all noise realizations and all experiments where the object was in fact detected. The SCNR for this problem was about 2.6 dB and the x coordinate of the object is 2.2 m. Fig. 2(c) clearly shows that the relevant decision statistic rises to a significant level above the detection threshold of zero well before the array actually passes over the buried object. In particular, these statistics become substantial when the array is located at $x = 1.95$ m which is over 25 cm from the location of the buried object.

As a second example, we consider detecting an object at $(x, y, z) = (2.2, -0.7, -0.05)$. Unlike the first case, the object is located outside of the direct field of view of the array. The detection results are given in Fig. 3(a) while in Fig. 3(b), the plot of average likelihood statistics less threshold are shown for at SCNR of about 1. These plots show that even when the object is located significantly off the axis of the array, we still retain a strong degree of forward looking, predictive capability. In particular, non-negligible test statistics are reliably observed when the array is located about 30 cm from the object.

6 Conclusions

In this paper, we have presented an approach for the detection and localization of objects from near field sensor data. Our statistical signal processing approach is tailored both to the sensor and the data collection method. The approach we have taken casts the detection problem in the form of a statistical hypothesis test. Using a novel state-space model for the clutter, we employ a Kalman filter to whiten the data and use a rolling window, multiple-model approach to ascertain the location of a object. Preliminary simulations indicate that this approach can provide significant forward and side looking capability thereby increasing the area over which an EMI sensor can reliably detect buried objects. In the future, we look to extend these processing methods to other detection

problems; specifically those arising in remote surveillance where target signatures have been reduced due to excessive clutter, foliage, or other obscuration.

ABSTRACT

The problem of mine detection and localization from array-based electromagnetic induction data is addressed. An efficient forward scattering model based on the Born approximation is employed. Using insight obtained from this model, a clutter model in the form of a state space system is developed which describes the correlation of the noise both across the sensing array and from one position of the array to the next as the measurement device proceeds down track. A multiple-model detection scheme based on the whitening properties of the Kalman filter is employed to perform the actual mine detection. This approach allows for the detection and localization of buried objects well before the array physically moves over mines. Examples are provided for mines buried directly in front and off to one side of the array.

Keywords: Mine detection, EMI arrays, Kalman filter

1. INTRODUCTION

The problem of detecting and localizing buried landmines from indirect observations of scattered electromagnetic radiation has received considerable attention in recent years. Of interest in this paper is the development of statistical signal processing methods for solving such problems based on data collected using an array of very low frequency electromagnetic induction sensors. From a signal processing perspective, the physics of this problem represents an unusual challenge. The majority of array processing algorithms are based on the assumption that the observed waves are propagating in free space and the unknown sources are in the far field. The resulting planewave model for the radiation incident on the sensors serves as the basis for all beamforming and high-resolution localization methods. For the applications of interest here, the objects are in the nearfield of the array and while the sensors are in freespace, the targets are located in a lossy halfspace. The typical array approaches are therefore not applicable.

In addition to the basic physics describing these problems, the data are typically obtained by sweeping the array in a fixed direction over a region of interest, as illustrated in Figure 1. The result is an “image” acquired over time whose number of rows is equal to the number of sensors in the array and whose number of columns is determined by the number of stops the array makes as it sweeps over the area. This implied temporal structure is the second unique image processing element present in this problem. In particular, it is imperative to detect the mine *before* the sensor array actually passes over its location. This requirement implies that any algorithm must process the image data in a real-time, column-by-column manner, continuously updating its decision as to mine presence and its estimate concerning the object’s location as new data are obtained by the scanning procedure.

The final challenging characteristic of this problem is the need to process data contaminated by “clutter.” Physically, such clutter can arise from a variety of inhomogeneities present in the soil including a random distribution of rocks and other discrete structures as well as the continuous, natural changes in the electromagnetic characteristics of the earth. From a signal processing perspective, we regard clutter as a correlated noise source present in the data. The correlation is evident first along the array from one sensor to the next and second along the collection track from one array position to the next. To adequately detect mines whose signals are obscured by such noise requires both careful modeling of the clutter and the development of processing methods explicitly based on these models.

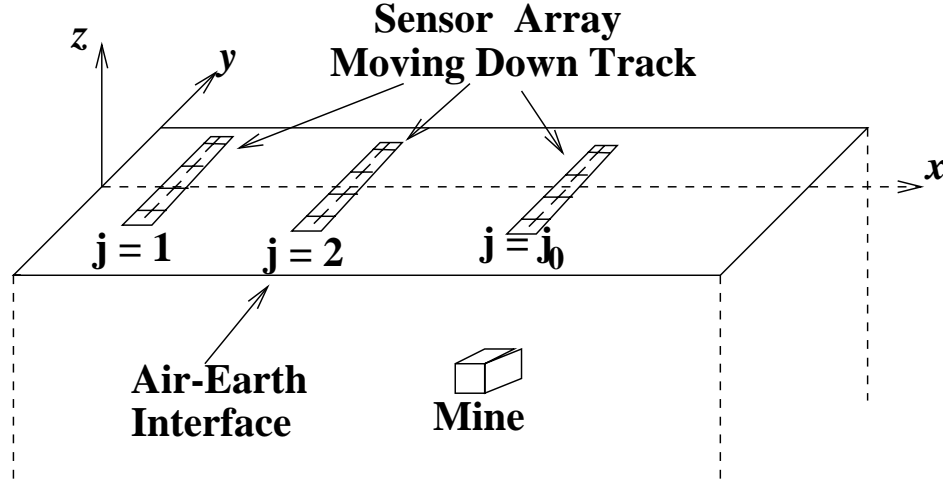

Figure 1. Data Acquisition Method for Subsurface Detection Problem

In this paper, we consider statistical signal processing methods for solving the mine detection problem outlined in the previous paragraphs. Our focus is on shallowly buried metallic anti-personal mines arising in the case of humanitarian demining. In Section 2, we describe a physical model relating the characteristics of the buried mine to the observations obtained over an array. We next use this physical model as the basis for a simple, analytical, stochastic model describing the distribution of clutter. In particular, the clutter model takes the form of a so-called “state-space” system. This system accounts both for the inter-element and inter-array correlation of the noise. In Section 4, we take advantage of the fact that the Kalman filter can be used to decorrelate (or whiten) such noise processes to obtain a method for detecting mines. At each stop of the array, we perform a series of hypothesis tests. Under the null hypothesis for each test, no mine is present. Under the alternative, there is a mine located at one of a number of positions over a coarse scale grid. The whitening properties significantly simplify the formulation of the tests while retaining the optimality property of the procedure. We stop the array and declare the presence of a mine when the sequence of tests for a mine at a hypothesized location are “sufficiently convincing.” We show in the examples in Section 5 that this process is capable of detecting mines reliably (a) up to 20cm before the array actually passes over the mine and (b) under low clutter conditions, when the mine is located up to 30 cm from one side or another of the array. Finally, conclusions and future work are described in Section 6.

2. FORWARD MODEL

To fix notation, we assume that the array is situated in the $x - y$ plane and proceeds from $x = 0$ to $x = x_{max}$ stopping at N_s equally spaced locations to obtain data. The array is composed of a single

transmitter at $y = 0$ and N_r receivers equally spaced on either side of the array. All transducers are taken to be small current loops of radii r_p located z_p above the air-earth interface carrying I A of current with an $e^{-i\omega t}$ time dependence. We define $d_{m,n}$ to be the field measured by the m th element of the array at the n th stop between $x = 0$ and $x = x_{max}$. In this paper, we assume that the mine represents a small perturbation of constant conductivity σ S/m in the electromagnetic properties of the earth so that the first Born approximation¹ can be used to obtain a tractable physical model. For the case of a single mine, it can be shown that the relationship between the physical properties of the mine and y_{mn} is given by¹

$$d_{nm} = -\frac{\sigma(\omega\mu I r_p)^2}{4} \int_V A(\mathbf{r} - \mathbf{r}_0 + \mathbf{r}_n) A(\mathbf{r} - \mathbf{r}_0 + \mathbf{r}_m) d\mathbf{r} \quad (1)$$

where the quantity A represents the Green's function for the problem of a loop over a half-space, $\mathbf{r} = [x \ y \ z]^T$ is a point in three space represented in either Cartesian or polar coordinates, \mathbf{r}_0 is the position of the center of the mine, \mathbf{r}_n (\mathbf{r}_m) is the position of the transmitter (receiver), μ is the magnetic permeability and the integral is taken over the volume, V , of the prototypical mine centered at the origin. In [1], it is shown that the Green's function A can be well approximated as

$$A(\mathbf{r}) = \frac{2}{\pi k(\mathbf{r}) \sqrt{r r_p}} \left[\left(1 - \frac{1}{2} k(\mathbf{r})^2 \right) K(k(\mathbf{r})) - E(k(\mathbf{r})) \right] \quad (2)$$

$$k(\mathbf{r}) = \frac{4 r r_p}{(z + z_p)^2 + (r + r_p)^2} \quad (3)$$

where $r = \|\mathbf{r}\|$ is the distance to the physical point, $K(x)$ is the complete elliptic integral of the first kind, $E(x)$ is the complete elliptic integral of the second kind and the parameter $k(\mathbf{r})$ is in the range 0 to 1.

For the problem of interest in this paper, we have found by direct evaluation that $k(\mathbf{r}) \in [0, 0.6]$. Under this restriction, we have developed the following highly accurate, yet simple approximation to (2):

$$A(\mathbf{r}) = \frac{2}{\pi k(\mathbf{r}) \sqrt{r r_p}} \left(\beta_4 k^4(\mathbf{r}) + \beta_6 k^6(\mathbf{r}) \right) \quad (4)$$

with $\beta_4 = 0.0882$, $\beta_6 = 0.1321$ and $k(\mathbf{r})$ as in (3). The particular values of the β parameters are obtained by a least squares fit and the use of the fourth and sixth powers of k is motivated by the Taylor series expansion for the right hand side of (2). A semilogarithmic comparison of the right hand sides of (2) and (4) is shown in Figure 2. The solid line represents the exact combination of elliptic integrals while the dashed line is the polynomial approximation. It is clear that the approximation is, for all intents and purposes, the same as the exact expression. From a computational perspective however, (4) offers definite advantages over (2) in terms of speed of evaluation and ease of manipulation.

Given this model, the goals of the processing in this paper are the detection of the presence of a mine from noisy observations of d_{ij} and determination of \mathbf{r}_0 once a detection has been declared.

3. CLUTTER MODEL

Typically, white Gaussian noise is used as the clutter model for mine detection problems due to its tractability. Unfortunately, this simplified assumption leads to a degradation in detection performance. In this work we instead explicitly model the clutter or background process, leading to more robust performance. In particular, we develop a tractable yet realistic stochastic model describing the distribution of the data obtained over our receiver in the absence of a target. This statistical model then forms the basis for a decision-theoretic procedure for the localization of buried mines discussed in the remainder of this paper.

Figure 2. Comparison of exact and polynomial approximation to forward scattering model

The motivation for the mathematical form of our clutter model is actually provided by the nature of the signal observed over the array due only to a mine buried some distance away. The wavefield over the aperture of the array is rather smooth when a mine does in fact exist near the array. In Fig. 3, noiseless simulated data is shown for the case of a $.05 \times .05 \times .05$ m³ mine located at $\mathbf{r}_0 = \{x_0, y_0, z_0\} = \{2, .1, -.05\}$ m where an 8 element array of length .6m is positioned at $x \in \{0, .5, 1, 1.5\}$ m. These plots indicate the more general feature that the data over the array can be well modeled by a low order polynomial in y_i , the y position of the i th sensor in the array. In other words we can write

$$d_{m,n} = \sum_{j=0}^J \alpha_{j,n} y_m^j. \quad (5)$$

By defining the vectors $\mathbf{d}^T(n) = [d_{1,n} \ d_{2,n} \ \dots \ d_{N_r,n}]$ and $\boldsymbol{\alpha}^T(n) = [\alpha_{0,n} \ \alpha_{1,n} \ \dots \ \alpha_{J,n}]$, (5) is rewritten as

$$\mathbf{d}(n) = \mathbf{C}\boldsymbol{\alpha}(n). \quad (6)$$

where the (m, j) th element of \mathbf{C} is y_m^j .

The clutter model we employ in this work is based on the assumption that the random signal over the array in the absence of a mine is the sum of two components. The first portion is an additive zero mean, white Gaussian component of variance γ^2 representing sensor noise. The second component is intended to capture the effects due to the statistical distribution of the environmental factors not of primary interest in the detection problem. Here we assume that this signal will display the same basic smoothness as that seen in Fig. 3. That is it will be described by a low order polynomial. In the case of a mine, the coefficients of the polynomial are deterministically related to the position of the object relative to the array. For clutter however, these coefficients are taken to be random quantities. That is, $\boldsymbol{\alpha}(n)$ is a random vector. Such a model arises if we assume that the clutter represents the average effect on the sensor array of a random distribution of small scatterers. If each such scatterer results in a smooth signal over the array then so too will their sum. We note here that this choice of model certainly satisfies the criteria set forth in the Introduction that clutter essentially represents noise which is correlated from one array element to the next.

The second criteria is that the clutter should be correlated from one position of the array to the next. For example, a clutter vector at position n should be correlated to that at position $n + 1$. This implies

Figure 3. Data vectors, \mathbf{d}_j , obtained as array proceeds toward buried mine. Note the scale change in the plots.

the need to specify a dynamic model describing the evolution of $\boldsymbol{\alpha}(n)$. Toward this end, we employ the following model of the spatial evolution of $\boldsymbol{\alpha}(n)$:

$$\boldsymbol{\alpha}(n+1) = \boldsymbol{\alpha}(n) + \mathbf{B}(n)\mathbf{w}(n) \quad (7)$$

where $\mathbf{B} = \nu \text{diag}[\delta^{J/2}, \delta^{(J-1)/2}, \dots, 1]$, $\nu > 0$, $\delta \in (0, 1)$, and $\mathbf{w}(n)$ is a zero mean, unit variance, uncorrelated vector of Gaussian random variables. Finally, $\boldsymbol{\alpha}(0)$ is taken to be a zero mean Gaussian random vector with covariance matrix given by $\mathbf{B}^T \mathbf{B}$. Eq. (7) represents a random walk model for the vector $\boldsymbol{\alpha}(n)$. The matrix \mathbf{B} is such that variance of the additive noise is greatest for the higher order coefficients in (5) and decreases for the lower order α 's representing lower frequency components. The constant ν controls the overall power in the process and δ determines the relative variances among the coefficients.

To summarize, in the absence of a mine, the overall signal model we use for the remainder of the work is described by the following state-space model with $\boldsymbol{\alpha}(n)$ representing the state of the system:

$$\boldsymbol{\alpha}(n+1) = \boldsymbol{\alpha}(n) + \mathbf{B}\mathbf{w}(n) \quad (8)$$

$$\mathbf{d}(n) = \mathbf{C}\boldsymbol{\alpha}(n) + \mathbf{v}(n) \quad (9)$$

where $\mathbf{v}(n) \sim N(0, \gamma^2 \mathbf{I})$ is the additive white, sensor noise.

Sample paths of these clutter models are shown in Figs. 5(a) and 7(a) for an array consisting of 20 receiver elements for parameter choices described in greater depth in Section 5. In both cases, the variance of the $\mathbf{w}(n)$ is greater than that of $\mathbf{v}(n)$ so that the background “clutter to noise” ratio is assumed to be relatively large. These images indicate that our model of clutter possesses the desired features. As functions of y , they are quite smooth. As x (and hence n) increases, they display gradual changes except at a few points where the random walk model results in a sharp alteration of the “shape” of the profile.

In closing this section, we wish to emphasize that the clutter model described above is neither the only nor even necessarily the best such model for the processing of real data. Rather the precise model based on the underlying polynomial regression is intended more as a vehicle for demonstrating the efficacy of the detection algorithm described and tested in subsequent sections. Indeed, our approach towards detection is based only on the reasonable and generally unrestrictive assumption that one can describe the clutter using *some* state space model to capture the temporal correlation of the process. Any valid state space model will work and the problem of fitting field data to such a modeling structure represents an interesting and very worthwhile piece of future research.

4. DETECTION ALGORITHM

In this section, we develop our approach to the detection of buried mines from progressively obtained array EMI data. We begin by solving a simpler problem in which we assume that the mine can exist only at a known point in space and want only to determine whether the mine is present. The solution to this problem then allows for the solution to the problem where we lift the assumption of known location.

4.1. Case I: Known mine location

Assuming that the mine may only be located at position \mathbf{r}_0 , the first problem of interest is to determine whether the data we observe as the array proceeds down the track is just clutter or is comprised of clutter plus mine. From a statistical signal processing perspective, this amounts to a binary hypothesis test. Under the null hypothesis, H_0 , the data $\mathbf{d}(n)$ is comprised only of clutter and is therefore modeled using (8) and (9). Under the alternate hypothesis, the data are described by combining (8) and a modified observation equation:

$$\mathbf{d}(n) = \mathbf{s}_0(n) + \mathbf{C}\boldsymbol{\alpha}(n) + \mathbf{v}(n) \quad (10)$$

where $\mathbf{s}_0(n)$ is the signal over the array at time n arising from the mine at position \mathbf{r}_0 which can be computed using the model of Section 2.

A key difficulty in solving this binary decision problem is that the clutter is correlated. To overcome this problem, we employ a Kalman filter to “whiten” the data. In most cases, the Kalman filter is used to track the state of a stochastically evolving system. It is well known however that a bi-product of the minimum mean square error property of the filter is that it may be interpreted as a means of de-correlating a non-white noise sequence. Specifically, the Kalman filter takes as input the sequence $\mathbf{d}(n)$ and produces as output a new sequence $\mathbf{q}(n)$ termed the innovations. When there is no mine present, $\mathbf{q}(n)$ is a zero mean, unit variance, white Gaussian noise sequence. In the event that a mine is present, $\mathbf{q}(n)$ is again unit variance, white, and Gaussian, but now there is an added mean vector, $\boldsymbol{\rho}(n)$ (also known as a signature), which can be computed directly from $\mathbf{s}(n)$ and the matrices in the state space model for the noise.² Mathematically we have:

$$\text{Under } H_0 \quad \mathbf{q}(n) \sim N(0, \mathbf{I}) \quad (11)$$

$$\text{Under } H_1 \quad \mathbf{q}(n) \sim N(\boldsymbol{\rho}(n), \mathbf{I}) \quad (12)$$

That is, the detection problem now is one of determining whether or not there exists a known mean in a sequence of independent, unit covariance Gaussian random vectors.

In the case where the two hypotheses are to be distinguished based on a batch of data obtained between $n = 0$ and $n = N$, the problem stated in the previous paragraph has a well known solution given in the form of a likelihood ratio test. First, the following likelihood statistic is computed

$$l(N) = \sum_{j=0}^N \boldsymbol{\rho}^T(j)\mathbf{q}(j) - 0.5\boldsymbol{\rho}^T(j)\boldsymbol{\rho}(j). \quad (13)$$

Next, we compare $l(N)$ with a threshold $\tau(N)$. If $l(N) > \tau(N)$ we say that the mine is present otherwise, we continue to collect data. Typically, $\tau(N)$ is chosen such that the probability of false alarm P_{fa} (that is the probability of rejecting H_0 when H_0 is in fact true) is less than or equal to a predefined threshold.³ Under our Gaussian assumptions on the innovations, this threshold is³

$$\tau(N) = d(N) \operatorname{erfc}_*^{-1}(P_{fa}) - d^2(N)/2 \quad (14)$$

with

$$\operatorname{erfc}_*(x) = \frac{1}{\sqrt{2\pi}} \int_x^\infty e^{-x^2/2} dx \quad \text{and} \quad d^2(N) = \sum_{j=0}^N \boldsymbol{\rho}^T(j) \boldsymbol{\rho}(j)$$

For the demining application, we want the ability to declare the presence of a mine before the array actually passes the object. That is, we want to solve a sequential detection problem wherein at each n we decide whether to declare a mine, declare no mine, or move the array and collect more data. While well known methods exists for optimally solving this problem when $\boldsymbol{\rho}$ is independent of n , the solution to the problem for a time varying mean is less well studied. The algorithm in this paper represents a first attempt to solve this problem for the demining application.

Since we know where the mine is located, we can, in principle, take data up to but not including the time the sensor passes the mine. Thus, at each n we compute $l(n)$ as in (13) and for a fixed P_{fa} , perform the comparison to $\tau(n)$. We do not stop taking data until that point, n_0 , when the x coordinate of the array is such that at step $n_0 + 1$ the array would pass the mine. At that time we look at the sequence of decisions made for all previous n . If H_1 has been accepted more than Q times (in this paper $Q = 3$, that hypothesis is declared to be true.

We observe that we could have chosen the simpler approach of collecting data until time n_0 and then solving the fixed size binary hypothesis test. The methods described in the previous paragraph though are more easily generalized and provide greater insight into the more complex problem where we cannot wait until n_0 but must make the mine/no mine decision as rapidly as possible.

4.2. Case II: Unknown mine location

In the more realistic event that we know neither whether a mine is in a region of interest nor where it may be, we employ a “multiple model”² approach to the detection problem. As illustrated in Fig. 4, we hypothesize the existence of mines over a coarse grid extending in front of the moving array. Associated with the i th such mine location is a separate signature sequence $\boldsymbol{\rho}_i(n)$. At each n , we perform a separate binary likelihood ratio test for each location in the grid. When the array is set to pass those possible mine locations with a given x coordinate, we look to see if any of the hypotheses in that collection have been chosen more than M times. If none satisfies this criteria, we continue moving the array. If one location passes, we declare a mine. If more than one has been passed more than M times, we take as the actual mine detection that hypotheses which has exceeded its threshold by the widest margin at any time during the scan. Essentially, we take the most likely target if there are multiple possibilities.

The implementation of this procedure can be made quite efficient. Rather than keeping track of a large number of mine locations extending over the entire track of the array, we perform this procedure using a sliding window of hypothesized target positions. Let Δx be the distance the array moves from n to $n + 1$. We choose as the coarse grid of possible mine locations the points at the center of the squares on a grid of size $M\Delta x$. That is, it takes the array M steps to proceed through one column of the coarse scale grid. As shown in Fig. 4, assuming the array has been moving for a sufficiently long time so that the Kalman filter is operating in the steady state, there is a certain shift invariance to the detection problem. In particular, the mathematical forms of the hypotheses generated when the array is in column 1 and the mines in column

Figure 4. Relationship of moving array to coarse grid of possible mine locations. Rectangles represent positions of the array as it moves down the track. Circles represent hypothesized mine locations. There are $M = 4$ array positions per coarse grid cell.

2 (represented by the open boxes and circles) are identical to those obtained when the array is in column 2 and the mines are postulated to lie in column 3 (the darkened rectangles and circles). Clearly this holds for any array/mine combinations with identical relative spacings in the along-track direction.

We use this observation in the following manner. We begin by postulating mines over a $P \times P$ coarse grid in front of the array where P is chosen such that the response of the array when it is $PM\Delta x$ meters away is negligible. This grid (i.e. these hypotheses) are retained for the first M steps of the array. At the $M + 1$ st step, when the array is entering the second column, the grid looks very similar as in step 1 except the columns need to be renumbered. The first column, of the grid is removed since the array is leaving it. Each of the remaining columns are shifted to the left by one and a new column of hypotheses is added to the rightmost edge of the grid so that the overall array is still $P \times P$ only now looking further down track than was the case before. This procedure is repeated every M moves of the array.

This sliding window testing process is advantageous because it requires the storage of a fixed and relatively small number of signature vectors. Rather than having to maintain a $\rho(n)$ sequence for every conceivable combination of array locations and mine positions, we need only compute and store P^2M such sequences. For the EMI problems of interest here, excellent results are obtained in Section 5 for $P = 10$ and $M = 4$. The computation, storage, and manipulation of only 400 $\rho(n)$ sequences is relatively easy making this processing methodology quite amenable to real time implementation.

5. EXAMPLES

In this section, the performance of the detection approach is demonstrated and analyzed under a variety of noise conditions and mine placements. In all cases, the array is composed of a single transmitter located at $x = 0$ and 20 receivers with half equally spaced between $y = 5$ cm and $y = 50$ cm and the other half spaced between $y = -5$ cm and $y = -50$ cm. Thus, the overall length of the array is 1 meter. The transmitters and receivers are modeled as small circular loops of radius 2 cm located 10 cm above the air-earth interface and operating at 3 kHz. The array starts at $x = 0$ meters and proceeds in 75 equally spaced steps to $x = 3.7$ meters. The rolling grid of coarse scale hypothesized mine locations is composed of a 10 by 10

array of square cells stretching from about -90 cm to 90 cm in the y direction and extending about 2 meters in front of the array in the x direction. Finally, the mine-like target used in these simulations is modeled as a $5 \times 5 \times 5 \text{ cm}^3$ parallelepiped of contrast 1 S/m above the surrounding soil. Further, it is assumed that the burial depth of the mine is known *a priori*. Thus, the signature vectors are generated using this information. In practice, this assumption is not overly restrictive as range of burial depths is generally quite limited for a given demining application. Our scenario is meant to model the case of a shallowly buried anti-personnel mine, of interest for humanitarian demining.

For the low-frequency, Born-based inductive model discussed in Sec. 2, the electrical conductivity of the soil is approximated as zero. Moreover, the frequency and conductivity contrast of the mine enter the model only as multiplicative constants scaling the amplitude of the data. At higher frequencies and when an exact scattering model is employed, these various parameters will indeed play a larger role on the performance of the algorithm. For the work in this paper, however the key determination of performance is the relative strengths of the noise, clutter and target signatures. The measure used here is the signal to clutter plus noise ratio (SCNR) taken to be 20 times the base 10 logarithm of the ratio of the signal power to the noise plus clutter power taken over the entire data set obtained from $x = 0$ to $x = 3.7\text{m}$.

As a first example, we consider the detection of a mine located at $(x, y, z) = (2.2, -0.22, -0.05)$ m under a variety of SCNR. In Fig. 5(a) we display a sample data set. The mine, located in the image at $(x, y) = (2.2, -0.22)$ m, is barely discernible at this SCNR. In Fig. 5(b) the detection performance as a function of SCNR is shown. Each point represents the fraction of times the mine was detected in 100 runs of the algorithm using independent realizations of the clutter and noise processes for each run. The SCNR was changed by setting the variance of $\mathbf{v}(n)$ in (9) to 0.01 and increasing the variance of $\mathbf{w}(n)$ in (7) from 0.01 to 0.25 in steps of 0.02. It is clear, that strong performance is seen down to a SCNR of about -20 dB with a gradual decline in detection as the SCNR further degrades. At an SCNR of -15 dB the mine is detected essentially 100% of the time. Finally, since the mine was not located at one of the coarse scale grid points, a detection was declared if the estimated mine location was one of the four neighbors nearest the true mine location on the hypothesis grid.

In Fig. 6, we display the average value of the likelihood statistic less the threshold (i.e. $l - \tau$ from (13) and (14)) as a function of the position of the sensing array as the array proceeds toward the mine. The average is taken over all noise realizations and all experiments where the mine was in fact detected according to the criterion described previously. The SCNR for this problem was about 2.6 dB and the x coordinate of the mine is again 2.2 m. The plot does not reach 2.2 m because of the coarse scale gridding of the mine hypotheses, which for this problem tests for mines located at $x = 2.1$ m and $x = 2.3$ m. Fig. 6 clearly shows that the relevant decision statistic rises to a significant level above the detection threshold of zero well before the array actually passes over the buried object. In particular, these statistics become substantial when the array is located at $x = 1.95$ m which is over 25 cm from the location of the buried mine.

As a second example, we consider the problem of detecting a mine at $(x, y, z) = (2.2, -0.7, -0.05)$. This placement of the mine is interesting because, unlike the first case, the mine is located outside of the direct field of view of the EMI array. In particular, the array extends to $y = -50$ cm; however the mine is located at $y = -70$ cm. A sample data set at an SCNR of about 1.8 dB is shown in Fig. 7(a) and the detection results are given in Fig. 7(b). As in the first problem, the signature of the mine, which should be evident at around $x = 2.2$ m and $y \in (-.3, -.5)$ m, is obscured by the clutter; however the detection rate is quite high even to an SCNR of about -20dB. In Fig. 8, the plot of average likelihood statistics less threshold are shown for this problem at at SCNR of about 1. These plots show that even when the mine is located significantly off the axis of the array, we still retain a strong degree of forward looking, predictive capability. In particular, non-negligible test statistics are reliably observed for this scenario when the array is located at $x = 1.9$ m which is about 30 cm from the mine.

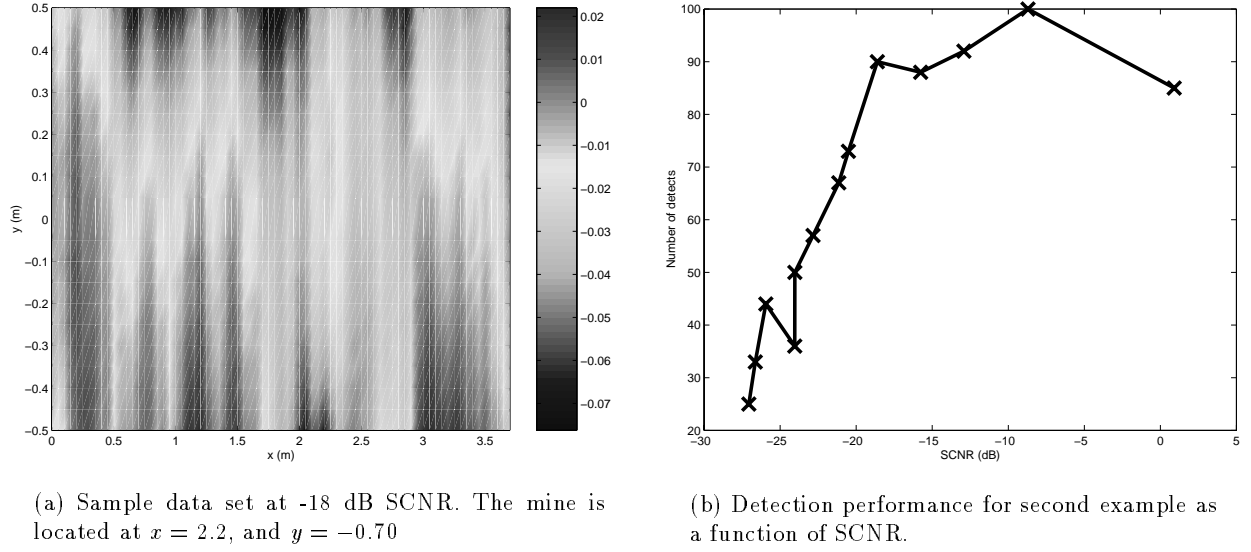

Figure 7. Sample data set and detection results for second example

Figure 8. Average value of likelihood statistic in excess of threshold as array approaches mine location for second problem. Detection requires this value to exceed zero. The dashed line indicates the x coordinate of the mine.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we have presented an approach for the detection and localization of buried landmines from EMI sensor data. Our statistical signal processing approach is tailored both to the sensor (an array of EMI transducers) and the data collection method (progressive acquisition as the array proceeds down track). The approach we have taken casts the detection problem in the form of a statistical hypothesis test. Using a novel state-space model for the clutter, we employ a Kalman filter to whiten the data and use a rolling window, multiple-model approach to ascertain the location of a mine. Preliminary simulations indicate that this approach can provide significant forward and side looking capability thereby increasing the area over which an EMI sensor can reliably detect buried mines.

While the work in this paper has been directed towards an EMI sensing device, the general detection methodology can be extended and applied to *any* scheme in which an array of sensors collects data in a progressive manner. All that is required is a forward model to generate the rather modest sized library of target signatures and a state-space or other recursive model for the clutter. With this in mind, future research efforts stemming from this project include the following:

1. Development of an estimation-based methods to better localize the detected object. Here we are interested in developing a non-linear least squares method which takes the coarse grid estimates generated by the algorithm in this paper and provides a more accurate determination of the mine's true position.
2. Development of methods for “discounting” detected mines from the data set. After the mine has been detected, we want to remove its effects from the data thereby allowing the array to continue down track looking for other buried objects. Failure to perform such discounting generally degrades subsequent performance.
3. Development of a full EMI scattering model for use in generation of target signatures.
4. Identification of state space type model for EMI array from real field data.
5. Extension and adaptation of these methods to ground penetrating radar (GPR) sensor.
6. Use of Kalman filtering ideas for fusion of GPR and EMI sensor data.

An important component associated with the GPR problem is the computation of the scattered fields produced by buried objects when illuminated by the radar source. The choice of technique for computing these fields is often driven by a variety of factors including computational complexity and the flexibility to handle easily a wide range of configurations of scatterers. Based on the fact that objects of interest for many GPR applications have relatively simple shapes such as cylinders and spheres, it is apparent that transition matrix (T-matrix) approach is well suited to the GPR forward problem.

The T-matrix technique is based on the expansion of the fields and the Green's function in spherical (3D) or cylindrical (2D) harmonic series. Considerable work has focused on the generation of efficient recursive T-matrix techniques for computing the scattered field from a single, electrically large, dielectric object. The approach taken in these applications is to tessellate the object into many smaller scatterers. Thus, even though the number of scatterers is large, the order of harmonics used to expand the basis functions is small thereby keeping the computational load relatively small. However, if one wants to find the scattered field from multiple, electrically large, tessellated objects, the number of scatterers grows quite quickly thereby increasing the complexity of the problem considerably. A natural alternative is to treat each object as a single scatterer (i.e. bypass the tessellation) but increase the order of the harmonic expansions for each object. Unfortunately, this approach is hindered by difficulties related to the slow convergence of the harmonic expansions.

Here, we present a modified, stable recursive T-matrix algorithm to calculate the scattered field from a heterogeneous collection of spatially separated objects based on these higher order expansions. Motivated by the GPR problem, we consider the calculation of the scattered field produced by a group of parallel cylinders buried in a lossy medium. In the most general case, these objects can be dielectric or metallic, electrically small (fraction of λ) or large ($1-2 \lambda$). The modification, which will be described in the talk accompanying this abstract, circumvents the slow convergence of the series by replacing the product of two translation matrices with product of three such matrices two of which yield the identity.

In the talk we will also discuss the verification of this algorithm against previously published results for scattered fields from multiple cylinders, compare the computational advantages of this higher order technique relative to the tessellated approach, and provide examples demonstrating the ability of this code to compute fields for GPR-relevant scattering scenarios such as mine detection and hazardous waste removal.

ABSTRACT

We apply high-dimensional analysis of variance (HANOVA) and sequential probability ratio test (SPRT) to detect buried land mines from array ground penetrating radar (GPR) measurements. The GPR array surveys a region of interest in a progressive manner starting at a known position and moving step by step in a fixed direction. Detection method consists of two parts. Because, at each stop, path lengths are different from radar pairs to a mine target, there exists statistically significant difference among received signals when a mine target is present. At first, we use HANOVA to test for statistical significance at each stop. The HANOVA compares multiple sets of data for statistical difference. While HANOVA detects difference among received signals in time-domain, it does not incorporate new data as the GPR array moves down-track. So secondly, we resort to sequential detection to look for changes in result of HANOVA along the GPR array stops. It turns out to be a sequential probability ratio test to detect transient curved signals. This SPRT allows real-time processing as new data are obtained by the GPR array. Performance of this test is analyzed through the probability of detection and mean time between false alarms. Finally, real data and computer simulation are processed to verify the method.

Keywords: Analysis of variance (ANOVA), sequential probability ratio test (SPRT), transient signal, curved data, GPR signal

1. INTRODUCTION

The use of ground penetrating radar (GPR) arrays for detecting buried objects has received considerable attention in recent years in areas such as landmine and unexploded ordnance remediation, utility line mapping, and archaeology.¹ A typical GPR array configuration for such applications is shown in Fig. 1. Here one uniform linear array of transmitters and a second uniform linear array of receivers are simultaneously moved down a linear track. At every stop of the system, each transmitter emits a short pulse of electromagnetic energy which interacts with the surrounding medium. Based on observations of scattered fields collected by the corresponding receiver the objective of the problem is to determine if a mine is present in the field of view of the array.

Current processing methods for this problem fall into one of three categories. First, pattern matching methods² employ techniques such as fuzzy set theory and neural networks. Such methods can be fast but also require extensive training to function well. Moreover, performance analysis is limited to Monte-Carlo simulations. Second, image-then-detect techniques³ employ a beamforming or backpropagation approach to build an image of the subsurface which is then post-processed to detect objects. Such methods generally require the data from the full GPR scan to form an image and are thus not well suited to on-line computations in which information is processed sequentially as the array proceeds down track. Finally, there has been some very interesting work done in the area of statistical processing methods⁴ where one can examine quantities such as detection rates, false alarm probabilities, etc.; however the techniques in⁴ for instance are based on highly complex electromagnetic models for the GPR sensor and are thus computationally intensive.

Here we view the GPR array detection problem in a blind signal detection framework and employ statistical methods to process the GPR returns. By “blind”, we mean that the exact form of signal reflected from a mine is unknown. What we know is that this received signal becomes stronger as the GPR array moves toward a mine and then the signal becomes weaker after the array passes over the mine. Theoretical analysis and computer simulation

Figure 1. GPR, a) a single GPR system, b) a GPR array.

indicate that this change follows a hyperbolic curve, though parameters of this hyperbolic curve are not known beforehand. On the other hand, different T/R pair registers a different hyperbolic curve, it is so because T/R pairs are spatially separated. This information allows us to exploit two generic properties of the signal transmission process. First, for any given stop of the array, the presence of a mine close to a T/R pair results in a jump in the mean value of the observed signal relative to that seen in other pairs. Thus, we develop a high-dimensional ANOVA test⁵ to detect this change. Second, physical principles dictate that as the array moves from one stop to the next, this change will increase and then decrease; that is, the change will be transient in space domain.¹ A sequential detector is employed to track and detect this spatial up-and-down change as the GPR array moves down-track.

The paper is organized as follows. Section 2 discusses physical model of a GPR system and corresponding mathematic model. In Section 3, we present a statistical algorithm to detect mines and analyze its performance in mean time between false alarms and probability of detection. Both field data and simulation are used to show how the algorithm works. Conclusion and direction of future work is given in Section 4.

2. MODEL

2.1. GPR Model

At first, we consider a single GPR system.⁶ It consists one transmitter and one receiver. After each transmission, the receiver collects echo for a certain amount of time. There are two to three components in received signal. One is measurement noise, assumed to be white and Gaussian. The second component is reflection from ground-air interface, which we call clutter. Clutter is always present and changes as the GPR moves. We assume that it varies slowly as the array moves down the track so that it can be estimated and taken out by subtraction.

In Fig. 2 we plot the clutter subtracted observation for single T/R pair obtained from field data as a function of down-track position of the array. Each column of this image is a time-series of observation for a given stop of the array. As can be seen from this figure signal is transient in two ways. First, it appears only when the array is in the vicinity (≈ 0.5 meter) of the mine. For most systems this implies that there are on the order of tens of stops of the array when the mine can be detected out of hundreds to thousands of array positions in a typical GPR survey. Second, when the array is positioned close to the object, the effects are only seen in a portion of the time-series. Signal reflected from the mine always comes behind clutter and attenuates quickly in soil. Before proceeding, we make two observations regarding the signals in Fig. 2. First in general the precise form of the signal of interest is typically unknown due to variations caused by fluctuations in the electrical properties of the soil, unmodeled physical effects such as surface roughness, and variability in the signature caused by the unknown orientation of the mine relative to the sensor. Indeed, Fig. 2 is typical of the variability seen in practice. Second, for clarity, we have displayed signals from two mines which are relatively easy to detect. Generally, even after removing the clutter other sources of noise and interference can significantly reduce the detectability of the desired signal and increase number of false-alarms. In Fig. 3, we can see that besides signals reflected from two mines, there are other interferences as well.

Figure 2. Signal generated from two objects buried at position 1.5m and 3.0m.

Figure 3. Signal from other three T/R pairs, from left to right, pair 2, 3, and 4.

2.2. Mathematic Model

Based on this discussion, at down-track position n of the array, after clutter has been removed, we have the classic binary hypothesis model for the GPR signal returns

$$\begin{aligned} H_0 : \quad & \mathbf{x}_m(n) = \mathbf{w}_m(n) \\ H_1 : \quad & \mathbf{x}_m(n) = \mathbf{s}_m(n) + \mathbf{w}_m(n) \end{aligned} \quad (1)$$

for $m = 1, \dots, M$, $n = 1, \dots, N$, M is number of T/R pairs, N is number of array stops. Here $\mathbf{x}_m(n)$, $\mathbf{s}_m(n)$, $\mathbf{w}_m(n)$ are column vectors of length K , representing time series of observation, signal, and noise from the i th T/R pair. The noise is assumed to be white and Gaussian with zero-mean and variance σ_m^2 . While the exact structure of \mathbf{s}_m is unknown, we see that the effects of this signal are to cause a jump in the mean of the \mathbf{x}_m for those n where a mine is in the field of view of the GPR. Thus the statistical problem of interest in this work is to detect this transient signal based on M such observation vectors at N steps.

As detailed in the remainder of this paper, we approach this problem in two steps. First, we develop a method for detecting the presence of \mathbf{s}_m for a fixed location of the GPR array. Second, we use this test in a sequential manner to process the returns as the array acquires new data.

At a given position of the array since we do not know of \mathbf{s}_m the statistical problem we pose is

$$\begin{aligned} H_0 : \quad & \boldsymbol{\mu}_m = \mathbf{0} \\ H_1 : \quad & \boldsymbol{\mu}_m \neq \mathbf{0}, \quad m = 1, \dots, M \end{aligned}$$

with $\boldsymbol{\mu}_m = E[\mathbf{x}_m]$. In many cases, analysis of variance (ANOVA) is used to solve this problem. Recently however, Fan,⁷ Fan and Lin,⁵ has noted that the performance of ANOVA suffers for problems when the signal of interest is

Figure 4. Flowchart, 4 vectors of input.

limited to a small number of samples in the overall observation vector as is the case for the GPR problem of interest here. Fan proposed a high-dimensional ANOVA which uses a portion of observation. Fan’s original work was limited to problems in which the first k samples were used, with k found from the data. Here we consider a generalization of Fan’s work to take into account the fact that for the GPR problem the transient object is significant over a window not generally starting with the first sample. Following the HANOVA, we turn to a sequential probability ratio test (SPRT) to make on-line detection as new data is acquired.

3. ALGORITHM

3.1. Estimation and detection

Our method consists of two steps, as shown in Fig. 4. Here the GPR array has four T/R pairs. At each stop of the GPR array, we receive four vectors of observation. These vectors are input to a high-dimensional ANOVA and the HANOVA generates one test statistic X^2 . Next, X^2 is fed into a sequential detector and produces a final test statistic $U(n)$. When $U(n)$ exceeds a preset threshold, a mine is declared.

Before describing HANOVA, it is helpful to see why in some cases ANOVA loses its discrimination power. For example, assume we have one observation vector of size $K \times 1$, $\mathbf{x}_1 \sim N(\boldsymbol{\mu}, \sigma_1^2 \mathbf{I})$ and we wish to test $H_0 : \boldsymbol{\mu} = \mathbf{0}$ vs. $H_1 : \boldsymbol{\mu} = \boldsymbol{\mu}_1$. Standard ANOVA is to estimate $\boldsymbol{\mu}$ by \mathbf{x}_1 and use the testing procedure $X_1^2 = \|\mathbf{x}_1\|^2$. The approximate power of the standard ANOVA estimator-correlator test is

$$P_d(H_1|H_1) = Q\left(\gamma - \frac{\sum_{k=1}^K \mu_1^2(k)}{\sigma_1^2 \sqrt{2K}}\right) \quad (2)$$

where γ the test threshold and Q the complementary cumulative distribution function and strictly decreasing. If $\boldsymbol{\mu}_1$ is different from $\mathbf{0}$ for only a small number of k then as K goes large, $\sum_{k=1}^K \mu_1^2(k) \ll \sqrt{K}$. From (2), we then conclude that testing all dimensions of the data actually causes the test to lose power due to the accumulation of stochastic noise. This deterioration is reflected in the factor $1/\sqrt{2K}$. Fig. 5 shows how much target signal differs from background, it is noticeable that target signal does not appear for the first hundreds of dimensions and it quickly attenuates to zero after that. Fig. 6(a) shows that if starting from point 1, one begins to increase dimensions tested of signal of Fig. 5(c), the probability of detection at first increases, i.e., when more signal is taken into computation, and then decreases when signal runs out. On the other hand, if one fixes the end point around 500 and start from point 1, testing fewer and fewer dimensions, the probability of detection achieves its maximum around 300. Thus it provides us with an idea which portion of time series to test for statistical significance.

Based on this observation, Fan *et al.* developed an adaptive HANOVA test of the form described previously. We generalize it to GPR returns to form a two-end HANOVA, namely, testing a middle portion of time-series. Fig. 7 shows results from an ANOVA and a HANOVA test for the signals in Fig. 2. The HANOVA truncates observation vectors of length K to length L by two steps 1) discarding the first k_1 components which are consisted of ground-bounce only (the target reflected signal always comes after the ground-bounce) and 2) discarding the last k_2 elements which represent signal that has been attenuated too much to be meaningful for signal processing. Both the ANOVA and HANOVA tests easily detect the stronger signal, at position 1.5m. We want to be able to find the very weak target at 3.0m. For this target, the HANOVA shows improved performance. Specifically, the peak in the HANOVA case is more clearly visible above the nominal “noise floor.”

Figure 5. Received signal, a) clutter and noise, b) signal plus clutter and noise, c) signal only

Figure 6. Probability of detection a) start from point 1 and test more and more dimensions of observations b) fix the end point and test fewer dimensions from point 1

Generalizing HANOVA to multiple observations, we build the test statistic as

$$X^2 = \sum_{m=1}^M \sigma_m^{-2} \|\mathbf{x}_m - \bar{\mathbf{x}}\|^2 \quad (3)$$

with $\bar{\mathbf{x}} = \sum_{m=1}^M \sigma_m^{-2} \mathbf{x}_m / \sum_{m=1}^M \sigma_m^{-2}$. It is easily shown that

$$X^2 \sim \chi_{ML}^2(\delta^2) \quad (4)$$

where

$$\delta^2 = \sum_{m=1}^M \sigma_m^{-2} \|\boldsymbol{\mu}_m - \bar{\boldsymbol{\mu}}\|^2 \quad (5)$$

with $\bar{\boldsymbol{\mu}} = \sum_{m=1}^M \sigma_m^{-2} \boldsymbol{\mu}_m / \sum_{m=1}^M \sigma_m^{-2}$ and $\chi_{ML}^2(\delta^2)$ is the χ^2 distribution with ML degrees of freedom and non-centrality parameter δ^2 .

While HANOVA detects difference among observations at one stop of the array, it does not capture the curvature structure seen as the array moves down-track. To improve detection performance, we employ a sequential detection scheme based on the processing of the HANOVA statistic to look for the transient signal from one stop of the GPR array to the next. Hence, the two hypotheses are

$$\begin{aligned} H_0 : & \quad X^2(n) \sim \chi_{ML}^2(0) \\ H_1 : & \quad X^2(n) \sim \chi_{ML}^2(\delta^2(n)) \end{aligned} \quad (6)$$

for $n = 1, \dots, N$ where $\delta^2(n)$ is defined in (5). At stop n , the log likelihood ratio for this problem is

$$u(n) = \ln \frac{p_n(X^2(n))}{p_0(X^2(n))} \quad (7)$$

Figure 7. Test statistic, a) result of an ANOVA, using all dimensions of observations, b) result of a HANOVA, using truncated observations.

Figure 8. Test statistic $U(n)$ of sequential detection, solid line: HANOVA followed by SPRT, dash line: ANOVA followed by SPRT.

where $p_n(X^2(n)) \sim \chi_{ML}^2(\delta^2(n))$ evaluated at $X^2(n)$ and $p_0(X^2(n)) \sim \chi_{ML}^2(0)$ evaluated at $X^2(n)$. One difficulty with generating $u(n)$ is that $\delta^2(n)$ is typically not known *a priori* since the underlying μ_m are not assumed known. Here we construct a generalized log likelihood statistic. Typically, this is done by replacing $\delta^2(n)$ by its maximum likelihood estimate which for this problem is $X^2(n)$. After some experimentation in real data and computer simulation, we have found that performance can be improved by incorporating a one-step delay into the processing. Specifically, we estimate $\delta^2(n)$ as $X^2(n-1)$.

The full algorithm then is essentially a repeated SPRT⁸ and is summarized by the following steps,

- $U_1 = 0$.
- FOR $n = 2, \dots, N$
 - $\hat{\delta}^2(n) = X^2(n-1)$
 - Form $u(n)$ according to (7)
 - $U(n) = \max(0, U(n-1) + u(n))$.
 - IF $U(n) > \alpha$, declare object.
- ENDFOR

where α is a preset threshold. Fig. 8 shows the result of the algorithm applied on HANOVA output of Fig. 7. Clearly, sequential detection using results of HANOVA has a better performance.

3.2. Performance

Performance of this algorithm is studied in terms of mean time between false alarms and probability of detection. Under H_0 , the test statistic changes as a Markov chain,⁹ with update $u(n)$ at each step. Under H_1 , the update $u(n)$ is changing, and therefore, the test statistics $U(n)$ can be described as an inhomogeneous Markov chain. One method

Figure 9. Performance, a) mean time between false alarms with different threshold and number of quantization levels, b) probability of detection at different signal to noise ratio, from top to bottom, SNR = 1.85dB, 2.2dB, 2.8dB.

of analyzing Markov chain is a matrix approach.⁹ First, since L is usually very large, in the order of hundreds, and therefore ML is large, χ^2 distribution can be approximated by a Gaussian distribution. We then have

$$\begin{aligned} H_0 : X^2(n) &\sim N(ML, 2ML) \\ H_1 : X^2(n) &\sim N(ML + \delta^2(n), 2ML + 4\delta^2(n)). \end{aligned}$$

Second, suppose the update $u(n)$ and the interval $[-\alpha, \alpha]$ is uniformly quantized to $2k + 1$ levels such that $v_0 = 0$, and $v_k = \alpha$. Let $\pi_{nl} = \Pr\{U_n = v_l | N > n\}$ for integer $l \in [0, k - 1]$, and $\pi_n = [\pi_{n0}, \pi_{n1}, \dots, \pi_{n(k-1)}]^T$ denote the probabilities of $U_n = v_k$ on the condition that there is no alarm until after sample time n . We can write the transition matrix $C^{(n)}$ at step n as⁹

$$C^{(n)} = \begin{bmatrix} p_n^0 & p_n^{-1} & \cdots & p_n^{-\gamma+1} \\ p_n(1) & p_n(0) & \cdots & p_n(-\gamma+2) \\ p_n(2) & p_n(1) & \cdots & p_n(-\gamma+3) \\ \vdots & \vdots & \ddots & \vdots \\ p_n(\gamma-1) & p_n(\gamma-2) & \cdots & p_n(0) \end{bmatrix} \quad (8)$$

where

$$p_n(l) = \Pr(\log \frac{f_1^{(n-1)}(X^2(n))}{f_0(X^2(n))} = v_l) \quad (9)$$

and elements in first row of Eq. 8 are $p_n^i = \sum_{l=-\infty}^i p_n(l)$. Here $f_1^{(n-1)}(X^2(n))$ denotes the PDF of $X^2(n)$ under the alternative hypothesis H_1 and using $X^2(n-1)$ to estimate $\delta^2(n)$. Under H_1 , the transition matrix $C^{(n)}$ can be built using Eq. 8 for different n , since signal is time varying. The probability of detecting a signal of length n_d is then

$$P_d(n_d) = 1 - \mathbf{1}^T \prod_{n=1}^{n_d} C^{(n)} \pi_0 \quad (10)$$

where $\mathbf{1}$ is a column vector of all ones. The mean time between false alarms \bar{T} is found to be⁹

$$\bar{T} = \mathbf{1}^T (\mathbf{I} - C^{(0)})^{-1} \mathbf{e}_1 \quad (11)$$

in which $C^{(0)}$ is the transition matrix under the signal-absent statistics and \mathbf{e}_1 is a column vector containing a one in position 1 and zeros elsewhere. With more levels of quantization, we obtain more accurate estimation of P_d and \bar{T} . Fig. 9(a) shows the mean time between false alarms under the null hypothesis H_0 , for different thresholds.

Here, we define the signal to noise ratio as

$$\text{SNR} = 10 \log_{10} \frac{\sum_{n=n_1}^{n_2} \mathbf{s}_n^T \mathbf{s}_n}{(n_2 - n_1 + 1)L\sigma_m^2} \quad (12)$$

Figure 10. Probability of detection versus transient length of the signal.

where n_1, n_2 are chosen to include those GPR stops where a mine is close. As noise level reduces, probability of detection increases, as shown in Fig. 9(b). Finally, we simulated transient signals of different lengths on a computer. Fig. 10 shows the probability of detection at a fixed threshold when the length of the signal is changing. Generally, increasing signal length improves its SNR. As expected, a signal of large transient length can be detected at a higher probability.

4. CONCLUDING REMARKS

In this paper, we have proposed a sequential, high-dimensional ANOVA to process multichannel GPR returns. The method works in two directions: first it looks for statistically significant difference among multichannel observations, second, it carries out a sequential detection as new data are obtained. The HANOVA is powerful in the sense of maximizing probability of detecting statistically significant difference among sets of observations. Sequential detection enables real-time processing as new data are collected. The method has a relatively low computational complexity. We have demonstrated the performance of this technique on a sample of field data. Future research will focus on adaptive sampling of received signal to take into consideration of roughness of ground-air interface; on-line localization will be integrated to allow detect-localize-detect and thus provides higher probability of detection.

A Nonlinear Shape Reconstruction Algorithm For Cross-Borehole Electromagnetic Tomography Using Adjoint Fields And Level Sets

We consider the problem of recovering the shapes and locations of a collection of inclusions in an inhomogeneous medium from limited observations of scattered electromagnetic fields. In particular, we are concerned with a crosswell tomography problem arising in environmental monitoring and remediation. Here one starts with a pair of boreholes. The first is equipped with an array of electromagnetic sources and the second with an array of receivers. The medium between the two boreholes consists of a known inhomogeneous (e.g. layered) background, and some unknown localized inclusions, for example pollution plumes. The inclusions differ from the background medium in their complex electrical permittivities. The objective of the problem is the characterization of these structures from time harmonic data collected at a small number (less than 10) of frequencies.

The limited data set does not support the recovery of a fine scale collection of pixelated permittivity values. However, in many applications, including ours, it can be assumed that some prior information about the physical parameters inside the inclusions is available. For example, the permittivities inside the inclusions might be known constants. In these cases, all that remains is the recovery of the number, size, shape and locations of the inclusions.

We apply a two-step nonlinear inversion scheme to this problem with prior information. In the first step, we try to determine basic information about the number and the locations of the unknown objects by employing a recently developed nonlinear generalization of the algebraic reconstruction technique (ART) in x-ray tomography, to the given problem. The second step of the reconstruction makes use of level set methods as well as the prior information at our disposal. Introducing level set calculations based on the output of nonlinear ART allows us to recover more precise information regarding the shapes and sizes of the inclusions.

An essential feature of this inversion scheme is that the practical realizations of the two steps are closely linked with each other. In fact, the level set step simply continues with the same inversion routine as it is already used for nonlinear ART. All that has to be done numerically when switching from one step to the other is to add a post-processing routine to the calculated update formula. This yields already the correct deformation rule for the considered level sets.

In the talk accompanying this abstract we will provide a more detailed description and analysis of the various components of this inversion routine. Included in this discussion will be numerous examples demonstrating the utility of our method for problems of practical interest.

The inverse scattering problem (ISP) is characterized by a desire to determine the internal structure of a medium given scattered energy obtained along the boundary. Typical methods for performing the inversion amount to formulating the reconstruction problem as a solution to a regularized, nonlinear optimization problem and performing the optimization using an iterative algorithm. Rapid convergence often can be achieved through using a Newton-type approach where each iteration is decomposed into two steps. First, an incremental improvement is made to the estimated material properties by solving a least squares problem. Second, the new profile is used to solve for the internal field distribution over the region.

Although such an algorithm along with proper regularization can address the problem of ill-posedness, the Newton approach is known to be computationally complex. Constructing the matrices defining the least-squares problem requires the matrix representation of resolvent for the second kind integral equation relating the scattered to the incident fields for an inhomogeneous medium whose properties are defined by the current estimate of the material parameters. Direct knowledge of this resolvent also is of use in determining these fields. Explicitly determining this resolvent requires the costly inversion of a large dense matrix.

In this paper, we consider a lower complexity method which constructs an approximation to the resolvent. By linearizing the formula for the resolvent about the increment to the material properties computed in the previous least-squares iteration, we obtain an expression in which the new resolvent is equal to the old resolvent plus an increment due to the change in the material properties. Construction of this increment requires the multiplication of three matrices. To reduce the computational burden of this task, we compute only a subset of “significant” elements of this increment matrix where the notion of significance is related to the sensitivity of the cost function to small changes in each component of this matrix.

We explore the use of this method in the context of a non-destructive testing modality known as thermal wave diffraction tomography. Here, a laser is used to induce heat diffusion on the top of a small sample of material. Based on reflection or transmission measurements of the thermal field, one desires an image of the internal structure of the sample which makes evident holes or other defects. It can be shown that the thermal field obeys a scalar Helmholtz equation with a complex propagation vector so that the physics of the problem are quite similar to those of inverse electrical conductivity problems for which inverse scattering methods are commonly employed.

Electromagnetic Modeling and Physics-based Processing Methods for Subsurface Object Characterization from Broadband Electromagnetic Induction Data

The use of broadband electromagnetic induction (BEMI) methods for the detection and characterization of buried objects has received considerable attention in recent years for applications ranging from environmental remediation to the detection and classification of buried landmines and unexploded ordinance. In this work, we describe an efficient modeling method and associated processing techniques for the extraction of target information from BEMI data. The utility of this approach is verified both on synthetic as well as experimental data collected from a fielded sensor.

We consider processing techniques based on an enhanced version of the inductive sensor model originally proposed by Das, McFee, Toews and Stuart (IEEE Trans. GRS, Vol. 28, No. 3, May 1990, pp. 278-287). The model conveniently encodes the quantities most relevant to the application at hand: a frequency dependent dipole scattering tensor used to characterize and classify the object, the spatial coordinates of the center of the target required for localization, and three Euler angles required to specify the orientation of the object. Moreover, under this model the elements of the dipole scattering tensor are independent of the orientation and location parameters and are in fact linearly related to the observed BEMI data.

Given this structure, we consider statistically optimal estimation methods for the determination of the dipole tensor, the object location, and orientation from noisy and cluttered BEMI data. The structure of the model leads to a computationally efficient, low dimensional, non-linear least squares algorithm. Specifically, we use the linearity of the model with respect to the dipole scattering tensor to eliminate this high dimensional set of unknowns from the optimization problem and concentrate on determining the location and orientation parameters: six in all. From these estimates, we can then trivially determine the optimal dipole structure.

A key element of our approach is the specification of a clutter model required for low SNR problems where the object contains little metal such as anti-personnel landmine remediation. In this paper, we develop a parametric stochastic model which captures the spatial correlation seen in typical data sets. The model is constructed to reflect the current methods in which BEMI data are collected. First, a dense set of spatial BEMI data in a known, object-free region is collected. These data along with a sparse collection of BEMI data taken in the immediate vicinity of a suspected target will be used to estimate the clutter model parameters and remove this noise source from the signal.

In the talk accompanying this abstract the utility of our processing approach and clutter model will be demonstrated using both synthetic and experimental BEMI data collected from GEM-3 sensor constructed Geophex Inc. The clutter model structure will be presented along with algorithms for estimating the parameters and performing clutter mitigation. The accuracy of the orientation and location estimates will be discussed. Finally, the use of the dipole moments for object classification will be demonstrated for both high and low metal content objects.

A Statistical Approach to Object Detection from Ground Penetrating Radar Arrays

The use of ground penetrating radar (GPR) arrays for detecting buried objects has received considerable attention in recent years in areas such as landmine and unexploded ordinance remediation, utility line mapping, and archaeology. A typical GPR configuration for such applications is comprised of one linear array of transmitters and a second array of receiving elements which are simultaneously moved down a linear track. At every stop of the system, each transmitter emits a short pulse of electromagnetic energy which interacts with the surrounding medium. Based on observations of scattered fields collected by the receivers the objective of the problem is to determine if an object is present in the field of view of the array.

From a signal processing perspective a number of factors make this problem quite challenging. First, the attenuation associated with the scattering of the GPR signal from the ground and target results in useful signal only over receivers located closest to the firing transmitter. In many functioning systems in fact only a single receiver is employed per transmitter. Thus, detection methods based on beamforming, MUSIC, or ESPRIT which require array-based observations cannot easily be employed. In essence then for GPR we have a multichannel (one channel per transmit/receiver pair), as opposed to an array, processing problem. Even if full array data were available, the assumptions underlying e.g. MUSIC (far field propagation, plane wave or at worst spherical wave structure) are violated. Indeed, to obtain a precise description of the received GPR signal one must resort to computationally intensive electromagnetic modeling methods to capture the complex physics associated with near field propagation and scattering of the transmitted GPR waveform off a buried object in the presence of a random rough air-ground interface. While such modeling can be done in principle, from a practical perspective such computationally intensive methods are not appropriate for use in a functioning GPR system.

Given these issues, here we view the problem in the framework of multichannel blind signal detection and employ statistical methods to process the GPR returns. This approach allows us to exploit two generic properties of the signal transmission process. First, for any given stop of the array, the presence of the mine close to a transmitter-receiver (T/R) pair results in a jump in the mean value of the observed signal relative to that seen in other pairs. Thus, we develop a widowed analysis of variance (ANOVA) test to detect this change. Second, physical principles dictate that as the array moves from one stop to the next, the magnitude of this jump first increases as the array approaches the object and then decreases as the sensors move past the location of the target. This behavior is exploited in the synthesis of a sequential detection strategy designed to recursively process the output of the ANOVA test as the GPR system moves down the track. The use of this sequential methods allows us to determine a priori important performance statistics for the GPR system, such as mean time between false alarms and average delay in declaring the presence of a target. In the talk accompanying this abstract, we provide a more detailed description and analysis of our algorithms as well as the physical models on which they are based. We will demonstrate the performance of this method both on synthetic data obtained from computational electromagnetic codes and on actual field data collected by a GPR system constructed by EG&G Inc.

Multiscale, adaptive methods for reduced order inverse scattering

The objective of an electromagnetic inverse scattering problem (ISP) is to use observations of scattered wavefields obtained on the boundary of a medium to ascertain the spatial distribution of permittivity internal to the region of interest. Typically, the solution to an ISP is approached by formulating and then solving a high dimensional non-linear optimization problem to recover the permittivity values in a fine scale discretization of the underlying region. The optimization functional usually contains one term encouraging fidelity to the data and one or more regularizers required to combat the inherently ill-posed nature of the inverse problem. In addition to the high computational complexity associated with this technique, in previous work we shown that a uniform, fine scale discretization of the permittivity does not represent the best use of the data. More precisely, using information theoretic methods it is possible to show that the level of uncertainty in the reconstructed permittivity grows with the distance of the pixel from the sources and receivers. Motivated by this observation, here we consider an inversion approach designed to obtain a low order representation of the permittivity in which fine scale information is adaptively distributed in a more rational manner.

Our approach is based on the use of a two dimensional frame of quadratic B-splines to represent the unknown permittivity. This family of functions has the convenient property that coarse scale members can be defined as a superposition of finer scale B-splines. We use this nesting property in the synthesis of a multiscale inversion routine. We begin by representing the permittivity as a superposition of a few, coarse scale spline functions. After determining the optimal expansion coefficients, the remainder of the procedure is a loop in which we alternate between adding degrees of freedom to improve the reconstruction, and removing unnecessary detail to control the complexity of the estimate.

We have found that this approach to inversion is useful in a number of ways. First, by adaptively placing fine scale information only where it is really required, the dimensionality of the problem is kept low (hundreds rather than thousands of unknowns) thereby leading to a significant reduction in computational complexity relative to a single, fine grid approach. Second, a common problem with all non-linear ISPs is convergence of the problem to a local minimum of the cost function. The multiscale nature of our approach can in fact lead to convergence to a lower cost minimum than would otherwise be the case. Finally, we can use the same information theoretic techniques previously mentioned to quantify the reduction in uncertainty associated with our lower order method.

The talk accompanying this abstract will provide a more detailed description and analysis of our approach. We will demonstrate its utility using as an example a cross-borehole radar tomography problem motivated by applications in environmental remediation and monitoring. As an example of the typical performance of our approach for this application, the multiscale algorithm adaptively converges to an estimate of the profile containing on the order of 300 B-spline functions when the underlying discretization contains 4096 pixels representing a saving of about 92%. Despite the smaller number of unknowns, the low order reconstruction is of comparable quality to its fine scale counterpart.

A Unified Statistically-Based Approach to the Modeling and Processing of EMI Time and Frequency Domain Sensor Data

In the past decade, significant effort has been devoted to the processing of electromagnetic induction (EMI) data for purposes of buried object detection and characterization. Current EMI sensors operate either in the frequency domain using a stepped frequency approach to probe the subsurface or directly in the time domain. Time domain systems generally measure the transient response of the earth and any embedded objects to pulsed input. The data collected by such sensors take the form either of samples of the time response or integrals of the response over a collection of time windows. In this paper, we describe a unified approach to both the modeling and the processing of data from these apparently dissimilar sensors.

One popular approach to EMI sensor modeling is to describe the response of the sensor in terms of a superposition of decaying exponentials in time, or equivalently, one pole transfer functions in frequency. The decay rates/pole positions can then be used to characterize the object. While useful, this model fails to explicitly take into account spatial information which may be obtained as the sensor collects data over a region above and surrounding the object. To overcome this shortcoming, we propose a hybrid model. The spatial structure is captured using the technique in Das *et. al.*, (*IEEE. Trans. Geoscience and Remote Sensing*, **28**, 278-287, May, 1990) while the temporal/Fourier content of the data are represented using the exponential/single pole structure. The result is a closed form model for the spatial-temporal and spatial-Fourier response of an EMI sensor parameterized directly in terms of a small number of quantities, nine, which directly describe the location, orientation, and class of the object under investigation.

Using this model, we will present a statistical signal processing framework for object characterization and sensor optimization. First, the Maximum likelihood estimator for the parameter vector will be derived for swept frequency, sampled time, and integrated time sensors. We will describe the implementation of the non-linear search routine required to determine these estimates. A Bayesian classifier will be employed to map the ML parameter estimates to object class. Processing results will be provided using both synthetic data as well as real sensor data. Finally, using the asymptotic properties of our estimator and standard decision-theoretic methods, we will discuss how the overall modeling/processing approach can be of use to optimize sensor design. For example, our approach provides a mechanism for determining the “best” frequencies or time gates to discern one object from another.

Efficient T-Matrix Methods for GPR Forward Modeling

An important component associated with the GPR problem is the computation of the scattered fields produced by buried objects when illuminated by the radar source. The choice of technique for computing these fields is often driven by a variety of factors including computational complexity and the flexibility to handle easily a wide range of configurations of scatterers. Based on the fact that objects of interest for many GPR applications have relatively simple shapes such as cylinders and spheres, it is apparent that transition matrix (T-matrix) approach is well suited to the GPR forward problem.

The T-matrix technique is based on the expansion of the fields and the Green's function in spherical (3D) or cylindrical (2D) harmonic series. Considerable work has focused on the generation of efficient recursive T-matrix techniques for computing the scattered field from a single, electrically large, dielectric object. The approach taken in these applications is to tessellate the object into many smaller scatterers. Thus, even though the number of scatterers is large, the order of harmonics used to expand the basis functions is small thereby keeping the computational load relatively small. However, if one wants to find the scattered field from multiple, electrically large, tessellated objects, the number of scatterers grows quite quickly thereby increasing the complexity of the problem considerably. A natural alternative is to treat each object as a single scatterer (i.e. bypass the tessellation) but increase the order of the harmonic expansions for each object. Unfortunately, this approach is hindered by difficulties related to the slow convergence of the harmonic expansions.

Here, we present a modified, stable recursive T-matrix algorithm to calculate the scattered field from a heterogeneous collection of spatially separated objects based on these higher order expansions. Motivated by the GPR problem, we consider the calculation of the scattered field produced by a group of parallel cylinders buried in a lossy medium. In the most general case, these objects can be dielectric or metallic, electrically small (fraction of λ) or large ($1-2 \lambda$). The modification, which will be described in the talk accompanying this abstract, circumvents the slow convergence of the series by replacing the product of two translation matrices with product of three such matrices two of which yield the identity.

In the talk we will also discuss the verification of this algorithm against previously published results for scattered fields from multiple cylinders, compare the computational advantages of this higher order technique relative to the tessellated approach, and provide examples demonstrating the ability of this code to compute fields for GPR-relevant scattering scenarios such as mine detection and hazardous waste removal.

Simultaneous multiple regularization parameter selection by means of the L-hypersurface with applications to linear inverse problems posed in the wavelet transform domain

M. Belge, M. Kilmer and E. L. Miller

235 Forsyth Building
Northeastern University
Boston, MA 02115

ABSTRACT

In this paper, we introduce the L-hypersurface method for use in linear inverse problems. The new method is intended to select multiple regularization parameters simultaneously. It is a multidimensional extension of classical L-curve method and hence does not require any specific knowledge about the noise level or signal semi-norm. We give examples of the L-hypersurface method applied to the linear inverse problems posed in the wavelet domain and evaluate the performance of the new method on a signal restoration experiment.

Keywords: Inverse problems, wavelets, regularization parameters

1. INTRODUCTION

The term inverse problems refers to the estimation of an unknown quantity, called an object, from its noise corrupted functionals. Such problems arise in a variety of fields including image processing, medical imaging and geophysical prospecting. For example, a common image processing problem which we explore later in this paper is that of deconvolution where one observes a blurred and noise corrupted version of the original image and seeks to recover the original. In this work, we consider the following discrete linear inverse problem

$$\mathbf{g} = \mathbf{H}\mathbf{f} + \mathbf{n} \quad (1)$$

where \mathbf{H} is a known matrix representing the degradation, \mathbf{g} is the vector holding the data, \mathbf{f} is the desired object to be estimated and \mathbf{n} denotes zero mean white Gaussian noise. The problem of estimating \mathbf{f} from \mathbf{g} is said to be ill-posed if the operator \mathbf{H} is not invertible or its inverse is unstable.^{1,2} In such a case direct inversion is not advisable and a unique and stable estimate $\hat{\mathbf{f}}$ is sought by incorporating some *a priori* information about unknown image \mathbf{f} . Such a technique is called regularization. The prior information is usually specified in the form of a smoothness constraint which is just some (semi)norm of \mathbf{f} . The regularized solution is found by minimizing the following expression with respect to \mathbf{f}

$$J(\mathbf{f}, \boldsymbol{\alpha}) = \|\mathbf{g} - \mathbf{H}\mathbf{f}\|^2 + \Phi(\boldsymbol{\alpha}, \mathbf{f}) \quad (2)$$

where Φ expresses the prior for \mathbf{f} and is dependent on a set of parameters $\boldsymbol{\alpha} = [\alpha_1, \dots, \alpha_M]^T$ (called regularization or smoothing parameters). A typical example is $\Phi(\boldsymbol{\alpha}, \mathbf{f}) = \alpha \|\mathbf{L}\mathbf{f}\|_2^2$ with \mathbf{L} being a regularization operator (usually a differential operator). In this case, α governs the tradeoff between the fidelity to the data term and smoothness of the solution term. Once the form of prior information (form of Φ in (2)) has been determined, the overall quality of the estimate is affected only by the choice of regularization parameters and therefore the choice of regularization parameters $\boldsymbol{\alpha}$ is a crucial part of the inversion process.

The problem of choosing a suitable regularization parameter which would yield an estimate as close to the original object as possible has received considerable attention in the past and is still an open problem. There are methods which rely on prior information such as a bound on the (semi)norm of the signal or the noise level. A well known example is the Morozov's discrepancy principle.² On the other hand, methods such as Generalized Cross Validation (GCV)³ and the L-curve^{4,5} do not require any side information. We note that all of the methods mentioned above deal with choosing a *single* parameter. As more sophisticated inversion algorithms are developed, the need for using multiple regularization parameters is becoming increasingly important. For example, in the solution of image restoration problems posed in the wavelet domain one needs multiple regularization parameters to capture the scale or orientation dependent structure of the underlying image.⁶ Another example is the inverse problem of electrocardiography⁷ where one needs both temporal and spatial regularization constraints to obtain a useful solution.

Extension of methods developed for a single parameter to choose multiple regularization parameters is often a non-trivial task. In this paper, we introduce the L-hypersurface method for use in linear inverse problems which require multiple regularization parameters. The L-hypersurface is based on the classical L-curve method. It is an M dimensional function of the regularization parameters and provides significant information about the likelihood of a particular parameter set being optimum. In the next section, we provide some background information on the L-curve method and then introduce the L-hypersurface method in Sect. 3. In Sect. 4, we present a brief introduction to the solution of discrete linear inverse problems posed in the wavelet domain. In Sect. 5 we present result obtained by applying the L-hypersurface to the linear inverse problems posed in the wavelet domain and then conclude the paper in Sect. 6.

2. THE L-CURVE METHOD

A convenient tool for choosing a single regularization parameter which does not require any side information is the L-curve method popularized by Hansen^{4,5} *et. al.*. The L-curve is simply a logarithmic plot of residual norm (the first term on the r.h.s. of (2)) versus the log of the reconstruction (semi)norm (second term on the r.h.s. of (2)) for a set of admissible regularization parameters. In this way, the L-curve displays the compromise between the minimization of these two quantities. It has been argued and numerically shown that the so called "corner" of the L-curve, defined as the point with maximum curvature, corresponds to a point where regularization and perturbation errors are balanced.⁴

In Fig. 1 we plotted a typical L-curve along with its curvature and the error between the original and restored signals for a range of regularization parameters. The experiment for which the L-curve was computed was the reconstruction of a 1-D signal using Tikhonov regularization with identity.¹ The circle indicates the corner of the L-curve defined to be the point with maximum curvature. The part of the L-curve to the left of the corner contains a region where the regularization parameter is getting smaller and the error between the original and reconstructed signals is dominated by the perturbation errors. The solution (semi)norm is very sensitive to small changes in the regularization parameter indicating a noisy solution. On the other hand, the part of the L-curve to the right of the corner is a region where the regularization parameter is gradually increasing and the residual norm is the most sensitive to the changes in the regularization parameter. In this region, the restored signal is excessively smooth. These two regions are clearly separated by the corner point, hence the corner corresponds to a point where regularization and perturbation errors are approximately balanced. Supporting this observation, the corner of the L-curve in this example indicates a point which is very close to the point where the error between the original and restored signals is a minimum (bottom figure in Fig. 1).

3. L-HYPERSURFACE: A NEW METHOD FOR SIMULTANEOUS DETERMINATION OF MULTIPLE REGULARIZATION PARAMETERS

As mentioned in the introduction, in order to obtain a useful solution for the inverse problem of electrocardiography,⁷ one needs both temporal and spatial regularization constraints. Facing the problem of choosing two or more parameters simultaneously Brooks⁷ *et. al.* tried to extend the idea of L-curve by drawing the residual norm against two side constraint norms. They named the resulting plot the "L-surface" (L-hypersurface). Although, they enjoyed some success in choosing the regularization parameters, it was apparent that the interpretation of such a surface was very difficult.

Figure 1. A typical L-curve, its curvature and error between original and restored signals. Circle indicates the point with maximum curvature. $\mathbf{f}^*(\alpha)$ is the estimate of \mathbf{f} using α as the regularization parameter.

Considering these difficulties, we propose using the *Gaussian curvature* of the L-hypersurface as a means to choose multiple regularization parameters. To clarify this idea, consider the following inversion scheme:

$$\mathbf{f}^*(\alpha) = \arg \min_{\mathbf{f}} \left\{ \|\mathbf{g} - \mathbf{H}\mathbf{f}\|^2 + \sum_{i=1}^M \alpha_i \|\mathbf{R}_i \mathbf{f}\|_p^p \right\}, \quad (3)$$

where $\|\mathbf{R}_i \mathbf{f}\|_p^p$, $1 \leq i \leq M$, are the constraints on the solution (semi)norm and α_i are the corresponding regularization parameters and $1 \leq p \leq 2$. The cost function in (3) represents a multiply constrained least squares problem and includes many popular image restoration schemes as its special cases. For example, by taking $\mathbf{R}_i = \mathbf{D}^{(i)}$ (i. e. the i th order differentiation) and $p = 2$ we obtain the classical Sobolev regularization. The wavelet domain inversion algorithm introduced by the authors is obtained if the problem is posed in the wavelet domain and the \mathbf{R}_i are the operators extracting the desired portions of the wavelet transform of the object \mathbf{f} .⁶ For example, we can take \mathbf{R}_1 as the operator extracting the scaling coefficients and \mathbf{R}_2 as the operator extracting the wavelet coefficients for a doubly constrained problem.

To construct the L-hypersurface, we first introduce the following quantities

$$\mathbf{f}^*(\alpha) = \arg \min_{\mathbf{f}} J(\mathbf{f}, \alpha) \quad (4)$$

$$z(\alpha) = \log \|\mathbf{g} - \mathbf{H}\mathbf{f}^*(\alpha)\|_2^2 \quad (5)$$

$$x_j(\alpha) = \log \|\mathbf{R}_j \mathbf{f}^*(\alpha)\|_p^p, \quad j = 1, \dots, M \quad (6)$$

With the above definitions, the L-hypersurface is defined as a subset of \mathcal{R}^{M+1} associated with the map $\mathcal{S}(\alpha) : U \rightarrow$

Figure 2. A typical L-hypersurface, its curvature and the error between the original and restored signals.

\mathcal{R}^{M+1} , $\alpha \in U$, $U = \bigcup_{j=1}^M [a_j, b_j]$ such that

$$\mathcal{S}(\alpha) = (x_1(\alpha), \dots, x_M(\alpha), z(\alpha)). \quad (7)$$

In simple terms the L-hypersurface is a plot of the residual norm as a function of the constraint norms drawn in log scale for a range of regularization parameters.

If the surface \mathcal{S} defined above is smooth with no self intersections and has a definite tangent plane at all points it is said to be regular.⁸ A regular surface possesses an interesting geometrical quantity called Gaussian curvature which measures how much the surface is warped at a point. A plane has 0 Gaussian curvature while a sphere has constant Gaussian curvature at all points. The Gaussian curvature reduces to the regular curvature for a 1-D curve.

Instead of considering \mathcal{S} , we consider its Gaussian curvature field as a function of regularization parameters. This approach is motivated by the analogous results for the L-curve method. If we consider the L-curve and its curvature in Fig 1., we observe that the curvature plot provides the location of turning points which are practically the only interesting points on the L-curve. Given the curvature plot we can easily determine the correct regularization parameter. Motivated by this fact, we will omit displaying the L-hypersurface itself. The reason is that the interpretation of the curvature plot is much easier than the L-hypersurface and also the curvature plot provides an automatic way of locating the regularization parameters if we define the L-hypersurface selection of the regularization parameters as the point with the maximum curvature on the Gaussian curvature plot. This is more easily understood by looking at a typical L-hypersurface, as displayed in Fig. 2. In the leftmost plot in Fig. 2, we display the L-hypersurface for a least squares problem with first and second order derivatives of the object as constraints. The middle and the rightmost plots are the curvature of the L-hypersurface and the norm of the error between the original and estimated objects. We observe that the points on the curvature plot where the curvature achieves a local maximum seems to track the local minimum of the estimation error surface. Note that, locating the correct regularization parameters by just examining the shape of the L-hypersurface is more difficult.

By using elementary calculus, one can show that the L-hypersurface for the model problem in (3) is regular. The Gaussian curvature of S can be easily computed given the first and second order partial derivatives of $z(\alpha)$ with respect to $x_i(\alpha)$, $1 \leq i \leq M$, and is given by the following expression⁹

$$\kappa(\alpha) = \frac{(-1)^M}{w^{M+1}} |\mathbf{P}| \quad (8)$$

where $w^2 = 1 + \sum_{i=1}^M (\frac{\partial z}{\partial x_i})^2$, $\mathbf{P}_{i,j} = \frac{\partial^2 z}{\partial x_i \partial x_j}$ and derivatives are evaluated at $q = (x_1(\alpha), \dots, x_M(\alpha), z(\alpha))$. In the next section, we present the application of the L-hypersurface method to the discrete linear inverse problems posed in the wavelet domain.

4. WAVELET DOMAIN ADAPTIVE EDGE-PRESERVING IMAGE RESTORATION

Recently, there has been much interest in the wavelet domain formulation and solution of linear inverse problems, especially in the area of image processing. Part of the reason is the collection of mathematical results indicating that

wavelets are especially useful for representing functions that contain discontinuities. The wavelet transform¹⁰ of an object produces a set of scaling coefficients and a set of wavelet coefficients. The scaling coefficients are obtained by first filtering the object by a low pass filter and then down sampling the resulting signal. The wavelet coefficients are obtained by first filtering the object by a high pass filter and then down sampling. Wavelet coefficients obtained in this way are close to zero at regions where the object is smooth and significant only at regions where there is a high intensity change. On the other hand, the scaling coefficients appear to be a low resolution representation of the original object.

The wavelet domain formulation of a linear inverse problem presents an interesting challenge since the scale-space structure of the object may be highly irregular. A direct result of this phenomena is that one typically needs more than one regularization parameter to adapt to the changes in the scale-space structure of the object. We can represent the problem in (1) in the wavelet domain as⁶

$$\begin{aligned}\mathcal{W}_d \mathbf{g} &= (\mathcal{W}_d \mathbf{H} \mathcal{W}_h^T) \mathcal{W}_h \mathbf{f} + \mathcal{W}_d \mathbf{n} \\ \hat{\mathbf{g}} &= \hat{\mathbf{H}} \hat{\mathbf{f}} + \hat{\mathbf{u}},\end{aligned}\tag{9}$$

where \mathcal{W}_d and \mathcal{W}_h are wavelet transform matrices with possibly different scaling functions, $\hat{\mathbf{g}}$, $\hat{\mathbf{f}}$ and $\hat{\mathbf{n}}$ are the vectors holding the scaling and wavelet coefficients of the data, the original image and the disturbance, \mathbf{H} is the wavelet domain representation of our linear degradation operator \mathbf{H} and $\mathcal{W}_h^T \mathcal{W}_h = I$ follows from the orthogonality of the wavelet transform. Note that, since wavelet transform is orthogonal $\hat{\mathbf{u}}$ is again Gaussian with zero mean and variance σ^2 .

In previous work,⁶ the authors introduced a wavelet domain image restoration scheme where an estimate of \mathbf{f} is found by minimizing the following cost function

$$J(\hat{\mathbf{f}}, \alpha) = \|\hat{\mathbf{g}} - \hat{\mathbf{H}} \hat{\mathbf{f}}\|_2^2 + \sum_j \alpha_j \|\hat{\mathbf{R}}_j \hat{\mathbf{f}}\|_p^p,\tag{10}$$

where $\hat{\mathbf{R}}_j$ are the operators extracting the desired portions of the wavelet transform (such as scaling coefficients) and $1 \leq p \leq 2$. The l_p norm of the wavelet coefficients are used as the regularization function since the recent results in the area of image coding and denoising suggest that the distribution of wavelet coefficients are notably non-Gaussian hence using $p < 2$ is more appropriate.¹¹

There are a variety of methods for structuring the regularizer through the choice of the matrices $\hat{\mathbf{R}}_j$ in (10). For example, we may employ a Besov regularization scheme for which the fundamental assumption is that the regularization parameter increases exponentially with scale as we go to finer scales in the wavelet domain. That is,

$$\alpha_j = \alpha_1 2^{-\lambda(j-j_0)}, \quad j_0 \leq j \leq J-1,\tag{11}$$

where j_0 is the lowest (i.e. coarsest) and $J-1$ the highest scales of interest. In this case we need to determine two regularization parameters, α_0 and α_1 for the scaling and coarsest scale wavelet coefficients respectively (assuming that λ and p are pre-specified). Correspondingly, we have two $\hat{\mathbf{R}}_j$ matrices: $\hat{\mathbf{R}}_1 \mathbf{f}$ is the vector containing scaling coefficients and $\hat{\mathbf{R}}_2 \mathbf{f}$ is the vector of wavelet coefficients. On the other hand, a level dependent regularization scheme can be developed. In this case we need to choose $M+1$ parameters simultaneously and we have $M+1$ $\hat{\mathbf{R}}_j$ matrices: $\hat{\mathbf{R}}_1 \mathbf{f}$ is the vector of scaling coefficients and each of the vectors $\hat{\mathbf{R}}_j \mathbf{f}$, $2 \leq j \leq M+1$ contains the wavelet coefficients at scale j . We note that an efficient optimization method exists to compute the estimate $\hat{\mathbf{f}}^*$ once the regularization parameters are determined.⁶

Both of the above cases can be handled by the means of the appropriate L-hypersurfaces. For the implementation, we only need a set of derivatives as given in (8). Formulas for these quantities are provided in appendices.

5. SIMULATION STUDY

In this section, the performance of the L-hypersurface method for choosing two regularization parameters, $\alpha = [\alpha_1, \alpha_2]$, will be measured by the classical efficiency E_L ¹²

$$E_L = \frac{\min_{\alpha} \|\mathbf{f}^*(\alpha) - \mathbf{f}\|_2}{\|\mathbf{f}^*(\alpha_L) - \mathbf{f}\|_2},\tag{12}$$

Figure 3. From left to right: A typical L-hypersurface for the model experiment, the error between original and restored signals and the histogram of E_L values over 100 experiments.

where α_L is obtained by the L-hypersurface method and the vector of optimal regularization parameters α are those minimizing the error between the original and the estimated objects. A value close to one obtained for E_L indicates a performance close to optimal while a value for E_L close to zero indicates bad performance. The global performance of the L-hypersurface method was evaluated by observing the values of E_L obtained on 100 experiments which differed only by simulated noise. These 100 efficiency values were then used to create a histogram by partitioning the range $[0, 1]$ into ten intervals of equal length. We believe that such a histogram is a good summary of the performance of the L-surface method.

The signal to be reconstructed is the 256 point “Blocks” sequence extracted from Donoho’s Wavelab software package.¹³ It was degraded by a Gaussian convolutional kernel with $\sigma = 2.0$. Zero mean white Gaussian noise was added to obtain a SNR of 30dB. The inversion scenario in (10) was implemented with \mathbf{R}_1 being the operator extracting the scaling coefficients and \mathbf{R}_2 being the operator extracting the wavelet coefficients. We used $p = 1.0$ norm and set $\lambda = 1.0$. The signal was decomposed by a 5-level wavelet decomposition with Haar wavelets. For the calculation of Gaussian curvature, we used the derivatives obtained analytically.

Fig. 3 summarizes the results obtained in this experiment. The top leftmost plot shows the Gaussian curvature plot for a typical experiment. In the middle, we have the surface obtained by plotting the norm of the error between original and reconstructed signals. There is an extended ridge along the α_1 direction in this plot. This ridge seems to track the points where the error between the original and restored signals is locally minimum. Such behavior here is not specific to this experiment but rather general. We performed numerous experiments by changing the signal, degradation or noise level and obtained exactly the same results.

In the rightmost figures, we plot the histograms of E_L values obtained on 100 experiments. From this plot, we observe that the regularization parameters obtained by the L-hypersurface method produce restorations which are almost as good as the ones obtained by the optimal method.

Figure 4 shows an example of the L-hypersurface method applied to an image restoration experiment. As seen in Fig 5, the original Mandrill image was blurred by a Gaussian kernel of width 2 pixels and then zero mean white Gaussian noise was added to the blurred image to set the SNR at 30dB. We restored the degraded image by our multiscale image restoration scheme with $p = 1.0$ norm. However, in this case we utilized a 3-level wavelet decomposition and assigned a different regularization parameter for each scale in the wavelet domain. For scaling coefficients we used $\alpha_0 = 10^{-5}$ as the regularization parameter. Figure 4 shows the L-hypersurface obtained for this experiment. The L-hypersurface is a function of three regularization parameters. Therefore, each figure in Figure 4 shows a slice of the L-hypersurface with the regularization parameter corresponding to the lowest scale being constant. This example shows that, the L-hypersurface tracks well the minima in the RMSE ($RMSE = \sqrt{\frac{1}{N} \|\mathbf{f} - \mathbf{f}^*(\alpha)\|_2^2}$, N =number of pixels in the image \mathbf{f}) surface along which the restoration error is close to being minimum. Higher dimensional L-hypersurfaces can be obtained by just augmenting the parameter set.

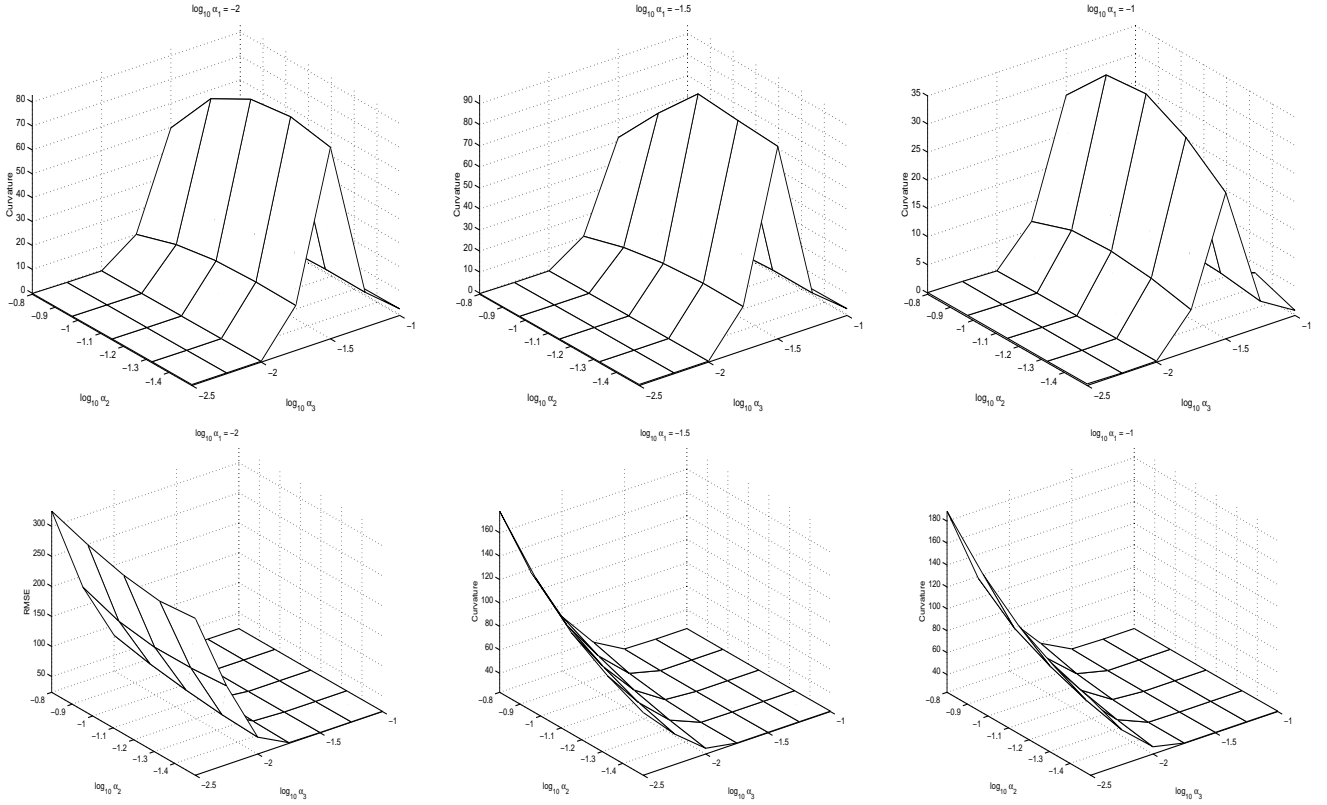

Figure 4. L-hypersurface cuts and corresponding RMSE plots for an image restoration experiment.

6. CONCLUSIONS AND DISCUSSION

In this paper, we presented a new method for choosing multiple regularization parameters simultaneously without using any side information. The method is called the L-hypersurface and is based on the popular L-curve method. Instead of directly looking at the surface obtained by plotting the residual norm against the side constraint norms, we look at its Gaussian curvature. From numerical examples, it was seen that the points where Gaussian curvature reaches a local maxima appear to be closely tied to the local minima of the mean square error surface. We choose the regularization parameters as those maximizing the Gaussian curvature of the L-hypersurface. Monte Carlo simulations show that this selection method is indeed very good and produces results comparable to the optimal method.

In the context of image restoration, multiple parameter regularization problems arise quite naturally. For example, a simple restoration strategy which minimizes the norm of the gradient of an image as the side constraint could in fact use two parameters corresponding to the gradients in the horizontal and vertical directions because those might be quite different (for example the image under consideration might be a layered in horizontal direction while being smooth in vertical direction). Another example would be a wavelet transform domain restoration algorithm where each subband is regularized differently as described in Sect. 4. We hope that the L-hypersurface method will be actually useful in these cases.

As the future work, we will consider the computational efficient implementations of the L-hypersurface and investigate the theoretical properties of the L-hypersurface.

APPENDIX A. FORMULAS FOR THE IMPLEMENTATION OF THE L-HYPERSURFACE FOR THE INVERSE PROBLEMS POSED IN THE WAVELET DOMAIN

A.1. Characterization of Solutions

In this section, we present the necessary formulas for the implementation of the L-hypersurface method for wavelet domain multiscale object restoration algorithm (10). The formulae are given for the case of a 1-D signal but extension to 2-D signals is straightforward. We begin with defining the solution $\mathbf{f}^*(\boldsymbol{\alpha})$.

$$\mathbf{U} = \text{diag} \left[\frac{\alpha_i}{\left(|\hat{f}_i^*|^2 + \beta \right)^{1-p/2}} \right], \quad \alpha_i = \alpha_j \text{ if } i \in I_j \quad (13)$$

$$\hat{\mathbf{H}}^T \left(\hat{\mathbf{H}}\mathbf{f}^* - \hat{\mathbf{g}} \right) + \frac{p}{2} \mathbf{U}\mathbf{f}^* = 0, \quad (14)$$

where I_j is the index set for the wavelet coefficients at scale j , \hat{f}_i^* is the i th element of the vector \mathbf{f}^* and $\beta > 0$ is a small stabilization constant. Note that, the equations (14) do not represent an exact solution to (10). The l_p norm term at the right hand side of (10) has been slightly perturbed to avoid indifferentiability of the cost function. Equation (14) give the conditions that must be satisfied by \mathbf{f}^* . An iterative algorithm based on (14) can be developed to approximate the solution \mathbf{f}^* .⁶

A.2. Formulas for the L-hypersurface

By (8), the only quantities that we need to compute the Gaussian curvature of the L-hypersurface at a point $\boldsymbol{\alpha} = (\alpha_1, \alpha_2, \dots, \alpha_M)$ are the first and second order partial derivatives of the residual norm $z(\boldsymbol{\alpha})$ with respect to M constraint norms $x_i(\boldsymbol{\alpha})$, $1 \leq i \leq M$. Since $z(\boldsymbol{\alpha})$ is not explicitly defined in terms of the constraint norms, we obtain the necessary derivatives by implicit differentiation. We first define the following quantities:

$$\mathbf{J} = \begin{bmatrix} \frac{\partial x_1}{\partial \alpha_1} & \cdots & \frac{\partial x_M}{\partial \alpha_1} \\ \vdots & \ddots & \vdots \\ \frac{\partial x_1}{\partial \alpha_M} & \cdots & \frac{\partial x_M}{\partial \alpha_M} \end{bmatrix}, \quad \mathbf{D}_{\boldsymbol{\alpha}}^2 = \begin{bmatrix} \frac{\partial^2}{\partial \alpha_1^2} & \cdots & \frac{\partial}{\partial \alpha_1 \partial \alpha_M} \\ \vdots & \ddots & \vdots \\ \frac{\partial^2}{\partial \alpha_M \partial \alpha_1} & \cdots & \frac{\partial^2}{\partial \alpha_M^2} \end{bmatrix}, \quad \mathbf{d}_{\boldsymbol{\alpha}} = \begin{bmatrix} \frac{\partial}{\partial \alpha_1} \\ \vdots \\ \frac{\partial}{\partial \alpha_M} \end{bmatrix}. \quad (15)$$

Note that, $\mathbf{d}_{\boldsymbol{\alpha}}$ and $\mathbf{D}_{\boldsymbol{\alpha}}^2$ are operators which represent first and second order differentiation with respect to the variables $\boldsymbol{\alpha} = [\alpha_1, \dots, \alpha_M]^T$. By the definitions above, the partial differentials of z with respect to \mathbf{x} are given by:

$$\frac{\partial z}{\partial x_i} = \mathbf{d}_{\boldsymbol{\alpha}}^T \mathbf{J}^{-1} \mathbf{e}_i$$

$$\frac{\partial^2 z}{\partial x_i \partial x_j} = \mathbf{e}_j^T \mathbf{J}^{-T} \mathbf{D}_{\alpha}^2 \mathbf{J}^{-1} \mathbf{e}_i - \mathbf{d}_{\alpha}^T \mathbf{J}^{-1} \begin{bmatrix} \mathbf{e}_j^T \mathbf{J}^{-T} \mathbf{D}_{\alpha}^2 x_1 \\ \vdots \\ \mathbf{e}_j^T \mathbf{J}^{-T} \mathbf{D}_{\alpha}^2 x_M \end{bmatrix} \mathbf{J}^{-1} \mathbf{e}_i, \quad (16)$$

where \mathbf{e}_i denotes the unit vector with all zero entries except for the i th one and $1 \leq i, j \leq M$. Remembering the formulas $\mathbf{P}_{i,j} = \frac{\partial^2 z}{\partial x_i \partial x_j}$ and $w^2 = 1 + \sum_{i=1}^M (\frac{\partial z}{\partial x_i})^2$ we realize that the curvature at the point α can be readily computed by just plugging in the values $\frac{\partial z}{\partial \alpha_i}$, $\frac{\partial^2 z}{\partial \alpha_i \partial \alpha_j}$, $\frac{\partial x_m}{\partial \alpha_i}$, $\frac{\partial^2 x_m}{\partial \alpha_i \partial \alpha_j}$ into the equations in (16). These partial derivatives can be calculated in a straightforward but tedious way from (14).

A common problem in many application areas is the detection and localization of targets with known structure based on observations of scattered electromagnetic or acoustic fields. In recent years, there has been considerable work in methods for solving such problems in a manner which bypasses the need to solve a large, ill-posed inverse scattering problem. These processing methods extract from the data a small number of geometric parameters describing the target distribution. In previous work, we have considered algorithms of this type for locating targets in the nearfield of a linear receiver array. Initial results based on the use of high resolution array processing techniques indicate that these methods provide highly accurate localization of arbitrary collection of buried metallic and dielectric objects.

In this paper, we examine issues of performance and sensitivity analysis associated with these processing methods. Because our techniques are statistical in nature, we are able to develop explicit expressions for the error variance (or bounds on this quantity) which provide hard limits on the best performance achievable from the use of these array processing techniques. We show that these bounds are easily and elegantly obtained when one employs a T-matrix model to describe the scattering processes.

A key assumption underlying the success thus far of our methods is that we know the number of targets for which we are looking as well as their material properties. In this paper, we explore the sensitivity of our localization techniques to show how our detection schemes behave when the actual parameters are different from the ones used in the algorithm. For example, we determine the degradation in performance when the actual shape of the target differs from the one the algorithm assumes. Of particular interest are sensitivity to changes in target shape and material properties. We establish analytical bounds for sensitivity against changes in these parameters, and verify these bounds with Monte-Carlo runs.

In addition, we determine "detectability" of targets for a given geometry. For example, we find the minimum radii of objects for a certain soil type or minimum distance between two objects to achieve a particular detection probability for a fixed false alarm rate. In the talk, we will show examples of sensitivity analyses and detectability problems for multiple mine-like and drum-like objects.

ABSTRACT TEXT:

The use of ground penetrating radar (GPR) for mine detection is complicated by clutter associated with a rough air-ground interface and sensor noise. One way of improving detector performance is to employ array measurements as a means of providing data diversity which can increase detection probabilities and decrease false alarm rates. Here we develop a decision-theoretic, sequential detection algorithm for processing such GPR data. Our approach takes into account the interface, the nature of the mine signature seen in the data, and most importantly, signal diversity from array measurements. It is a low complexity technique specifically designed to optimally process the data as they are collected by the sensor and is thus applicable to real-time applications. The algorithm consists of a three step procedure. First, a windowed analysis of variance (ANOVA) procedure is used to process the array-data at each stop of the system. Second, a sequential, generalized likelihood ratio test is developed to recursively take the ANOVA output and generate a final test statistic as the array proceeds down the track. Finally, comparing this statistic to a threshold at each stop of the array indicates if and when a detection is declared. Field data from EG&G is used to demonstrate the validity of our algorithm. Experimental results and theoretical analysis show that the algorithm exhibits robust performance and a high detection probability for a given false alarm rate.

Abstract

A common problem in image processing is recovery of an image given noisy linear functionals of the original. While it has been shown that in certain situations, models possessing a $1/f$ -type power spectrum perform well as regularizers to stabilize these ill-posed inverse problems, the optimal parameters for the model are rarely known a priori. Previously, it was demonstrated that the expectation maximization (EM) algorithm can satisfactorily perform the estimation of the model parameters in the unblurred one-dimensional case. In this paper, we extend this analysis to the situation of two-dimensional objects and an environment which includes blurring. We show that again the EM algorithm performs well. In addition, we examine performance in terms of the variance of the estimates and bounds on these quantities.

1. Introduction

A common image processing problem is the reconstruction of an image given data which is a noisy and blurred representation of the original. Examples of such problems are found in application areas ranging from medical imaging and geophysical exploration to non-destructive testing and radar signal processing. Here we consider a discrete version of such linear inverse problems which takes the mathematical form

$$\mathbf{y} = \mathbf{T}\mathbf{g} + \mathbf{n} \quad (1)$$

where \mathbf{g} is a vector of coefficients representing the image to be recovered, \mathbf{T} is the blurring kernel, \mathbf{n} is

additive noise and \mathbf{y} is the data. For simplicity, the noise vector, \mathbf{n} , is taken to be zero mean, white, and Gaussian (i.e. $\mathbf{n} \sim (0, \sigma^2 \mathbf{I})$). We assume that \mathbf{g} is a zero mean, Gaussian vector with an unknown covariance matrix, $\mathbf{P}_{\mathbf{g}}$. As we discuss below, this model for \mathbf{g} constitutes a prior distribution and serves to aid in the regularization of the recovery of \mathbf{g} from \mathbf{y} .

For most practical problems, \mathbf{T} is highly ill-conditioned so that even small perturbations in the data cause large high frequency artifacts in the reconstruction. To counteract the ill-conditioning, some form of regularization is required. Generally, the regularization imposes a low-pass or smoothness constraint upon the solution. In particular, we consider a regularized least squares estimator which defines the reconstructed image, $\hat{\mathbf{g}}$, as the solution to the following optimization problem:

$$\hat{\mathbf{g}} = \arg \min_{\mathbf{g}} \|\mathbf{y} - \mathbf{T}\mathbf{g}\|_{\mathbf{R}^{-1}}^2 + \|\mathbf{g}\|_{\mathbf{P}_0^{-1}}^2, \quad (2)$$

where $\|\mathbf{x}\|_{\mathbf{A}}^2 = \mathbf{x}^T \mathbf{A} \mathbf{x}$, the matrix $\mathbf{R} = \sigma^2 \mathbf{I}$ is the noise covariance, and \mathbf{P}_0^{-1} is used to stabilize the solution typically by limiting the amount of high frequency information in $\hat{\mathbf{g}}$.

It can be shown that the minimum mean square error (MSE) of this estimation scheme is achieved when the regularization matrix \mathbf{P}_0 is equal to the covariance matrix of \mathbf{g} . As we assume that $\mathbf{P}_{\mathbf{g}}$ is not known *a priori*, it is necessary to estimate simultaneously both the matrix as well as \mathbf{g} . In this work, we assume the availability of only a single data vector \mathbf{y} so that sample covariance matrix estimation schemes are inapplicable. Rather, we employ a low-order, parametric model for $\mathbf{P}_{\mathbf{g}}$ such that this matrix can be completely described by a small vector of hyperparameters.

To describe \mathbf{g} we employ a family of models which have been shown to accurately represent stochastic processes with $1/f$ -type power spectra. These

*This work was supported by a grant from Textron Systems Division, NSF CAREER Grant MIP-9623721, and a sub-contract GC123920NDG from Boston University under the AFOSR MURI Program on Reduced Signature Target Recognition.

model have been developed and used in characterizing signals such as Brownian motion and ocean height data [1]. Also, they have been shown to work well as regularizers for least squares-type reconstruction schemes like (2) primarily because the $1/f$ structure essentially imposes a lowpass filtering operation to the solution, penalizing against high frequency artifacts. These models are most naturally described in the wavelet transform domain where the covariance matrix is diagonal (i.e. the wavelet coefficients are uncorrelated for these processes) and the values of these diagonal elements are specified in terms of a vector of three hyperparameters [2]. For this model, it was shown by Wornell [3] that in the non-degraded (i.e. $\mathbf{T} = \mathbf{I}$) one dimensional case, an efficient estimation routine can be arrived at using the EM algorithm for jointly determining both this vector as well as \mathbf{g} itself. In this paper we extend the work to both the blurred case and to two dimensional image data.

The wavelet coefficients for \mathbf{g} will be specified as $\gamma_{\mathbf{k}}^{\mathbf{s}}$, where the two element vector \mathbf{s} is the scale indices in the horizontal and vertical directions, with smaller indices corresponding to coarser scales, and \mathbf{k} is the shift indices. The $1/f$ prior model is now defined in the transform domain as

$$\text{var}(\gamma_{\mathbf{k}}^{\mathbf{s}}) = \kappa 2^{-\alpha^T \mathbf{s}} = \kappa 2^{-\alpha_x s_x - \alpha_y s_y}, \quad (3)$$

where α and κ are the hyperparameters which define the model. The vector α contains the fractal parameters which specify the smoothness of the process in both the horizontal and vertical directions, and κ sets the overall power of the process. Upon selecting a unique ordering for the two scale and shift indices, we can reduce the notation to a single index as

$$\text{var}(\gamma_j) = \kappa 2^{-\alpha^T \mathbf{s}_j} = \kappa 2^{-\alpha_x s_j^x - \alpha_y s_j^y}. \quad (4)$$

These variances then form the diagonal elements the covariance matrix which we write as

$$\mathbf{P}_0 = \kappa \mathbf{F}(\alpha). \quad (5)$$

where \mathbf{F} is a diagonal matrix whose j th element is $2^{-\alpha_x s_j^x - \alpha_y s_j^y}$. To simplify notation, the dependence of \mathbf{F} upon α will be often assumed but not written.

The objective of this paper is the development of an efficient wavelet domain estimation method for determining both the hyperparameters of the model and the wavelet coefficients of the object. This is performed using an expectation-maximization algorithm.

2. EM Algorithm

Normally the large size of the matrices arising in image restoration problems would make an EM approach highly computationally complex. By working in the wavelet transform domain however, we are able to take advantage of the fact that many classes of both convolutional and non-convolution blurring matrices have very sparse transform domain representations [4] thereby lowering the cost associated with the EM algorithm. Significant additional savings are obtained through the use of the diagonal $1/f$ regularization matrix. Specifically, it was demonstrated in [3] that for the unblurred, one-dimensional case, operating in the wavelet transform domain and using the $1/f$ models allows the maximization step to be reduced to a fast root finding algorithm. In this paper and the accompanying talk, we extend this technique to the case of blurred data and to two dimensional image data. We demonstrate that the root finding algorithm is applicable to the solution of multiple fractal parameters by successively iterating between them. The complexity of the expectation step is reduced by applying a recently developed algorithm which simultaneously provides for (a) rapidly inverting the information matrix associated with (2) and (b) preconditioning the conjugate gradient algorithm used to estimate γ for a given set of hyperparameters [5].

The log-likelihood function for α and κ , derived from the multivariate Gaussian, is

$$\begin{aligned} l(\alpha, \kappa; \boldsymbol{\eta}) &= -\frac{1}{2} \boldsymbol{\eta}^T (\kappa \boldsymbol{\Theta} \mathbf{F} \boldsymbol{\Theta}^T + \mathbf{R})^{-1} \boldsymbol{\eta} \\ &\quad - \frac{1}{2} \log |(\kappa \boldsymbol{\Theta} \mathbf{F} \boldsymbol{\Theta}^T + \mathbf{R})|. \end{aligned} \quad (6)$$

Here, the entire problem is transformed to the wavelet transform domain. The matrix $\boldsymbol{\Theta}$ represents the transform domain version of \mathbf{T} while $\boldsymbol{\eta}$ contains the transform of \mathbf{y} . Finally, the noise covariance matrix is \mathbf{R} . The Expectation step of the EM algorithm for the Gaussian case consists of constructing the estimate of the error covariance matrix for the current estimate of the parameter set, and computing the MAP estimate of $\hat{\gamma}$ as

$$\mathbf{C}^{(p)} = \left(\boldsymbol{\Theta}^T \mathbf{R}^{-1} \boldsymbol{\Theta} + \frac{1}{\kappa^{(p)}} (\mathbf{F}^{(p)})^{-1} \right)^{-1} \quad (7)$$

$$\hat{\gamma}^{(p)} = \mathbf{C}^{(p)} \boldsymbol{\Theta}^T \mathbf{R}^{-1} \boldsymbol{\eta}. \quad (8)$$

For convenience, we will define an additional vector, \mathbf{t} , which has the elements

$$t_j^{(p)} = \hat{\gamma}_j^{(p)2} + \mathbf{c}_j^{(p)}. \quad (9)$$

The maximization step consists of maximizing the following function

$$\begin{aligned} \begin{bmatrix} \boldsymbol{\alpha}^{(p+1)} \\ \kappa^{(p+1)} \end{bmatrix} &= \arg \max_{\boldsymbol{\alpha}, \kappa} \left(-N \log \kappa - \log |\mathbf{F}| \right. \\ &\quad \left. - \frac{1}{\kappa} \sum_j (\mathbf{F}^{-1} \mathbf{t}^{(p)})_j \right). \end{aligned} \quad (10)$$

Taking the derivative with respect to κ and setting it equal to zero gives the update solutions for κ as

$$\kappa^{(p+1)} = \frac{1}{N} \sum_j ((\mathbf{F}^{(p+1)})^{-1} \mathbf{t}^{(p)})_j. \quad (11)$$

To solve for $\boldsymbol{\alpha}$ we will use the relation that

$$\frac{\partial \mathbf{F}}{\partial \alpha_x} = -(\log 2) \mathbf{S}_x \mathbf{F} \quad (12)$$

where \mathbf{S}_x is a diagonal matrix of the scale coefficients associated with α_x . The derivative with respect to α_y is identical, thus we will show only the x results. Differentiating (11) and setting the result equal to 0 gives

$$0 = -(\log 2) \sum_j (\mathbf{F}^{-1} (\mathbf{S}_x - \frac{\text{tr} \mathbf{S}_x}{N} \mathbf{I}) \mathbf{t}^{(p)})_j. \quad (13)$$

Since \mathbf{F} , \mathbf{S}_x , and \mathbf{I} are diagonal matrices, the equation can be rewritten as

$$0 = \sum_j 2^{\alpha_x s_j^x} 2^{\alpha_y s_j^y} (s_j^x - \frac{\text{tr} \mathbf{S}_x}{N}) (t_j^{(p)}) = P(2^{\alpha_x}). \quad (14)$$

Which is a polynomial in 2^{α_x} with one sign change. The maximization with respect to α_x is therefore computed as the unique real positive root of this polynomial. Likewise, the counterpart equation in α_y is

$$0 = \sum_j 2^{\alpha_y s_j^y} 2^{\alpha_x s_j^x} (s_j^y - \frac{\text{tr} \mathbf{S}_y}{N}) (t_j^{(p)}) = P(2^{\alpha_y}). \quad (15)$$

It can be shown that (10) with respect to $\boldsymbol{\alpha}$ is a concave surface on the positive values and has a unique maximum. Further, solving (14) and (15) always increases the value of (6). Iterating between the equations thus continually moves towards the maximum until it converge to this maximum point. This is therefore the update solution for $\boldsymbol{\alpha}$.

Figure 1: Standard deviation of the parameter estimates.

The entire algorithm is now as follows:

1. Provide an initialization of the model parameters: κ and $\boldsymbol{\alpha}$.
2. Calculate the expectations using these parameters in equations (7), (8) and (9).
3. Solve for the updated $\boldsymbol{\alpha}$ by iterating on (14) and (15) until they converge.
4. Solve for κ using (11).
5. Repeat steps 2 thru 4 until $\|\hat{\boldsymbol{\gamma}}^{(p+1)} - \hat{\boldsymbol{\gamma}}^{(p)}\| < \epsilon$.

3. Estimation Variances

The performance bounds on the estimation of the model parameters is given by the Cramer-Rao bounds. The bounds are computed as the diagonal elements of the inverse of the Fisher information matrix which is given as [6]

$$\mathbf{J} = \begin{bmatrix} -E \frac{\partial^2 l}{\partial \kappa^2} & -E \frac{\partial^2 l}{\partial \kappa \partial \alpha_x} & -E \frac{\partial^2 l}{\partial \kappa \partial \alpha_y} \\ -E \frac{\partial^2 l}{\partial \kappa \partial \alpha_x} & -E \frac{\partial^2 l}{\partial \alpha_x^2} & -E \frac{\partial^2 l}{\partial \alpha_x \partial \alpha_y} \\ -E \frac{\partial^2 l}{\partial \kappa \partial \alpha_y} & -E \frac{\partial^2 l}{\partial \alpha_x \partial \alpha_y} & -E \frac{\partial^2 l}{\partial \alpha_y^2} \end{bmatrix}. \quad (16)$$

The inverse of this matrix provides the bound on the error covariance matrix (ECM). Extensive analysis of the parameter estimation performance can be achieved using these formulas. We will present here an examination of the performance versus SNR.

Figure 2: Normalized MSE in estimate of γ for a mismatched model. Here model energy is kept constant to provide a constant level of regularization.

Fig. 1 shows the standard deviations in the parameter estimates as a function of the SNR. The solid line is the CRB and is calculated from the inverse of (16). The results of Monte Carlo simulations are also shown to confirm the analysis. The true model parameters for this case are a κ of 10, and α_x and α_y of 1. We can see here that, as expected, the parameter estimates, specifically of α , improve as the SNR increases.

Next, we define the Normalized Mean Square Error (NMSE) as the ratio of the MSE in the estimate of \mathbf{g} obtained using arbitrary values for the hyperparameters in \mathbf{P}_0 to that of an estimator which knows the true values. It is easily shown that the NMSE is always greater than one and equals one exactly when the true model parameter values are used. In Fig. 2, the NMSE for this situation is shown where α_x is mismatched. The sensitivity to the mismatched parameter increases as SNR increases; however, the results of Fig. 1 indicate that the large SNR case is exactly where we can achieve accurate model estimates. Conversely, at low SNRs, the NMSE plots of Fig. 2 show a only a moderate degradation from optimal performance. Thus, we conclude from Figs. 1 and 2 that the EM algorithm provides accuracy exactly where such performance is needed in the recovery of \mathbf{g} and the effects of degraded model estimates at low SNR do not translate into large relative losses in our ability to recover \mathbf{g} .

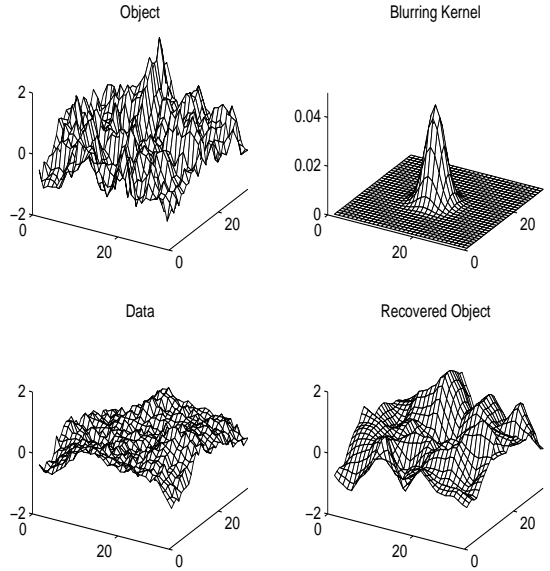

Figure 3: The reconstruction of an image. The blurring function is a Gaussian kernel of $\sigma = 2$ and the SNR is 10.8 dB.

Similar analysis can be performed versus the degree of blurring imposed by \mathbf{T} . Again in this situation, we find that the parameter estimation performs well in precisely the same situations in which object reconstruction is sensitive to a closely matched model. Where the parameter estimation is poor, model mismatch is not as much of a concern.

4. Example

In Figs. 3 and 4, we show the quality of the reconstructions available with the $1/f$ model and the convergence properties of the EM algorithm. The upper left plot is of a 32×32 pixel image of a fractal with $\alpha_x = 1.5$, $\alpha_y = 1.9$ and $\kappa = 10$. The image is blurred with a Gaussian kernel of $\sigma = 2$ which has significant energy content in approximately a 8×8 pixel area, and then corrupted by additive noise. The signal to noise ratio is 10.8 dB. The recovery is shown after 6 iterations of the EM algorithm. The EM algorithm moves quickly to the vicinity of the minimum of the cost function and further iteration does not significantly lower the cost function nor effect the reconstruction. In the case of this experiment, the algorithm converged to hyperparameters of $\hat{\alpha}_x = 1.2$, $\hat{\alpha}_y = 2.4$, and $\hat{\kappa} = 6.8$.

The lower plot in Figure 4 shows the error between the reconstruction and the original at each iteration

Figure 4: The convergence of the cost function and the error between the object and the reconstruction.

of the algorithm. As was shown in [7] the recovery is robust to small mismatches in the fractal parameters α (and to mismatches up to an order of magnitude upon the regularization level κ), therefore the discrepancy between the algorithm's hyperparameters and the true hyperparameters does not translate to a large error in the reconstruction. The MSE obtainable with the matched model was .086. The coarse scale features of the object (i.e. the large peaks) have been recovered quite well both in terms of their locations and amplitudes.

5. Conclusions and Future Work

Previous work has shown that the $1/f$ models produce satisfactory results for estimating one dimensional signals in noise and that the structure of the models in the wavelet transform domain allows for accurate and efficient estimation of the model parameters. In this paper, we extended this analysis to two-dimensional image problems and an environment which includes blurrings. By revising the expectation step to operate upon a statistic calculated from the estimates of the object and the error covariance matrix, we again achieve the computational simplicity of the unblurred case. Further, we show that multiple fractal parameters can be estimated by iterating upon the polynomials. Lastly we showed a method to evaluate the performance of the parameter estimates

and their effect upon the estimates of the object.

The algorithm presented assumes a Gaussian distribution to the object and noise and a cost function that minimizes the mean squared error. However the structure of the model should be exploitable with other distributions and cost functions associated with other criteria such as edge preservation [8]. By pursuing a similar approach to that presented here, one could develop efficient EM algorithms for a variety of problems.

Electromagnetic Inversion for Multi-Bistatic Ground Penetrating Radar

Peter M. Johansen¹, Carey M. Rappaport, Anthony J. Devaney, and Eric L. Miller
Center for Electromagnetics Research
Forsyth Building
Northeastern University, Boston, MA 02115

In recent years there has been an increasing interest in use of ground penetrating radar (GPR) for detection of buried land mines or other objects located in the ground. To achieve an accurate image it is important that the inversion algorithm be based on an accurate forward model relating the buried objects to the measured electric field. Such model must at least include a model of the antennas and take into account the presence of the air/soil interface.

In this talk we present an electromagnetic inversion scheme for GPR imaging based on a forward model in which both the antennas and the air/soil interface are explicitly described. The presented forward model is an extension of the model in [1] where the air/soil interface is neglected. Consequently, the present model more accurately describes the physical GPR-configuration, and a better reconstructed image is expected in practice.

The GPR is assumed to be operated in a stepped-frequency mode and the data are collected in a multi-bistatic survey (multiple independent transmitter and receiver antennas). The forward model is based upon the electric dyadic Green's function for a lossy dielectric half space. This dyadic Green's function is constructed from the Green's function for free space using the Fresnel reflection and transmission coefficients. The antennas are modeled by applying Kern's scattering matrix formulation [1]. Also, the dispersion of the soil is accounted for by including a realistic soil model. To analytically calculate the pseudo inverse, the forward model is linearized using the Born approximation. Various regularization schemes are employed to stabilize the analytic inversion. Numerical examples are provided to illustrate the impact of the air/soil interface and the differences among the various regularization schemes.

Boston, MA 02115

In recent years there has been considerable work in the development of inversion methods which, rather than forming an image of a medium, extract directly from the data information relevant to the distribution of desired targets located in the region under investigation. One such application of these methods is the detection and localization of buried landmines from low frequency electromagnetic induction (EMI) measurements. In this work we consider the development of inversion techniques adapted to the processing of data from an EMI array which surveys a region in a progressive manner starting at a known position and moving in a straight line to a final location. The use of space diversity coupled with advanced signal processing techniques will be shown to improve detection/false alarm performance and localization accuracy relative to a more typical mono-static EMI system.

We begin by developing a forward model relating the observed data directly to the pertinent physical characteristics of the targets of interest including size, shape, orientation, and electromagnetic properties. Our model is obtained using a reciprocity argument and the full three dimensional Maxwell's equations. For simplicity, we restrict our attention to a linearized model obtained under the first Born approximation. The final measurement model expresses the data at the receiver array as a linear combination of physically derived target signature vectors. The vectors carry information about the geometric structure of the buried objects. The weights represent the relative contrast of the objects and the number of vectors is equal to the number of mines in the receiver field of view.

This forward model lends itself particularly well to the analysis of the mine detection/localization problem and to the synthesis of adaptive algorithms for identifying buried mines. We will show how the above model can be used to provide quantitative results on the manner in which detection and false alarm rates and localization accuracy is dependent on the size, orientation, and position of the mines relative to the sensor array. We demonstrate how this analysis and the scattering model can be used as the basis for the synthesis of algorithms for performing mine detection and localization. Because the array is sensitive to mines in a full 3D volume, we can obtain detection and localization information before the array passes directly over or adjacent to the mine. We will discuss algorithms which provide this forward looking information in conjunction with accuracy estimates both of which are progressively refined and updated as the EMI array moves toward the buried object.

Efficient methods for the solution and analysis of statistical linear inverse problems in the wavelet transform domain*

Eric L. Miller

email: elmiller@cdsp.neu.edu

March 10, 1997

Abstract

We present efficient, wavelet domain algorithms for computing the error variances and pre-conditioning the normal equations for a large class of linear inverse problems. An iterative method based on the optimization of a diagonal dominance criteria is introduced to determine an optimal ordering of the rows and columns of the so-called information matrix. This ordering, combined with the judicious use of the block matrix inversion formula allows for the easy extraction of the error variances in a manner which does not require the full inversion of the information matrix. We demonstrate that this algorithm leads naturally to the specification of a left-preconditioner for a conjugate gradient solution to the normal equations associated with the MAP problem.

1 Introduction

In this paper, we consider computational issues associated with the use of maximum *a posteriori* (MAP) estimation methods for linear restoration (i.e. inverse) problems posed in the wavelet transform domain. An MAP approach provides a framework for performance analysis via the examination of second-order error statistics. Such information can be especially valuable for quantitatively understanding how issues such as the structure of space varying blurring operators or sparse and irregular sampling patterns impact the accuracy of the reconstruction. Additionally, wavelet-based methods are useful for a number of reasons. Large classes of both convolutional and non-convolutional blurring operators have sparse matrix representations in the wavelet transform domain thereby leading to efficient inversion methods based on conjugate-gradient type algorithms. A second advantage of a multiscale approach is the availability of a useful class of so-called $1/f$ statistical models/regularizers specified directly in the transform domain. Finally, wavelet-domain error variance analysis

have proved useful for rigorously capturing the nature of the ill-posedness in these inverse problems [1–3].

An important difficulty with such variance analysis is computational complexity. The error variances are the diagonal elements of the error covariance matrix (ECM). The quantities available from the problem statement allow only for the direct specification of the *inverse* of the ECM, called the information matrix. Thus, obtaining the error-variances requires the inversion of the information matrix a task requiring a costly order N^3 operations with N the number of samples in the signal or pixels in an image. In this work, we develop and demonstrate a wavelet-domain algorithm which exploits both the sparsity of the operator matrices and the covariance structure of the $1/f$ -type prior models to lower significantly this computational burden for a wide class of linear inverse problems.

2 Problem Formulation

We consider inverse problems of the form

$$\mathbf{y} = \mathbf{T}\mathbf{g} + \mathbf{w} \quad (1)$$

where \mathbf{g} is a lexicographically ordered vector of pixel values of the image to be recovered, \mathbf{w} is additive white Gaussian noise (i.e. $\mathbf{w} \sim \mathcal{N}(0, r\mathbf{I})$), \mathbf{y} is the data vector and \mathbf{T} is a matrix representing the blurring operation. As is discussed in [2], transformation of (1) to a multiscale domain is achieved by defining two orthonormal wavelet transform matrices, \mathbf{W}_y and \mathbf{W}_g , and applying them to (1) as

$$\mathbf{W}_y \mathbf{y} = [\mathbf{W}_y \mathbf{T} \mathbf{W}_g^T] [\mathbf{W}_g \mathbf{g}] + \mathbf{W}_y \mathbf{w}$$

or equivalently

$$\boldsymbol{\eta} = \boldsymbol{\Theta} \boldsymbol{\gamma} + \boldsymbol{\nu}. \quad (2)$$

In (2), \mathbf{W}_g takes \mathbf{g} into a vector $\boldsymbol{\gamma}$ comprised of all the wavelet coefficients and coarsest scale scaling coefficients in a two dimensional wavelet transform of \mathbf{g} . A similar interpretation holds for \mathbf{W}_y , $\boldsymbol{\eta}$, and $\boldsymbol{\nu}$. The matrix $\boldsymbol{\Theta}$ is the standard form wavelet transform of the matrix \mathbf{T} . As \mathbf{W}_y is orthonormal, $\boldsymbol{\nu} \sim \mathcal{N}(0, r\mathbf{I})$. Finally, $\boldsymbol{\gamma}$ is assumed to be distributed as a $1/f$ -type process and is thus zero mean with a diagonal covariance matrix denoted by \mathbf{P}_0 [2].

Figure 1: FLOP Comparison

For the problem defined by (2), the MAP estimate of γ given η is given as the solution to the normal equations:

$$(\Theta^T \mathbf{R}^{-1} \Theta + \mathbf{P}_0^{-1}) \hat{\gamma} = \Theta^T \mathbf{R}^{-1} \eta \quad (3)$$

where $\mathbf{L} = \Theta^T \mathbf{R}^{-1} \Theta + \mathbf{P}_0^{-1}$ is the information matrix. The problem of interest here is computing the error variances for this linear restoration problem. For the model in (2), the error covariance matrix, \mathbf{P} , is equal to \mathbf{L}^{-1} . The major difficulty with obtaining the error variances lies in the fact that even for small images \mathbf{L} is a large matrix making direct inversion impractical.

3 Outline of Inversion Method

Our method for solving this problem is motivated by the results in [3] indicating that for ill-posed problems $\hat{\gamma}$ can be divided into two sub-vectors: $\hat{\gamma}_1$ and $\hat{\gamma}_2$ corresponding to those coefficients for which the data do and do not provide “significant” information. Given this decomposition, the rows and column of (3) are re-ordered to obtain a permuted form of the normal equations:

$$\begin{bmatrix} \tilde{\mathbf{L}}_{11} & \tilde{\mathbf{L}}_{12} \\ \tilde{\mathbf{L}}_{12}^T & \tilde{\mathbf{L}}_{22} \end{bmatrix} \begin{bmatrix} \hat{\gamma}_1 \\ \hat{\gamma}_2 \end{bmatrix} = \begin{bmatrix} \mathbf{v}_1 \\ \mathbf{v}_2 \end{bmatrix} \quad (4)$$

where $\mathbf{v} = \Pi \Theta^T \mathbf{R}^{-1} \eta$, $\tilde{\mathbf{L}} = \Pi \mathbf{L} \Pi^T$, and Π is the permutation matrix that takes the vector $\hat{\gamma}$ to a vector with $\hat{\gamma}_1$ as the first collection of elements and $\hat{\gamma}_2$ as the second. It was observed in [3] that $\tilde{\mathbf{L}}_{11}$ was small and dense, $\tilde{\mathbf{L}}_{22}$ was large but well approximated as diagonal, and $\tilde{\mathbf{L}}_{12}$ was rectangular and sparse. It was shown that $\tilde{\mathbf{L}}^{-1}$ could be found with an algorithm whose complexity was dominated by the inversion of the small matrix $\tilde{\mathbf{L}}_{11}$. The primary problem was that Π was built based on knowing the error variances which meant that $\tilde{\mathbf{P}}$ had already been calculated.

In the talk accompanying this paper, we describe an algorithm for constructing Π in a manner which does not require prior knowledge of $\tilde{\mathbf{P}}$. The algorithm is composed of the following three stages:

1. **Building L.** The Schwartz inequality is used to construct a subset of the elements of $\Theta^T \mathbf{R}^{-1} \Theta$ without performing the matrix-matrix products.
2. **Permuting L.** We determine a permutation of

Figure 2: Relative trace difference

the rows and columns which addresses the tradeoff between having a large $\tilde{\mathbf{L}}_{22}$ and a loss in accuracy associated with its approximation as diagonal. An efficient, iterative method based on the sequential “local” optimization of a diagonal dominance criteria is introduced to determine a family of permutation matrices corresponding to various size $\tilde{\mathbf{L}}_{22}$.

3. **Inverting L.** Using the block-matrix inversion formula, we extract the error variances.

A by-product of this method is a matrix which serves as a left-preconditioner for the normal equations resulting in improved convergence of the CG algorithm at a fraction of the original computational cost.

As an example of the performance of this approach, in Figures 1 and 2, we compare the FLOP counts and accuracy results for our algorithm against direct inversion of the information matrix for a space-varying problem where T corresponds to convolution with a Gaussian window whose width varies sinusoidally in both spatial dimensions. Accuracy is measured as the 1-norm of the error in the variance calculation due to our method divided by the 1 norm of the exact variances. It is evident that over a wide range of SNRs, about three orders of magnitude in computational savings can be obtained with a lose in accuracy of well under 1%. In the talk accompanying this paper, we will provide a detailed description and analysis of this computational approach, demonstrate its effectiveness on a variety of problems, and consider the issue of pre-conditioning.

Motivations and Goals

Development of detection, localization, and characterization methods for buried UXO from array-based EM and GPR sensing systems

- System types
 - Multi-monostatic such as GEM-3
 - Multi-multistatic such as FAR
- Algorithm characteristics
 - Statistically-based
 - Exploit spatial, spectral, and temporal diversity
 - Recursive implementation
 - Employ simplest possible physical model

Technical approach: Overview

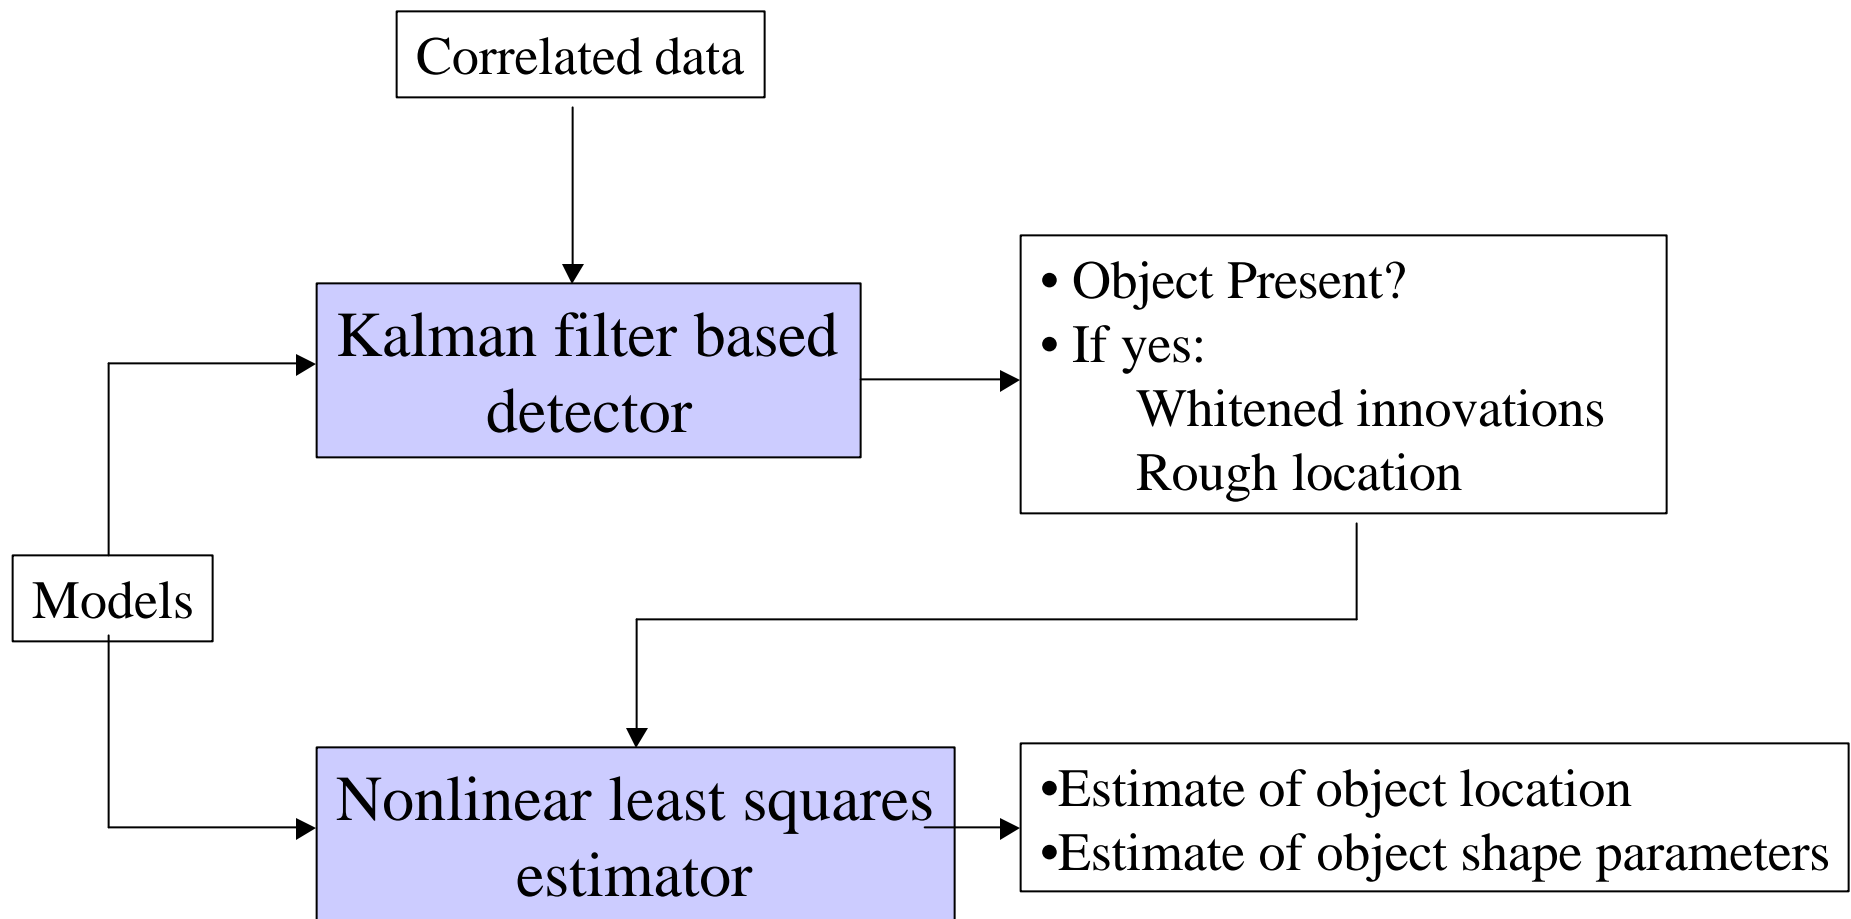

- EM projects
 - Recursive detection and localization
 - Spatial/spectral analysis for orientation estimation and target characterization
- Radar projects
 - Matched field methods for multi-target detection and localization
 - Detection and characterization from FAR data

EM Project 1: Recursive, Model-Based Detection and Localization

- Collect data one stop at a time
- Algorithm Goals
 - Detect as soon as possible
 - Localize
- Methods & Models
 - Physical target models
 - Recursive, stochastic clutter models
 - Statistical methods for detection, localization

Processing flow

Example

- System
 - Single transmitter
 - Ten receivers on either side (\oplus 50cm)
 - Scan 75 positions between 0 and 3.7 m
- Randomize over mine location and size

Example (cont)

- Detection
 - Based on single, nominal mine size and burial depth
 - Coarse localization: 20 cm x 20 cm spacing
- Localization / classification
 - Used detection results to generate initial position guess

Why Whiten?

Raw Data

Filtered Innovations

Performance on this case

Parameter	True Value (cm)	Estimate (cm)
Major Axis Length	10.98	10.93
Minor Axis Length	4.33	4.39
Down Track Position	265.83	265.83
Cross Track Position	21.16	21.15
Depth Below Array	18.63	18.64

Errors in center estimates

EM Project 2:

UXO Orientation Estimation and Classification

- Goals
 - Estimation of target orientation and spectral dipole moment functions from multi-frequency spatial EM data
- Hypotheses/Approach
 - Classification from orientation-independent dipole moment spectrum
 - Estimate orientation explicitly
 - Entirely model based
- Team: NU, OU, Geophex

The model

$$y = \mathbf{d}^T [\mathbf{R}^T \mathbf{D} \mathbf{R}] \mathbf{x}$$

- y = datum at location r and frequency ω
- \mathbf{x}, \mathbf{d} = 3×1 vectors of (x, y, z) field components dependent on positions of transmitter, receiver and mine
- \mathbf{R} = 3×3 rotation matrix encoding orientation of object
- \mathbf{D} = diagonal matrix holding frequency dependent dipole moments

The Processing

- Goals:
 - Determine two unique elements per frequency of \mathbf{D}
 - Determine two orientation angles buried in \mathbf{R}
- Method:
 - Estimation of dipole moments = linear MAP problem
 - Estimation of angles = nonlinear ML problem
 - Performance analysis: CRB readily available
 - Lots of structure.
 - Looking into efficient implementation
 - Also looking into sub-optimal, still faster methods

Example

- 20dB SNR
- 10 x 10 grid of measurements
- Non-permeable
- 20 log. Spaced frequencies between 1 Hz and 20kHz
- Assume position previously determined

Dipole moments

Cost versus rotation angles

Estimated dipole moments

Reconstructed object

Radar Project 1:

Array Processing for Multi-Object Near-Field Detection

- Goals
 - Employ high resolution array processing methods to detect multiple objects in near field of antenna array
- Hypotheses/approach
 - Use of model-based array processing would allow for discrimination of closely spaced objects
 - Matched field processing with various forward solvers assuming homogeneous medium
 - Closed form CRB analysis
- Team: NU

Experimental Setup

Well separated metal objects

Closely spaced metallic objects

Simple physical model

Well separated: Easily locates both scatterers

Closely spaced: Cannot see separate objects

Advanced model, close objects

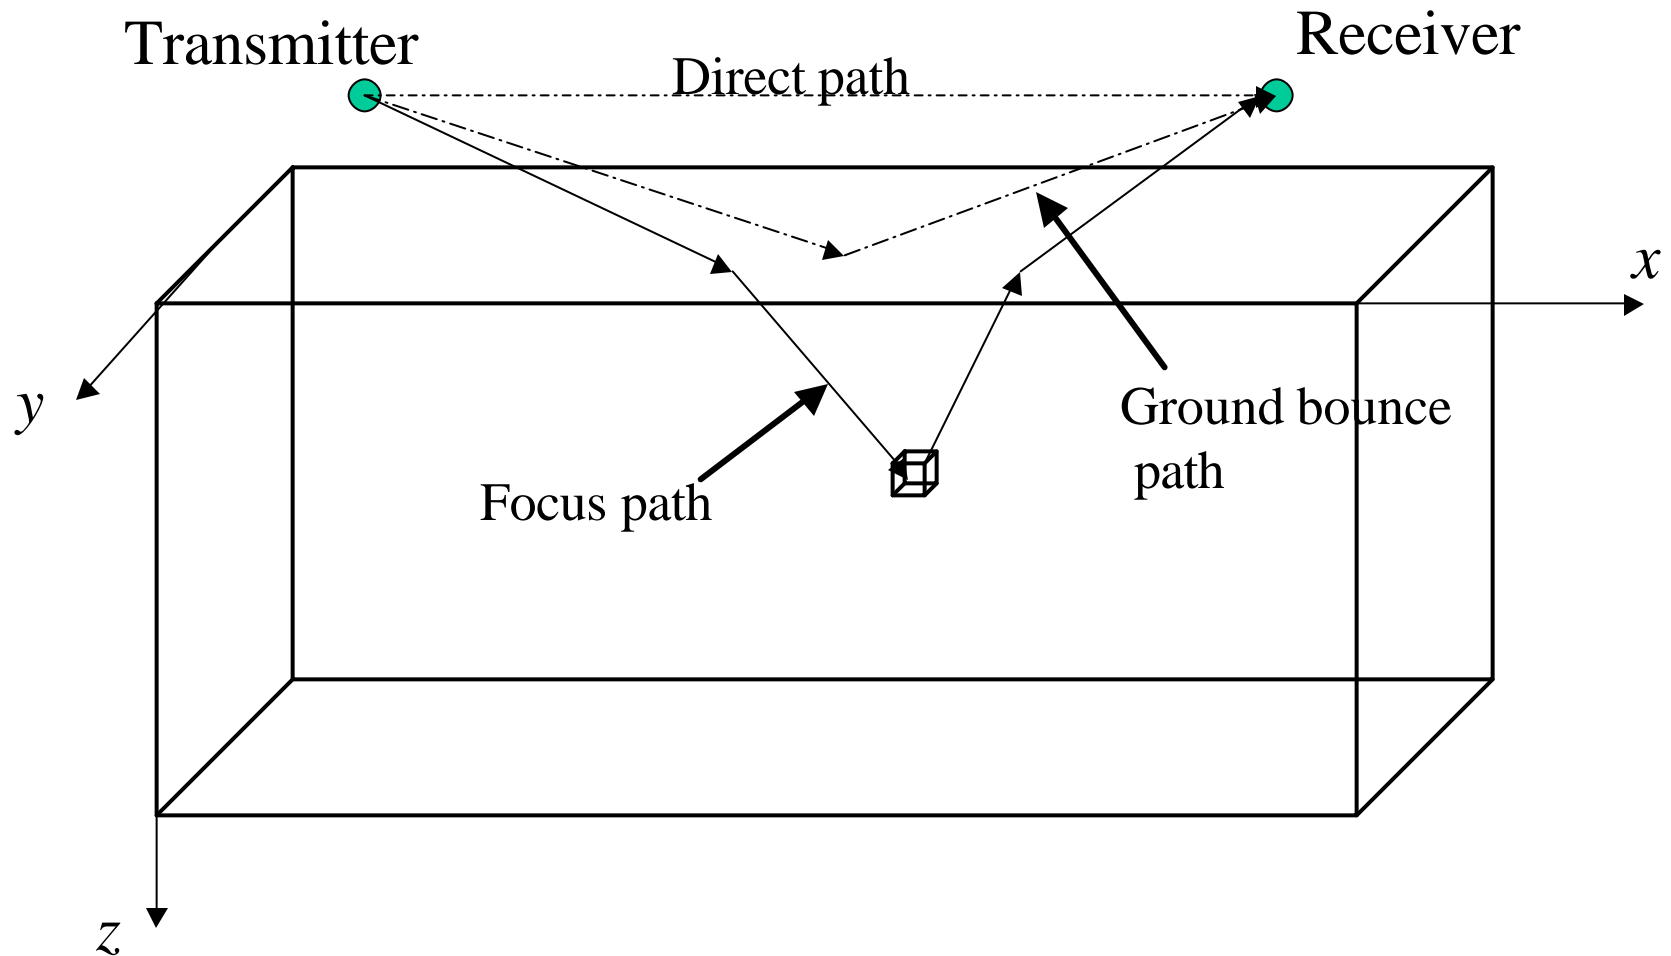

Both objects well localized

Radar Project 2: FAR Processing

- Goals
 - Detection and localization of buried objects from FAR-type data
- Hypotheses/approach
 - Detection can be done using stochastic, recursive change detection methods
 - Localization using delay estimation based on hybrid ray-optics/FDTD model
- Team: NU and GeoCenters

FAR System Overview

Layer-based detection

- **Target:**
 - Elliptical anomaly with correlated structure across layers
- **Approach:**
 - Statistical model for background texture/clutter
 - Recursively whiten data and identify cross-layer anomalies

Localization and classification

- Model
 - Received signal superposition of delayed and scaled base signal with delays coming from half-space ray-optics approximation
 - Base signal is target dependent and calculated from FDTD simulation
- Processing
 - Time delay estimation gives target location
 - Multiple model approach gives target type

Conclusions

- EM Projects
 - Demonstrated utility of model based, statistical methods for detection and localization
 - Near real time implementation possible
- Radar projects
 - Demonstrated feasibility for finding multiple objects in near field of array
 - Implementable approach to FAR detection, localization, and classification

Next Steps and Transition

- EM
 - Project 1: Verify using data from array-based system
 - Project 2: Continued work using GEM-3 data
 - Goal: merge the two for overall approach to EM ATR
- Radar
 - Project 1:
 - Many extensions (3D models, include interface, clutter models, unknown object characteristics ...).
 - Requires 's and  / 
 - Project 2: Just getting off the ground

The Processing

- Estimate unique elements of the symmetric matrix
 $\mathbf{B} = \mathbf{R}^T \mathbf{D} \mathbf{R}$.
 - Small (6x6) linear least squares estimation problem
 - Closed form performance analysis
- From estimate of \mathbf{B} , determine dipole moments (2) and rotation angles (2)
 - Can write dipole moments as function of angles
 - Therefore solution = 2D non-linear least squares estimation problem for angles.
 - CRB analysis easily available
 - Also quick

QMR-BASED PROJECTION TECHNIQUES FOR THE SOLUTION OF NON-HERMITIAN SYSTEMS WITH MULTIPLE RIGHT-HAND SIDES*

MISHA KILMER[†], ERIC MILLER[‡], AND CAREY RAPPAPORT[‡]

Abstract. In this work we consider the simultaneous solution of large linear systems of the form $Ax^{(j)} = b^{(j)}$, $j = 1, \dots, K$, where A is sparse and non-Hermitian. We describe single-seed and block-seed projection approaches to these multiple right-hand side problems that are based on the QMR and block QMR algorithms, respectively. We use (block) QMR to solve the (block) seed system and generate the relevant biorthogonal subspaces. Approximate solutions to the nonseed systems are simultaneously generated by minimizing their appropriately projected (block) residuals. After the initial (block) seed has converged, the process is repeated by choosing a new (block) seed from among the remaining nonconverged systems and using the previously generated approximate solutions as initial guesses for the new seed and nonseed systems. We give theory for the single-seed case that helps explain the convergence behavior under certain conditions. Implementation details for both the single-seed and block-seed algorithms are discussed and advantages of the block-seed algorithm in cache-based serial and parallel environments are noted. The computational savings of our methods over using QMR to solve each system individually are illustrated in two examples.

Key words. QMR, projection, Krylov subspace, iterative methods, block Krylov

1. Introduction. In many applications one desires the solution of multiple linear systems of the form

$$(1.1) \quad Ax^{(j)} = b^{(j)}, \quad j = 1, \dots, K,$$

involving the same $N \times N$ coefficient matrix A but K different right-hand sides $b^{(j)}$, all of which are available simultaneously. Such problems arise, for instance, in the numerical solution of frequency-domain electromagnetic wave scattering; here, the right-hand sides might correspond to incident fields over the scatterer induced either by plane waves at various angles of incidence or by excitation sources at different locations.

Systems involving large, sparse matrices make good candidates for solution by iterative Krylov subspace methods since storage is kept to a minimum and matrix-vector products can be done efficiently. However, the naive approach of solving each of the K linear systems independently using a Krylov subspace method does not take advantage of the fact that the $b^{(j)}$'s, and hence the $x^{(j)}$'s, may be *closely related* due to the underlying physical nature of the problem. By closely related, we mean that the solution to the j th system has large components in the initial directions of the k -dimensional ($k \ll N$) Krylov subspace generated from one of the other systems. Projection-type techniques for both the Hermitian and non-Hermitian cases,

discussed in more detail below, that specifically exploit such shared information have been proposed (e.g., see [5, 26, 24] and the references therein).

Another alternative is to use a block Krylov subspace algorithm to solve the systems simultaneously [16, 23, 4, 8, 15]. Essentially these methods seek solutions in block Krylov subspaces, or some deflated version thereof, generated by the matrix A and the $N \times K$ matrix $R = B - AX_0$; here the columns of B are the $b^{(j)}$ and the columns of X_0 are the initial estimates for each of the systems. However, this approach can be more expensive in terms of storage than projection techniques because the length of the recurrences to update the iterates depends on the number of right-hand sides, or, in the case of deflation [8], the number of right-hand sides corresponding to the deflated Krylov sequences. Also, if a deflation technique is used, a deflation tolerance must be specified in advance, and we have found in experiments that the performance and convergence of the systems depend in a somewhat unpredictable manner on this value. On the other hand, block Krylov subspace algorithms have the advantage that they are better suited to parallelism [17, 14, 15] and make use of higher level BLAS [2]. Therefore, in this paper we develop new single and block-seed projection approaches based on the QMR and block QMR algorithms, respectively; our block-seed method exploits the best properties of the block QMR algorithm while preserving the basic properties of our sequential projection technique. To our knowledge, ours is the first block-seed projection algorithm for non-Hermitian linear systems with multiple right-hand sides; in particular, as our algorithm is built around the BL-QMR algorithm of [8], it incorporates a deflation strategy.

Specifically, the idea of a projection technique is to first select one of the systems as “seed” and solve it by an iterative Krylov subspace method. As the relevant subspaces are generated, the approximations to the other systems are simultaneously updated by projecting the residual onto a particular subspace and by either enforcing a Galerkin-type condition [11, 25] or minimizing the projected residual [24]. Such methods are sometimes referred to as Lanczos–Galerkin approaches [21].

Smith [25] and Joly [11] both consider a projection approach based on BiCG for nonsymmetric A . In [11] a similar approach for CGS is also given. However, the BiCG-projection approach can exhibit the potentially erratic convergence behavior observed when applying BiCG to a single linear system (see the results in [24]). Simoncini and Gallopoulos [24] also present an approach to solving (1.1) when A is nonsymmetric.

Our single-seed projection algorithm is most similar in concept to the project-minimize approach in [24]. However, as a result of the underlying unsymmetric Lanczos process, we do not need to store the basis vectors, we do not need to predetermine a subspace dimension, and we show that the approximate solutions and residuals to the nonseed systems are cheaply computed and available at every stage of the algorithm because they are updated with short-term recurrences. Since we are minimizing quantities rather than enforcing Galerkin conditions, the convergence behavior should be less erratic than methods based on the latter. As noted and as we illustrate in Theorem 3.4, the success of our single-seed method depends on the closeness, in the sense described above, among the right-hand sides. The block-seed approach we introduce here is more efficient when the right-hand sides are not all close.

This paper is organized as follows. In section 2, we give the necessary background on the QMR approach. We give an outline of our single-seed projection approach and discuss its convergence in section 3. Background on the block QMR algorithm is presented in section 4. The block variant of our QMR-projection algorithm is reported in section 5, and related computational issues are discussed in section 6. Section 7

gives numerical results, and section 8 reports conclusions and future work.

2. Background: The QMR algorithm. The quasi-minimal residual (QMR) algorithm was introduced by Freund and Nachtigal in [9]. The original algorithm was based on three-term recurrences. In [10], the authors proposed a mathematically equivalent algorithm which employed coupled two-term recurrences. Since the latter variant has been found to be more numerically stable for solving linear systems, in numerical experiments we use this implementation. However, to simplify the notation in this section and in section 3, and to be consistent with the notation in section 5, we will follow the notation in [9]. Further, for simplicity, we consider only the version without look-ahead but note that our algorithm could be adapted to account for look-ahead.

In the remainder of the paper, the notation $\|\cdot\|$ always refers to the Euclidean norm $\|\cdot\|_2$. The superscript T is used to denote the transpose operation, and superscript $*$ is used to denote the conjugate transpose operation.

A Krylov subspace of dimension k generated by a matrix G and a vector q is defined according to

$$K_k(G, q) = \text{span}\{q, Gq, G^2q, \dots, G^{k-1}q\}.$$

The QMR algorithm is a Krylov-subspace-based iterative method that can be used to solve non-Hermitian linear systems of the form $Ax = b$, $A \in \mathcal{C}^{N \times N}$. At the k th iteration, the current solution estimate has the form

$$(2.1) \quad x_k = x_0 + V_k z_k,$$

where x_0 denotes the initial guess and $V_k = [v_1, v_2, \dots, v_k]$ is an $N \times k$ matrix whose columns are basis vectors for $K_k(A, v_1)$ with $v_1 = r_0/\|r_0\|$ and $r_0 = b - Ax_0$. The length k vector z_k is chosen as the solution to a particular minimization problem, as discussed below. Those basis vectors are generated via the nonsymmetric Lanczos process (see [22]) and are constructed to be biorthogonal to vectors $w_i, i = 1, \dots, k$, which form a basis for $K_k(A^T, w_1)$.¹ The columns of the $N \times k$ matrix W_k are the w_i .

From biorthogonality it follows that

$$(2.2) \quad W_{k+1}^T V_{k+1} = D_{k+1}, \quad D_{k+1} = \text{diag}(\delta_1, \dots, \delta_{k+1}), \quad \delta_i \neq 0.$$

Also as a result of the Lanczos algorithm we obtain the relation

$$(2.3) \quad AV_k = V_{k+1} \bar{T}_k,$$

where \bar{T}_k is a $(k+1) \times k$ tridiagonal matrix. Using (2.1), (2.2), and (2.3), and setting $\beta = \|r_0\|$, at the k th iteration the residual, $r_k = b - Ax_k$, is given by [22]

$$(2.4) \quad r_k = V_{k+1}(\beta e_1 - \bar{T}_k z_k),$$

where e_1 denotes the first Cartesian unit vector. Since the columns of V_{k+1} are not orthonormal,

$$\|r_k\| \leq \|V_{k+1}\| \|\beta e_1 - \bar{T}_k z_k\|.$$

¹Here we always take $w_1 \equiv v_1$, but note that other choices are possible. A version of the algorithm is also possible using $K_k(A^*, w_1)$ for the second Krylov subspace.

The QMR algorithm determines z_k by minimizing the norm of the quasi-residual term [9]; that is,

$$z_k = \arg \min_{z \in \mathbb{C}^{k \times 1}} \|\beta e_1 - \bar{T}_k z\|.$$

We make the following alternate observation. From (2.4) and using biorthogonality,

$$\|D_{k+1}^{-1} W_{k+1}^T r_k\| = \|\beta e_1 - \bar{T}_k z_k\|.$$

Thus, the z_k which defines the k th QMR iterate can also be thought of as the one that minimizes the norm of the residual projected onto a smaller dimensional subspace. We will make use of this alternate definition of the QMR iterates in subsequent sections.

3. The single-seed QMR-projection algorithm. In this section we describe a single-seed QMR-projection algorithm for solving linear systems of the form (1.1). Our algorithm proceeds as follows. First, we select one system, say, system j , to serve as “seed” and apply QMR (without look-ahead) to the seed system. In the following, we use $r_0^{j,l}$ to denote the initial residual to system l , where l denotes the index of any of the nonconverged systems given the starting guess $x_0^{j,l}$. We use $r_k^{j,l}$ to denote the residual of system l after k iterations. Since different choices of seed lead to different Krylov subspaces and hence different iterates, the superscript j is used to denote that this is the residual at the k th iteration for system l when system j was used as seed. By the beginning of the k th iterate, QMR has generated biorthogonal bases for two k -dimensional Krylov subspaces, $K_k(A, r_0^{j,j})$ and $K_k(A^T, r_0^{j,j})$. We denote the respective bases by the vectors $v_{j,i}$ and $w_{j,i}$, $i = 1, \dots, k$: the subscript j is used to indicate that this particular set was generated using system j as seed. These vectors are the columns of the $N \times k$ matrices $V_{j,k}$ and $W_{j,k}$, respectively. The corresponding $(k+1) \times k$ tridiagonal matrix is denoted as $\bar{T}_{j,k}$ (compare to (2.3)). By the end of the k th iterate, QMR has also generated the unnormalized versions of the vectors $v_{j,k+1}$ and $w_{j,k+1}$ for use in the $(k+1)$ st iteration.

Let us comment on the values of $x_0^{j,l}$. If we suppose that j was the seed system and converged after m steps and that the index of the next seed system is j^* , then we set $x_0^{j^*,l} = x_m^{j,l}$ for all indices l such that system l has not already converged.

In the previous section, we have seen that the k th iterate corresponding to the seed system is given by

$$x_k^{j,j} = x_0^{j,j} + V_{j,k} z_k^{j,j} \quad \text{with} \quad z_k^{j,j} = \arg \min_{z \in \mathbb{C}^{k \times 1}} \|\beta e_1 - \bar{T}_{j,k} z\|.$$

Now we also want the k th iterate of the (nonconverged) nonseed system, say, system l , to lie in $x_0^{j,l} + K_k(A, r_0^{j,l})$, in other words,

$$(3.1) \quad x_k^{j,l} = x_0^{j,l} + V_{j,k} z_k^{j,l}, \quad l \neq j.$$

Next we must decide how to define $z_k^{j,l}$. From (2.3) (with $V_{j,k}$ in place of V_k) and (3.1),

$$(3.2) \quad \begin{aligned} r_k^{j,l} &= b^{(l)} - A x_k^{j,l} \\ &= r_0^{j,l} - V_{j,k+1} \bar{T}_{j,k} z_k^{j,l}. \end{aligned}$$

Therefore, using biorthogonality,

$$\|D_{j,k+1}^{-1} W_{j,k+1}^T r_k^{j,l}\| = \|D_{j,k+1}^{-1} W_{j,k+1}^T r_0^{j,l} - \bar{T}_{j,k} z_k^{j,l}\|.$$

Finally, we use the above equality to determine $z_k^{j,l}$:

$$(3.3) \quad z_k^{j,l} = \arg \min_{z \in \mathbb{C}^{k \times 1}} \|D_{j,k+1}^{-1} W_{j,k+1}^T r_0^{j,l} - \bar{T}_{j,k} z\|.$$

3.1. Computational issues. Let us sketch how to efficiently compute the iterates and residuals of the nonseed systems. More details can be found in [13]. As above, we will use the index l to denote an arbitrary nonseed system and j to denote the seed system.

Let the QR decomposition of $\bar{T}_{j,k}$ be

$$\bar{T}_{j,k} = Q_{j,k}^* \begin{bmatrix} R_{j,k} \\ 0 \end{bmatrix},$$

where $Q_{j,k}$ is a product of Givens rotations and $R_{j,k}$ is $k \times k$ upper triangular with upper bandwidth 2. It can be shown [13] that using the QR factorization to solve (3.3) results in the easily solved system

$$(3.4) \quad z_k^{j,l} = R_{j,k}^{-1} t_k^{j,l},$$

where $t_k^{j,l}$ differs from $t_{k-1}^{j,l}$ only in its last entry, which we shall denote by $y_k^{j,l}$. The norm of the projected residual in (3.3) is given by the scalar $|\tau_{k+1}^{j,l}|$. Further, $\tau_{k+1}^{j,l}$ and $y_k^{j,l}$ can be updated from $\gamma_{k+1}^{j,l}$ and $\tau_k^{j,l}$ with $\delta_{j,k} \equiv w_{j,k}^T v_{j,k}$:

$$(3.5) \quad \begin{bmatrix} y_k^{j,l} \\ \tau_{k+1}^{j,l} \end{bmatrix} = \begin{bmatrix} c_{j,k} & s_{j,k} \\ -s_{j,k} & c_{j,k} \end{bmatrix} \begin{bmatrix} \tau_k^{j,l} \\ \gamma_{k+1}^{j,l} \end{bmatrix} \quad \text{with} \quad \gamma_{k+1}^{j,l} \equiv \frac{1}{\delta_{j,k+1}} w_{j,k+1}^T r_0^{j,l},$$

where $c_{j,i} \in \mathcal{R}$, $s_{j,i} \in \mathcal{C}$, $c_{j,i}^2 + |s_{j,i}|^2 = 1$.

As in equation (4.8) of [9], we define $P_{j,k} = [p_{j,1}, p_{j,2}, \dots, p_{j,k}] \equiv V_{j,k} R_{j,k}^{-1}$. Since $R_{j,k}$ is upper triangular with bandwidth 2, there is a short-term recurrence relation for the $p_{j,k}$ [9]. Using (3.1) and (3.4), the k th iterate of the l th system is given by

$$(3.6) \quad x_k^{j,l} = x_{k-1}^{j,l} + y_k^{j,l} p_{j,k}.$$

From this, we derive an iterative update for $r_k^{j,l}$ that does not require any additional matrix-vector products per iteration as follows.

LEMMA 3.1. *The residual at the k th iteration corresponding to the l th system is given by*

$$r_k^{j,l} = r_{k-1}^{j,l} - y_k^{j,l} f_{j,k}, \quad \text{where} \quad f_{j,k} \equiv A p_{j,k},$$

and can be computed in $O(N)$ flops.

Proof. The proof follows from (3.6), the bandedness of $R_{j,k}$, and the definition of $p_{j,k}$ above. (A detailed proof can be found in [13].) \square

3.2. Seed selection. Clearly, the success of our QMR-projection approach at reducing the total number of matrix-vector products needed to solve all the systems to the desired tolerance depends on which and in what order systems are selected as seed. We use the approach in [24]; namely, we choose the seed index j such that the norm of the residual of the corresponding system is larger than all the remaining nonconverged systems. Developing more informed selection heuristics remains a subject for future research.

3.3. Theory. Suppose that QMR has been run once and that the initial seed system has converged after m steps. Our algorithm proceeds by choosing another seed and using as its initial guess that solution obtained via projection as the first system was solved. One of the results of this section is that in exact arithmetic, assuming A is diagonalizable, if some of the right eigenvectors are well approximated by Ritz vectors corresponding to the first Krylov subspace generated, the rate of convergence of the second seed system behaves as if the corresponding part of the spectrum of A is cut off. The proof technique follows along the lines of the proof of Lemma 3.2 in [5]. $\kappa_2(\cdot)$ denotes the 2-norm condition number of the argument.

We assume A is diagonalizable with eigendecomposition $A = \hat{Z}\Lambda\hat{S}$, where $\hat{S} = \hat{Z}^{-1}$. Here $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_N)$. We use \hat{z}_j to denote the j th column of \hat{Z} and \hat{s}_j^* to denote the j th row of \hat{S} . Without loss of generality, we may assume that $\|\hat{z}_j\| = 1$. After step m of QMR applied to the seed system, let $T_{1,m}U_{1,m} = U_{1,m}\Sigma_{1,m}$ be the eigendecomposition of $T_{1,m}$, where $T_{1,m}$ denotes the tridiagonal $m \times m$ leading submatrix of $\bar{T}_{1,m}$. Since QMR is built on top of the unsymmetric Lanczos process, in exact arithmetic if m is large enough, we expect some of the Ritz vectors given by the columns of $V_{1,m}U_{1,m}$ to be good approximations to, say, $n \leq m$ of the right eigenvectors² [1, 6, 7, 2] (assuming these eigenvectors are present in the starting vector for the first seed system). Under these definitions and assumptions, we have the following.

THEOREM 3.2. *Consider two systems $Ax^{(1)} = b^{(1)}$ and $Ax^{(2)} = b^{(2)}$ with A an $N \times N$ matrix. Let $x_0^{2,2}$ be the starting vector for the second system obtained via our projection approach after m steps of QMR have been run using the first system as seed; that is, $x_0^{2,2} = x_m^{1,2}$.*

Define \mathcal{I} as the set of indices of the n right eigenvectors that are well approximated by $n \leq N$ of the m Ritz vectors $V_{1,m}U_{1,m}$. Define $\bar{x}_0^{2,2}$ such that $x^{(2)} - \bar{x}_0^{2,2}$ is the projection of $x^{(2)} - x_0^{2,2}$ on $\text{span}\{\hat{z}_j, j \notin \mathcal{I}\}$. Let $\bar{x}_i^{2,2}$ be the i th iterate of GMRES applied to system 2 with initial guess $\bar{x}_0^{2,2}$. Then for any i

$$\|b^{(2)} - Ax_i^{2,2}\| \leq \kappa_2(V_{2,i+1})(\|b^{(2)} - A\bar{x}_i^{2,2}\| + \delta),$$

where

$$\delta = \sum_{k \in \mathcal{I}} |\lambda_k \tilde{p}(\lambda_k)| \|\hat{s}_j^* P_m e_0^{1,2}\|,$$

\tilde{p} is a particular i -degree polynomial with constant term 1, $e_0^{1,2} \equiv x^{(2)} - x_0^{1,2}$, and $P_m \equiv I - V_{1,m}(\bar{T}_{1,m}^* \bar{T}_{1,m})^{-1} \bar{T}_{1,m} D_{1,m+1}^{-1} W_{1,m+1}^T A$ is a projector.

Proof. Since A is diagonalizable, $e_0^{2,2} \equiv x^{(2)} - x_0^{2,2} = \sum_{k=1}^N \phi_k \hat{z}_k$ for some expansion coefficients ϕ_k . Hence, by definition

$$(3.7) \quad b^{(2)} - Ax_0^{2,2} = \sum_{k=1}^N \phi_k \lambda_k \hat{z}_k,$$

$$(3.8) \quad b^{(2)} - A\bar{x}_0^{2,2} = \sum_{k \notin \mathcal{I}} \phi_k \lambda_k \hat{z}_k.$$

²We caution the reader that our notation is somewhat unconventional, as we use n simply to denote an index $n \leq N$ and N to denote the dimension of the matrix.

Now if $\bar{x}_i^{2,2}$ is the i th GMRES iterate with $\bar{x}_0^{2,2}$ as the initial guess, there exists a polynomial \tilde{p}_i of degree less than or equal to i with $\tilde{p}_i(0) = 1$ such that

$$(3.9) \quad b^{(2)} - A\bar{x}_i^{2,2} = \sum_{k \notin \mathcal{I}} \phi_k \lambda_k \tilde{p}_i(\lambda_k) \hat{z}_k,$$

where \tilde{p}_i satisfies

$$(3.10) \quad \tilde{p}_i = \arg \min_{p \in \bar{\Pi}^i} \|p(A)(b^{(2)} - A\bar{x}_0^{2,2})\|.$$

Here, $\bar{\Pi}^i$ denotes the set of all polynomials with degree less than or equal to i with constant term 1. From Theorem 7.1 in [22], we have a bound on the i th QMR residual in terms of the i th GMRES residual:

$$(3.11) \quad \|b^{(2)} - A\bar{x}_i^{2,2}\| \leq \kappa_2(V_{2,i+1}) \min_{p \in \bar{\Pi}^i} \|p(A)(b^{(2)} - A\bar{x}_0^{2,2})\|.$$

Also,

$$(3.12) \quad \min_{p \in \bar{\Pi}^i} \|p(A)(b^{(2)} - A\bar{x}_0^{2,2})\| \leq \|\tilde{p}_i(A)(b^{(2)} - A\bar{x}_0^{2,2})\| = \left\| \sum_{k=1}^N \phi_k \lambda_k \tilde{p}_i(\lambda_k) \hat{z}_k \right\|.$$

Substituting this into (3.11) and using (3.9) and the triangle inequality gives

$$(3.13) \quad \|b^{(2)} - A\bar{x}_i^{2,2}\| \leq \kappa_2(V_{2,i+1}) \left(\|b^{(2)} - A\bar{x}_i^{2,2}\| + \sum_{k \in \mathcal{I}} |\lambda_k \tilde{p}_i(\lambda_k)| |\phi_k| \right).$$

Using the definition of $\bar{x}_0^{2,2}$ as $x_m^{1,2}$, it is straightforward to show

$$e_0^{2,2} = (I - V_{1,m}(\bar{T}_{1,m}^* \bar{T}_{1,m})^{-1} \bar{T}_{1,m}^* D_{1,m+1}^{-1} W_{1,m+1}^T A) e_0^{1,2} = P_m e_0^{1,2}.$$

It is easy to see that P_m is a projector since $(P_m)^2 = P_m$. By the definition of $e_0^{2,2}$ it follows that $P_m e_0^{1,2} = \sum_{k=1}^N \phi_k \hat{z}_k$. Using $\hat{s}_j^* \hat{z}_k = 1$ if $j = k$ and 0 otherwise leads to

$$(3.14) \quad |\hat{s}_j^* P_m e_0^{1,2}| = |\phi_j| \quad j \in \mathcal{I}.$$

Substituting (3.14) into (3.13), we obtain the desired result. \square

Now let us discuss why we expect δ to be small. First, it is clear that in exact arithmetic the Ritz vectors lie in $\mathcal{N}(P_m)$. For any vector $q \in \mathcal{C}^N$, since Z is full rank we may write $q = \hat{Z}c$ for the vector of expansion coefficients $c = \hat{Z}^{-1}q = \hat{S}q$ with components $c_j = \hat{s}_j^* q$. Now suppose $q \in \mathcal{R}(P_m)$. Since the columns of Z with indices in \mathcal{I} are approximated by n of the m Ritz vectors, by assumption, and since the Ritz vectors are in $\mathcal{N}(P_m)$, this implies $c_j \approx 0, j \in \mathcal{I}$, which by definition means $\hat{s}_j^* q \approx 0, j \in \mathcal{I}$. Therefore, with $q \equiv P_m e_0^{1,2}$, $|\phi_j| \approx 0, j \in \mathcal{I}$, so δ should be small in exact arithmetic. It is clear that the quality of the Ritz vector approximation and loss of biorthogonality (e.g., the actual $\mathcal{N}(P_m)$) will affect the size of δ in practice.

Using the definition of \tilde{p}_i in (3.10), we obtain in analogy with the standard GMRES upper bound for diagonalizable matrices [22] the following corollary.

COROLLARY 3.3. *Let \hat{Z}_n denote the $N \times (N - n)$ matrix with columns \hat{z}_j for $j \notin \mathcal{I}$. Then with δ defined as in Theorem 3.2 and P being the $(N - n) \times N$ matrix whose rows are the transposed unit vectors $e_k^T, k \notin \mathcal{I}$,*

$$\|b^{(2)} - A\bar{x}_i^{2,2}\|_2 \leq \kappa_2(V_{2,i+1}) \left(\min_{p \in \bar{\Pi}^i} \max_{\substack{\lambda_k \\ k \notin \mathcal{I}}} |p(\lambda_k)| \|\hat{Z}_n\| \|P \hat{S} \bar{r}_0^{2,2}\| + \delta \right).$$

Proof. The proof follows from the result of the theorem by first writing (3.9) as $\hat{Z}_n \tilde{p}(\hat{\Lambda}) \sum_{k \notin \mathcal{I}} \phi_k \lambda_k e_k$, where $\hat{\Lambda}$ is $\text{diag}(\lambda_k)_{k \notin \mathcal{I}}$, using the identity $e_k = P \hat{S} \hat{z}_k$, and taking norms. \square

Thus, under the assumptions we stated at the beginning of this section so that n right eigenvectors with indices in \mathcal{I} of A have been captured when the first seed system is solved, the second seed system converges in exact arithmetic as if the corresponding part of the spectrum of A has been cut off. The strength of this statement in practice is based on the size of δ , which is affected in finite precision arithmetic as noted above.

In the next theorem, we bound the residual norms of the nonseed systems. A proof and detailed discussion of the size of the upper bound are given in [13]. In short, when the right-hand sides are close and the quasi-residual of the seed system is being efficiently reduced, so are the residuals of the nonseed system.

THEOREM 3.4. *Let j denote the index of the seed system and l denote the index of a (nonconverged) nonseed system. Then*

$$(3.15) \quad \|r_k^{j,l}\| \leq \sqrt{k+1} \left(|\gamma_1^{j,l}| \left| \prod_{i=0}^{k-1} s_{j,k-i} \right| + \sum_{i=0}^{k-1} |\gamma_{k-i+1}^{j,l}| |c_{j,k-i}| \left| \prod_{m=0}^{i-1} s_{j,k-m} \right| \right) + \sqrt{N-k-1} \|h_k^{j,l}\|,$$

where $h_k^{j,l} = [\gamma_{k+2}^{j,l}, \dots, \gamma_N^{j,l}]^T$ and $s_{j,k}, c_{j,k}$ are as defined in section 3.1.

4. BL-QMR background. The BL-QMR algorithm of Freund and Malhotra attempts to solve (1.1) in the following way. First, given K vectors r_i and p vectors l_i , they define

$$R = [r_1, \dots, r_K], \quad L = [l_1, \dots, l_p].$$

The block Krylov sequences generated by R, A and L, A^T are

$$(4.1) \quad \{R, AR, A^2 R, \dots, A^{j-1} R, \dots\} \quad \text{and} \quad \{L, A^T L, \dots, (A^T)^{j-1} L, \dots\}.$$

However, if $A^{j-1} r_i$ (likewise $(A^T)^{j-1} l_i$) is linearly or nearly linearly dependent on the previous vectors, so are all $A^k r_i$ (likewise $(A^T)^k l_i$) for $k \geq j$. Thus, Freund and Malhotra propose scanning the vectors in the two sequences in (4.1) from left to right and deleting those which are linearly or nearly linearly dependent on previous ones. In the process they obtain deflated Krylov sequences whose vectors are linearly independent. We refer to the n -dimensional subspaces generated by these deflated sequences as $K_n^{\text{dl}}(A, R)$ and $K_n^{\text{dl}}(A^T, L)$. Note that in the presence of no deflation, $K_n^{\text{dl}}(A, R)$ and $K_n^{\text{dl}}(A^T, L)$ are spanned by the first n columns of (4.1) with $n \leq jK$ or $n \leq jp$, respectively.

Within BL-QMR is a Lanczos-type algorithm which incorporates the deflation as mentioned above in order to generate biorthogonal bases for $K_n^{\text{dl}}(A, R)$ and $K_n^{\text{dl}}(A^T, L)$: that is, two sequences of right and left Lanczos vectors

$$v_1, \dots, v_n \quad \text{and} \quad w_1, \dots, w_n, \quad n = 1, 2, \dots,$$

such that

$$(4.2) \quad \text{span}\{v_1, \dots, v_n\} = K_n^{\text{dl}}(A, R), \quad \text{span}\{w_1, \dots, w_n\} = K_n^{\text{dl}}(A^T, L),$$

$$w_j^T v_k = \begin{cases} 0 & \text{if } j \neq k, \\ \delta_j \neq 0 & \text{if } j = k. \end{cases}$$

Defining the $N \times n$ matrices $V_n = [v_1, \dots, v_n]$ and $W_n = [w_1, \dots, w_n]$, it follows that

$$W_n^T V_n = D_n \equiv \text{diag}(\delta_1, \dots, \delta_n), \quad n = 1, 2, \dots$$

Also, the matrix equation relating the v 's is

$$AV_\mu = V_n T_\mu + \hat{V}_\mu^{\text{dl}}, \quad \mu \geq 1,$$

where $\mu = n - m_{\text{cr}}$ and m_{cr} is defined by the fact that $K - m_{\text{cr}}$ is the total number of deflations performed in the v sequence up to iteration n in the Lanczos algorithm. Further, T_μ is $n \times \mu$ with lower bandwidth $K + 1$ and upper bandwidth $p + 1$. Also, $\hat{V}_\mu^{\text{dl}} = V_\mu^{\text{dl}} + E_\mu$, where V_μ^{dl} is $N \times \mu$ but has only $K - m_{\text{cr}}$ nonzero columns corresponding to vectors that are deflated and E_μ has nonzero entries in row i column $p + j$, $j = 1, \dots$, only if a deflation of the i th w occurs for $i > K$. We note that if deftol is the deflation tolerance, then $\|V_\mu^{\text{dl}}\| \leq \text{deftol} \sqrt{K - m_{\text{cr}}}$. For further details, the reader is referred to [8].

Now let us assume $R = [r_0^{(1)}, r_0^{(2)}, \dots, r_0^{(K)}]$; that is, the matrix R contains the initial residuals of each of the K systems we would like to solve. Thus, the v 's correspond to the initial residuals. The way the deflation strategy in [8] works is that if a v is deflated, one linear system is also set aside; then upon convergence of the remaining systems, the solution to the deflated system is updated using the solutions of the other systems. Thus, in what follows we consider only the updates to the nondeflated linear systems, and we denote with a subscript “cr” submatrices of the originals with m_{cr} columns that correspond to these systems.

Recall that when QMR is applied to a single linear system, the μ th iterate is an appropriate linear combination of the Lanczos vectors, plus the initial guess. Similarly, the block QMR iterate is defined as

$$X_{\mu, \text{cr}} = X_{0, \text{cr}} + V_\mu Z, \quad Z \in \mathcal{C}^{\mu \times m_{\text{cr}}}.$$

As with QMR, then, we need to find the matrix Z which determines the appropriate linear combination. Following [8], the residual block $R_{\mu, \text{cr}}$ related to $X_{\mu, \text{cr}}$ satisfies

$$\begin{aligned} R_{\mu, \text{cr}} &= B_{\text{cr}} - AX_{\mu, \text{cr}} \\ &= R_{0, \text{cr}} - AV_\mu Z \\ &= R_{0, \text{cr}} - V_n T_\mu Z - \hat{V}_\mu^{\text{dl}} Z \\ &= V_n \left(\begin{bmatrix} \beta_{\text{cr}} \\ 0 \end{bmatrix} - T_\mu Z \right) - \hat{V}_\mu^{\text{dl}} Z, \end{aligned}$$

where β_{cr} is $m_1 \times m_{\text{cr}}$ defined by taking the appropriate columns of β , with

$$V_{m_1} \beta + V_0^{\text{dl}} = R,$$

and m_1 is the number of columns of R (recall R has K columns) that are not deflated as the first K Lanczos vectors are created ($m_1 \leq K$). Here B contains the $b^{(j)}$'s as its columns, and B_{cr} is the submatrix of B with the appropriate m_{cr} columns.

Because the columns of V_n are not unitary and \hat{V}_μ^{dl} has nonzero columns, one cannot find Z such that $\|R_{\mu, \text{cr}}\|$ is minimal. Rather, we seek $Z = Z_\mu$ such that

$$Z_\mu = \arg \min_{Z \in \mathcal{C}^{\mu \times m_{\text{cr}}}} \left\| \begin{bmatrix} \beta_{\text{cr}} \\ 0 \end{bmatrix} - T_\mu Z \right\|.$$

Since T_μ is banded, the standard approach based on the QR factorization of T_μ is used to implicitly determine Z_μ and ultimately determine short-term recurrences for $X_{\mu,\text{cr}}$. Following [8] we have

$$T_\mu = (Q^{(\mu)})^* \begin{bmatrix} R^{(\mu)} \\ 0 \end{bmatrix}$$

for a unitary $n \times n$ matrix $Q^{(\mu)}$ and a nonsingular, $\mu \times \mu$, upper triangular matrix $R^{(\mu)}$. Thus,

$$Z_{(\mu)} = (R^{(\mu)})^{-1} t_\mu, \quad \text{where} \quad \begin{bmatrix} t_\mu \\ \tau_\mu \end{bmatrix} = Q^{(\mu)} \begin{bmatrix} \beta_{\text{cr}} \\ 0 \end{bmatrix}.$$

Finally,

$$\begin{aligned} X_{\mu,\text{cr}} &= X_{0,\text{cr}} + V_{(\mu)} (R^{(\mu)})^{-1} t_\mu \\ (4.3) \quad &= X_{\mu-1,\text{cr}} + p_\mu y_\mu^T, \end{aligned}$$

where p_μ and y_μ^T are given by (refer to [8, equations (5.10), (5.8)])

$$(4.4) \quad p_\mu = \left(v_\mu - \sum_{i=j^*}^{\mu-1} p_i \theta_i \right) / \theta_\mu, \quad \begin{bmatrix} y_\mu^T \\ \tau_\mu \end{bmatrix} = Q_\mu \begin{bmatrix} \tau_{\mu-1} \\ 0 \end{bmatrix}.$$

The θ_i are scalars corresponding to the last column of $R^{(\mu)}$, Q_μ (not to be confused with $Q^{(\mu)}$) is a particular matrix of Givens rotations described in (5.2) of [8], and j^* is an index described in [8] satisfying $(\mu - j^*) \leq 2m$.

5. The block QMR-projection method. In a manner similar to section 3, we describe a block QMR-projection approach to solving (1.1) that combines the advantageous properties of the block QMR algorithm and our single-seed projection algorithm.

Suppose that we select a subset of size $m < K$ linear systems to serve as “seed” from among the original K . Let \mathcal{I}_{m_1} be the index set i_1, \dots, i_m of the chosen systems. We use $\mathcal{I}_{m_1}^c$ to denote the indices from 1 to K which are not in \mathcal{I}_{m_1} . Let $b^{(j)}$ with $j \in \mathcal{I}_{m_1}$ be the m columns of the matrix $B^{(1)}$ and let the remaining $J = K - m$ right-hand sides (corresponding to nonseed systems indexed by $\mathcal{I}_{m_1}^c$) be the columns of the matrix $B^{(2)}$. We define $X_0^{(1)}$ as the matrix $[x_0^{(i_1)}, \dots, x_0^{(i_m)}]$ of initial guesses for the m seed systems, and $X_0^{(2)}$ as the matrix of initial guesses for the nonseed systems. The corresponding initial block residuals are $R_0^{(1)} = B^{(1)} - AX_0^{(1)}$ and $R_0^{(2)} = B^{(2)} - AX_0^{(2)}$.

The idea is to set R (and L) defined in the previous section to $R_0^{(1)}$ and run BL-QMR to solve the seed systems while using a projection idea to update the nonseed systems. Once BL-QMR converges on the seed system, the process is repeated by choosing a new subset, indexed by $\mathcal{I}_{m_2} \subset \mathcal{I}_{m_1}^c$, of the nonconverged, nonseed systems. The systems indexed by \mathcal{I}_{m_2} now serve as seed, where the columns of $X_0^{(1)}$ are understood to be the estimated solutions, generated in the first round of projected BL-QMR, to the systems with indices in \mathcal{I}_{m_2} . The remaining systems, indexed by $\mathcal{I}_{m_2}^c = \mathcal{I}_{m_1}^c \setminus \mathcal{I}_{m_2}$, are updated by projection. In the following, $X_\mu^{(1)}$ ($R_\mu^{(1)}$) denotes the μ th block iterate (residual) of the current block seed while $X_\mu^{(2)}$ ($R_\mu^{(2)}$) denotes the μ th block iterate (residual) of the current nonseed block. We shall further assume that m

is the number of *current* seed systems and J is the number of *current* nonconverged, nonseed systems. The numbers m and J can change at each round.

At iteration μ , we want our nonseed systems to also lie in the current Krylov subspace. That is, we desire

$$X_\mu^{(2)} \in X_0^{(2)} + K_\mu^{\text{dl}}(A, R_0^{(1)}).$$

Since the columns of V_μ span this subspace, this means

$$X_\mu^{(2)} = X_0^{(2)} + V_\mu Z_\mu^{(2)}$$

for some $\mu \times J$ matrix $Z_\mu^{(2)}$. Now we must decide how to define $Z_\mu^{(2)}$. We observe

$$\begin{aligned} R_\mu^{(2)} &= B^{(2)} - A(X_0^{(2)} + V_\mu Z_\mu^{(2)}) \\ &= R_0^{(2)} - V_n T_\mu Z_\mu^{(2)} - \hat{V}_\mu^{\text{dl}} Z_\mu^{(2)}. \end{aligned}$$

Using biorthogonality

$$D_n^{-1} W_n^T R_\mu^{(2)} = D_n^{-1} W_n^T R_0^{(2)} - T_\mu Z_\mu^{(2)} - D_n^{-1} W_n^T \hat{V}_\mu^{\text{dl}} Z_\mu^{(2)}.$$

Then

$$\|D_n^{-1} W_n^T R_\mu^{(2)}\| \leq \|D_n^{-1} W_n^T R_0^{(2)} - T_\mu Z_\mu^{(2)}\| + \|D_n^{-1} W_n^T \hat{V}_\mu^{\text{dl}} Z_\mu^{(2)}\|.$$

Note that if no deflations have occurred, \hat{V}_μ^{dl} is zero, so we have equality rather than inequality. Therefore, in analogy with the single-seed algorithm of section 3, we define

$$Z_\mu^{(2)} \equiv \arg \min_{Z \in \mathbb{C}^{\mu \times J}} \|D_n^{-1} W_n^T R_0^{(2)} - T_\mu Z\|.$$

Using the QR factorization of T_μ described in the previous section, we obtain

$$Z_\mu^{(2)} = \arg \min_{Z \in \mathbb{C}^{\mu \times J}} \left\| Q^{(\mu)} G_n - \begin{bmatrix} R^{(\mu)} \\ 0 \end{bmatrix} Z \right\|,$$

where G_n is the $n \times J$ matrix $G_n = D_n^{-1} W_n^T R_0^{(2)}$. If

$$(5.1) \quad \begin{bmatrix} t_\mu^{(2)} \\ \tau_\mu^{(2)} \end{bmatrix} = Q^{(\mu)} G_n,$$

we obtain

$$(5.2) \quad Z_\mu^{(2)} = (R^{(\mu)})^{-1} t_\mu^{(2)},$$

so that

$$(5.3) \quad \|D_n^{-1} W_n^T R_0^{(2)} - T_\mu Z_\mu^{(2)}\| = \|\tau_\mu^{(2)}\|.$$

Using $G_n^T = [G_{n-1}^T, g_n]$, together with (5.1) and the definition of $Q^{(\mu)}$ in (5.1) of [8], it is easy to show that

$$(5.4) \quad \begin{bmatrix} t_\mu^{(2)} \\ \tau_\mu^{(2)} \end{bmatrix} = \begin{bmatrix} I_{\mu-1} & 0 \\ 0 & Q_\mu \end{bmatrix} \begin{bmatrix} t_{\mu-1}^{(2)} \\ \tau_{\mu-1}^{(2)} \\ g_n^T \end{bmatrix} = \begin{bmatrix} t_{\mu-1}^{(2)} \\ Q_\mu \begin{bmatrix} \tau_{\mu-1}^{(2)} \\ g_n^T \end{bmatrix} \end{bmatrix}.$$

Thus, $t_\mu^{(2)}$ differs from $t_{\mu-1}^{(2)}$ only in its last row, which we call $(y_\mu^{(2)})^T$:

$$t_\mu^{(2)} = \begin{bmatrix} t_{\mu-1}^{(2)} \\ (y_\mu^{(2)})^T \end{bmatrix}, \text{ where } (y_\mu^{(2)})^T \in \mathcal{C}^{1 \times J}.$$

From the above relation and (5.4) it follows that to obtain $(y_\mu^{(2)})^T$ one need only perform a product with Q_μ :

$$\begin{bmatrix} (y_\mu^{(2)})^T \\ \tau_\mu^{(2)} \end{bmatrix} = Q_\mu \begin{bmatrix} \tau_{\mu-1}^{(2)} \\ g_n^T \end{bmatrix},$$

which, since Q_μ by definition is a product of m_{cr} Givens rotations, is an easy task.

With p_i defined as in (4.4), it is now easy to show that the μ th nonseed block iterate is

$$(5.5) \quad X_\mu^{(2)} = X_{\mu-1}^{(2)} + p_\mu (y_\mu^{(2)})^T.$$

Thus, we may readily show

$$(5.6) \quad R_\mu^{(2)} = R_{\mu-1}^{(2)} - A p_\mu (y_\mu^{(2)})^T.$$

However, using the definition of p_μ , we find an update formula for the block residual which does not actually require any additional matrix-vector products.

LEMMA 5.1. *$R_\mu^{(2)}$ can be updated from $R_{\mu-1}^{(2)}$ in at most $O(N(J+2m))$ additional floating point operations.*

Proof. By substituting (4.4) into (5.6), we obtain a formula for updating $R_\mu^{(2)}$:

$$(5.7) \quad R_\mu^{(2)} = R_{\mu-1}^{(2)} - f_\mu (y_\mu^{(2)})^T \quad \text{with} \quad f_i \equiv A p_i = \frac{1}{\theta_i} \left(A v_i - \sum_{k=j^*}^{i-1} \theta_k f_k \right).$$

Consider forming f_μ . Now the matrix-vector product $A v_\mu$ is computed in the course of the Lanczos process at iteration μ and need not be recomputed. Therefore, it is clear that to compute the length N vector f_μ requires at most $O(2mN)$ flops since $(\mu - j^*) \leq 2m$ by definition (see section 5 of [8]). We note that the computation of the outer product $f_\mu (y_\mu^{(2)})^T$ requires $O(JN)$ operations, and the proof is complete. \square

We note that a similar update is valid for $R_\mu^{(1)}$:

$$(5.8) \quad R_\mu^{(1)} = R_{\mu-1}^{(1)} - f_\mu (y_\mu^{(1)})^T.$$

6. Issues in practical computation for the block algorithm.

6.1. Block-seed selection heuristic. Clearly, the performance of our multiple-seed algorithm in terms of savings of matrix-vector products depends on which, and how many, systems are chosen to be seed. Deflation in BL-QMR solves the problem of removing redundancy if systems with starting residuals which are nearly linearly dependent are chosen as seed. Ideally, however, we would like to choose as seed systems some subset of the nonconverged systems which are in some sense optimally independent in order to increase the chance that the solutions to the nonseed systems will lie nearly in the Krylov subspaces generated by the seed systems, thereby ensuring the effectiveness of the projection process.

In our examples, we used the following heuristics to determine which and how many seed systems to use. First, we let $B = [b^{(1)}, \dots, b^{(K)}]$. Since $K \ll N$ was not too large in these examples, we computed a compact pivoted QR factorization of B ,

$$\tilde{B} \equiv B\Pi = QR, \quad Q \in \mathcal{C}^{N \times K}, \quad R \in \mathcal{C}^{K \times K},$$

to determine which of the remaining were most independent. Here, Π is just a permutation matrix which serves to permute the columns of B such that the first few columns of $B\Pi$ are the most independent. In particular, if ρ denotes the diagonal entries of R and if $|\rho(1)|/|\rho(i)| > \alpha$ for any $1 \leq i \leq K$, then we discard the corresponding column of \tilde{B} . The remaining m columns of \tilde{B} serve as the seed systems. We set the maximum value of α to 10^5 to ensure the columns were not too linearly dependent, but adjusted it lower if necessary so that the size of the seed block was no bigger than about $K/2$. On the next round of projected BL-QMR, however, we simply decided on a new number of seeds to use ($m \leftarrow \lceil m/2 \rceil$) and took those with the largest m relative residuals to serve as seed. More efficient means of selecting m for each round and for determining the m seeds need to be examined in the future.³

6.2. Loss of biorthogonality. One additional problem that we encountered in practice in using either our single-seed or our multiple-seed algorithm was that loss of biorthogonality could affect the accuracy of the $\gamma_n^{jl} = (1/\delta_{j,n})w_{j,n}^T r_0^{jl}$, or $g_n^T = (1/\delta_n)w_n^T R_0^{(2)}$. This loss of accuracy would thereby adversely affect the convergence of the computed solution. To avoid this difficulty for the block projection algorithm, we used the following fact. If no deflations were performed up to the μ th iteration when solving the single-seed system,

$$R_{\mu-1}^{(2)} = R_0^{(2)} - V_{n-1}T_{\mu-1}Z_{\mu-1}^{(2)} \Rightarrow g_n^T = \frac{1}{\delta_n}w_n^T R_{\mu-1}^{(2)} = \frac{1}{\delta_n}w_n^T R_0^{(2)},$$

where it is understood that $R_j^{(2)} = R_0^{(2)}$, $j < 0$. Thus, at the beginning of iteration $\mu \geq 1$, we computed g_n^T based on the current residual estimate, then updated the residual estimate using Lemma 5.1. If deflations do occur, observe

$$g_n^T = \frac{1}{\delta_n}w_n^T R_{\mu-1}^{(2)} - \frac{1}{\delta_n}w_n^T \hat{V}_{\mu-1}^{\text{dl}} Z_{\mu-1}^{(2)}.$$

In our examples, the second term was on the order of the deflation tolerance. This was because $\hat{V}_{\mu}^{\text{dl}} = V_{\mu}^{\text{dl}}$ since no w deflations occurred for indices larger than J . Hence nonzero columns of V_{dl} were nearly linear combinations of the first m_1 v 's for which $\frac{1}{\delta_n}w_n^T v = 0$. In this work we choose to ignore the second term rather than go to the extra expense of computing inner products with the nonzero columns of \hat{V}_{dl} .

Likewise, for the single-seed algorithm we use

$$\gamma_n^{jl} = \frac{1}{\delta_{j,n}}w_{j,n}^T r_0^{jl} = \frac{1}{\delta_{j,n}}w_{j,n}^T r_{n-2}^{jl}, \quad n \geq 2.$$

An investigation into the reason behind the success of these approaches in finite precision arithmetic will be the subject of future work. We note that a similar phenomenon was observed in [20] with respect to practical implementation of GMRES variants, and an explanation for such behavior in finite precision arithmetic was given.

³In the worst case, if the seed block is too small, then it could require many rounds and much computation for all the systems to converge, and performance could be worse than BL-QMR without projection. If the seed block is too large, gains in execution time over BL-QMR would probably also be reduced, and our algorithm's behavior would become more dependent on the deflation tolerance.

6.3. Computational aspects of the block-seed algorithm. It may be relatively expensive in terms of execution time to move data between the smaller, faster cache and the larger, slower main memory. When data is available in cache, it is desirable to use it as much as possible. The level-2 and level-3 BLAS are better for achieving this than level-1 BLAS operations. Thus, one advantage that the block Krylov subspace algorithms enjoy over standard Krylov subspace algorithms (and our single-seed algorithm) is that the former can be implemented to be rich in higher level BLAS operations, whereas the latter class of algorithms requires a large number of level-1 BLAS operations [14, 2].

Further, Krylov subspace algorithms require a large number of vector inner products relative to the remaining number of computations. These inner products, when implemented on a distributed memory parallel machine, correspond to synchronization points (that is, computation cannot proceed until all processors receive the result of the inner product) and require numerous smaller messages among processors [17]. Our single-seed method inherits these problems, although updates to the seed and nonseed systems can be done independently. Block Krylov subspace algorithms, however, can be implemented to provide more computation between communications and larger but fewer messages among processors [14, 17]. Below, we provide one implementation of the block-seed projection algorithm from the proceeding section. We do not claim that this implementation is optimal in terms of cache utilization or parallelism; our goal is to illustrate the potential efficiencies of the block-seed algorithm and show that it retains the same advantages that the block QMR algorithm enjoys.

Suppose that m is the number of right-hand sides in a given seed block and that J is the number of systems in the nonseed block. Let $m_1 \leq m$ be the number of linearly independent right Lanczos vectors that are formed, using deflation, from the initial residuals to the seed block. In the following, $V_{(k)} = [v_{m_1 k+1}, \dots, v_{m_1(k+1)}]$ and $W_{(k)} = [w_{m_1 k+1}, \dots, w_{m_1(k+1)}]$, $0 \leq k$.

ALGORITHM 1. $\mu = 1 = \phi$. Given $X_0^{(1)}, R_0^{(1)} \in C^{N \times m_1}$ and $X_0^{(2)}, R_0^{(2)} \in C^{N \times J}$; Given the m_1 columns of $V_{(1)}$ and $W_{(1)}$ and $D_{(1)} = \text{diag}(\delta_1, \dots, \delta_{m_1})$.

For $k = 2$ until seed block converges do

1. $V_{(k)} = AV_{(k-1)}$; $W_{(k)} = A^T W_{(k-1)}$.
2. If deflations occurred in the W (or V) sequence, update $V_{(k)}$ (or $W_{(k)}$).
3. Biorthogonalize the columns of $V_{(k)}$ against the columns of $V_{(k-2)}, V_{(k-1)}$; biorthogonalize the columns of $W_{(k)}$ against the columns of $W_{(k-2)}, W_{(k-1)}$.
4. Set $i = 0, j = 0, s = 1, \hat{s} = 1$. Set $\mu = \mu + 1$; $\phi = \phi + 1$.
5. For $n = (k-1)m_1 + 1, \dots, km_1$, set $i = i + 1$ and do
 - (a) If $V_{(k)}(:, i)$ does not exist, put $V_{(k)}(:, i) = AV_{(k)}(:, s)$ and biorthogonalize against ϕ_μ previous Lanczos pairs; $s = s + 1$.
 - (b) If $\|V_{(k)}(:, i)\| < \text{deftol}$, then $j = j + 1$ and deflate:
 - i. Compute $(y_\mu^{(1)})^T, (y_\mu^{(2)})^T, \tau_\mu^{(1)}, \tau_\mu^{(1)}$; compute f_μ, p_μ (via gaxpy's).
 - ii. "Delete" i th column of $V_{(k)}$, "shift" remaining columns left 1.
 - iii. Compute which system gets dropped from the seed block (that row of $y_\mu^{(1)}$ will have a zero entry).
 - iv. Let $y_\mu^{(i_v)}, f_\mu, p_\mu$ be the j th columns of $Y^{(i_v)}, i_v = 1, 2; F; P$.
 - v. Update deflation index sets. Set $\mu = \mu + 1$, goto step 5(a).
 - (c) Normalize $V_{(k)}(:, i)$ and set $\mu_n = \mu$; $j = j + 1$.
 - (d) If $W_{(k)}(:, i)$ does not exist, put $W_{(k)}(:, i) = A^T W_{(k)}(:, \hat{s})$ and biorthogonalize against μ_ϕ previous Lanczos pairs; $\hat{s} = \hat{s} + 1$.
 - (e) If $\|W_{(k)}(:, i)\| < \text{deftol}$, then deflate:

- i. “Delete” i th column of $W_{(k)}$, “shift” remaining columns left 1.
- ii. Update deflation index sets. Set $\phi = \phi + 1$, goto step 5(d).
- (f) Normalize $W_{(k)}(:, i)$. Set $\phi_n = \phi$ and $\delta_n = W_{(k)}(:, i)^T V_{(k)}(:, i)$.
- (g) Continue the MGS⁴ process on columns $\geq i$ of $V_{(k)}, W_{(k)}$.
- (h) Set $g_n^T = (1/\delta_n)W_{(k)}(:, i)^T R_{\mu-j}^{(2)}$.
- (i) Compute $(y_\mu^{(1)})^T, (y_\mu^{(2)})^T, \tau_\mu^{(1)}, \tau_\mu^{(2)}$; compute f_μ, p_μ (via gaxpy’s).
- (j) Let $y_\mu^{(i_v)}, f_\mu p_\mu$ be the j th columns of $Y^{(i_v)}, i_v = 1, 2; F; P$.
- 6. $X_\mu^{(1)} = X_{\mu-j}^{(1)} + P(Y^{(1)})^T$; $R_\mu^{(1)} = R_{\mu-j}^{(1)} - F(Y^{(1)})^T$.
- 7. $X_\mu^{(2)} = X_{\mu-j}^{(2)} + P(Y^{(2)})^T$; $R_\mu^{(2)} = R_{\mu-j}^{(2)} - F(Y^{(2)})^T$.
- 8. “Remove” deflated systems from $X_\mu^{(1)}$.

One benefit of this implementation is that A, A^T are accessed only once each block iteration, if no deflation occurs, and computing products of A and A^T with dense, rectangular matrices of Lanczos vectors makes better use of cache than products of A with a single vector. In step 2 (also 5(a), 5(d)) some columns of either or both of the current blocks may have to be biorthogonalized against some previous Lanczos vectors if certain previous deflations occurred in the V and/or W sequence. In step 3, the current blocks of Lanczos vectors are biorthogonalized against the appropriate columns⁵ of the previous two blocks. Considering the matrix $V_{(k)}$ (or $W_{(k)}$) rather than its columns separately, we can do this using level-2 BLAS with a two-sided modified Gram–Schmidt approach or, at the expense of some stability, we could accomplish this with level-3 BLAS via a block modified Gram–Schmidt approach [14]. For each deflation step, however, we incur the price of one matrix-vector product and several vector-wise inner products. It is possible to reorganize the algorithm so that a Lanczos block effectively decreases in size after deflation (possibly leaving left and right blocks of different sizes) and thereby put off this extra work until it can be done with higher-level BLAS, but as the notation is more tedious, we use the current implementation to illustrate our points.

Notice we are using modified Gram–Schmidt to biorthogonalize within the current block, but that computation toward updating the solution and residual blocks is done between each step of the process. Notice also that the block iterates and residuals are only updated after a new block of Lanczos vectors has been generated; this was done in order to minimize the number of accesses to the block iterates and residuals and to incorporate level-3 BLAS operations. The updating could be done (via level-2 BLAS operations) inside the innermost loop according to (4.3), (5.5), (5.7), (5.8), or one might opt to track the size of $\tau_\mu^{(1)}$ and update only when necessary.

One way to implement the algorithm on a distributed memory parallel machine is to row partition [17, 14] the matrices $F, P, V_{(k)}, W_{(k)}, X_\mu^{(i_v)}, R_\mu^{(i_v)}, i_v = 1, 2$. Thus, the matrix-multiplications with A, A^T , the biorthogonalization steps, and steps 5(b), (c), (e), (f), (h) require communication among processors; most of the other steps require only local updates of portions of the rectangular matrices. As in [17, section 3.1], it may be possible in a parallel implementation to exploit any computations that are mostly decoupled: for example, the updates to solution and residual blocks are somewhat independent of the generation of the Lanczos vectors and of each other.

⁴Modified Gram–Schmidt.

⁵If deflations have occurred in the W sequence, then one need only biorthogonalize $V_{(k)}$ against some of the columns of $W_{(k-2)}$ (or $W_{(k-1)}$), rather than against the whole block, and similarly for computing $W_{(k)}$ if deflations occurred in the V sequence.

Techniques for performing matrix-vector products with A, A^T in parallel should also be employed.

Before executing Algorithm 1, using our heuristic in section 6.1, we do a compact pivoted QR factorization of B to determine the seed block and therefore should not incur much overhead beyond what the BL-QMR algorithm in [8] would need to generate its initial block using deflation. Every other time that a seed must be chosen, we select those $\lceil m/2 \rceil$ systems with largest residual norm, so a small amount of additional computations/communication are needed at the seed selection steps.

Clearly, if the first time Algorithm 1 is called $J = 0$, it is just the block QMR algorithm with deflation. If $J \neq 0$, then the first time Algorithm 1 is executed, for a given k , the same number of solution vectors and residual vectors must be updated (at most) as if J had been 0: the difference is that updates are separated into updates on two different solution and residual blocks, and these updates are independent of one another. Thus, if Algorithm 1 is implemented in parallel, the independent updates may help compensate for the execution time that is due to processor communication. The computation of g_n^T and $(y_\mu^{(2)})^T$ are the most notable differences between the unprojected and projected algorithms. Overall, the block-seed projection approach may yield the following advantages over block QMR:

- fewer accesses to A and less communication among processors;
- smaller seed block sizes with the block-projection approach mean fewer flops are needed to compute products with A, A^T and fewer flops are needed to construct Lanczos pairs and to factor T_μ ;
- less storage per processor during a given run of Algorithm 1 (as fewer vectors are needed in the recurrences for p_μ, f_μ and the number of columns of $V_{(k)}, W_{(k)}$, etc., are reduced);
- updating the seed and nonseed blocks can be done independently.

7. Numerical results. In this section we give numerical results which indicate the potential effectiveness of our approach on electromagnetic scattering problems. All experiments were conducted in Matlab using IEEE double precision floating point arithmetic on a 600 MHz Pentium II processor. We compare our results with results from the Matlab implementation of block QMR with deflation, algorithm BL-QMR in [8]. For comparison purposes, the implementation of our block-seed algorithm mirrors the implementation of BL-QMR in [8] with modifications where necessary, rather than the one in the preceding section.

Mathematically, we would like to solve a two-dimensional Helmholtz-type equation for the scattered electric field $E(x, y)$:

$$(7.1) \quad (\Delta + k^2(x, y))E(x, y) = \chi_m(x, y)E_0(x, y) \quad \text{in } \Omega$$

with perfectly matched layer (PML) boundary conditions [3, 18]: the specific mathematical formulation we use is described in [12]. Here $k^2(x, y) = \omega^2 \mu_0 \epsilon(x, y)$ is the square of the wave number, with ω representing angular frequency and μ_0 a constant denoting the magnetic permeability. The function $\epsilon(x, y)$, called the electrical permittivity, is defined as $\epsilon = \epsilon_0 \epsilon_{rel} + i \frac{\sigma}{\omega}$ for some real $\sigma \geq 0$, $\epsilon_{rel} \geq 1$ with $i = \sqrt{-1}$ and ϵ_0 a constant (the permittivity of free-space). The value σ is the conductivity of the material. The function χ_m describes the properties of the buried object and has support only over the object location. $E_0(x, y)$ is the known incident electric field.

We discretize using finite differences, which leads to a matrix equation involving the matrix A which is $N \times N$, sparse, complex, and structured but neither symmetric nor Hermitian due to the boundary conditions. Because the matrix is highly indefinite,

FIG. 7.1. Physical configurations for Example 1 (left) and Example 2 (right).

we need to use a preconditioner to speed convergence. The preconditioner we use is the one described in [12], and we perform all preconditioning from the right.

For all algorithms, we take the initial starting guesses $x_0^{(j)}$ to be zero. We stop running our algorithms when the relative residual norms of all of the systems are less than $tol = 10^{-7}$. For the two block-based algorithms, ours and BL-QMR, we update (seed) block residuals via (5.8) ((5.7) is used for the nonseed block⁶). We monitor convergence of the current seed block by checking norms of the columns of $R_\mu^{(1)}$. However, the true norms of the residuals in the seed block were computed and checked to satisfy the convergence tolerance before the block was deemed to have converged. Since for these examples the major computational expense per iteration is the two matrix-vector products with applications of the preconditioner, we consider the total number of matrix-vector products required for all the systems to converge as our primary measure of success and discuss some timing results.

7.1. Example 1. In this experiment we would like to find the scattered electric fields caused when plane waves at various angles impinge on a horizontal air-soil interface and scatter from a $7\text{cm} \times 6\text{cm}$ object buried 5cm below the surface. Each angle corresponds to a different E_0 in (7.1), which in turn corresponds to a different right-hand side $b^{(j)}$ in (1.1). Figure 7.1 gives a physical illustration of the problem.

In this example, we use a soil type (referred to as “Seabee” in the literature [19]) and conduct experiments at two different frequencies, $\omega/(2\pi) = 45\text{ MHz}$ and 475 MHz . At 45 MHz , Seabee has $\epsilon_{rel} = 35.65$ and $\sigma = .13$, while at 475 MHz $\epsilon_{rel} = 21.31$ and $\sigma = .23$. We assumed that the buried object has $\epsilon_{rel} = 2.9$ and $\sigma = .001$ at both frequencies. For air, $\epsilon_{rel} = 1$, $\sigma = 0$. We have discretized at a rate of 50 points per wavelength of soil at 45 MHz and 20 points per wavelength at 475 MHz . In both cases, the total number of unknowns (N) is $(2^7 + 15)^2$.

We centered the buried object (refer to Figure 7.1) and considered the scattered field due to plane waves impinging on the surface at evenly spaced angles from -60 to 60 degrees from the normal. The second columns in Tables 7.1 and 7.2 give the total number of matrix-vector products needed if preconditioned QMR is applied to each system separately.⁷ The third column gives the total number of matrix-vector products needed if our preconditioned QMR with projection algorithm is used. The next several columns give the total number of matrix-vector products computed when solving the problem using BL-QMR with various deflation tolerances. The final

⁶Note that the latter needs to be computed each iteration to determine the update for the nonseed block, whereas one could use the bound in [8] to monitor convergence of the seed block at the possible expense of computing many extra matrix-vector products.

⁷Note that we define the matrix-vector product count as the number of multiplies by AM^{-1} or its transpose where M is the preconditioner.

TABLE 7.1

Example 1. 45 MHz: Number of matrix-vector products required for convergence by each of the methods (each system independently, single-seed QMR-projection, BL-QMR with deflation tolerances 10^{-8} , 10^{-9} , and 10^{-10} , and block QMR with projection) for experiments involving different numbers of right-hand sides (RHS). Dashes indicate no convergence of the method in under 300 iterations.

column shows results when our block-seed approach is used ($deftol = 10^{-9}$), where the seed blocks are chosen using the heuristic outlined in section 6.1 with $\alpha = 10^5$. Dashes indicate that the convergence tolerance was not met within $maxit = 300$ iterations.

As Table 7.1 shows, for the 45 MHz case, BL-QMR failed to converge after 300 iterations in all cases when the deflation tolerance was set to 10^{-8} , but it outperformed our single-seed projection method if the deflation tolerance was small enough. Our block-seed projection approach performs better than all the other methods in terms of the number of matrix-vector products; however, we note that for these nonoptimized implementations, the execution times for the best BL-QMR runs and our block algorithm are about the same. Solving sequentially took 4.5 times longer than our single-seed method and over 6 times longer than block-based algorithms.

At 475 MHz, we expected our $x^{(j)}$'s not to be as close as in the previous case due to the underlying physics of the problem, and therefore we did not expect as much savings with our single-seed projection approach. Indeed, Table 7.2 shows that the difference between the second and third columns is not as dramatic as in Table 7.1. Table 7.2 also shows that BL-QMR, with the deflation tolerance set at either 10^{-8} or 10^{-9} , outperforms our single-seed projection approach. However, comparing the last column with the others, we find that our block-seed projection approach can provide substantial savings over the other methods. There is also a difference in execution times: for example, for 25 systems our block-seed projection method takes about 6.2 minutes while BL-QMR with deflation tolerance of 10^{-9} takes about 7.1 minutes.

7.2. Example 2. For our second example, each of our K systems corresponds to solving for the scattered electric field from a buried object when the source of the incident field is a point source, located at position x_i, y_i above the earth (see Figure 7.1). We consider the case when the frequency is 480 MHz, and the soil has $\epsilon_{rel} = 6.5$ and $\sigma = .019$. As before, the buried object has $\epsilon_{rel} = 2.9$ and $\sigma = .001$. The buried object is $7\text{cm} \times 4\text{cm}$ buried 5cm deep and centered left to right. The width of each cell in the discrete grid is 1cm, and the total number of unknowns (N) is $(2^6 + 15)^2$. Our point sources are each located 3cm above the earth and either

vary in the horizontal direction, with 0 being in the middle, from -12cm to 12cm in 1cm increments or -17cm to 17cm in 1cm increments. The numbers of matrix-vector products required by each of the different methods to solve these systems are given in Table 7.3. However, as illustrated by the timing results in Table 7.4, both the single- and block-seed projection give dramatic improvements over BL-QMR without projection.⁸

8. Conclusions and future work. We have introduced two new projection approaches, based on QMR and block QMR, respectively, for solving multiple linear systems with the same coefficient matrix but different right-hand sides. Compared to solving each system separately by QMR, both approaches can significantly reduce the work and execution time needed to solve all the systems to within a specified tolerance provided there is sufficient shared information among the right-hand sides; the block-seed algorithm requires less shared information to perform well. We provided theory for the single-seed approach which suggests that under certain conditions in exact arithmetic, QMR on subsequent seed systems converges as if part of the spectrum has been cut off; we also gave an upper bound for the rate of convergence of the nonseed systems. More work needs to be done to determine convergence behavior of the block-seed algorithm in both exact and finite precision arithmetic.

As our numerical results showed, with appropriate deflation tolerance, the BL-QMR algorithm [8] could outperform our single-seed QMR-projection method in terms of matrix-vector product savings (although not always reflected in the execution times) particularly when the right-hand sides are not as close; however, our block-seed projection method consistently exhibited the greatest savings in such cases. The performance of our block-seed approach depends on our choices of successive seed blocks, and overall execution time depends on the actual implementation. We gave one block-seed selection heuristic and discussed possible efficiencies of block-seed algorithm. Determining good seed selection strategies, efficient serial and parallel implementations, and formal time comparisons with other methods remain subjects for future research.

⁸Part of the improvement can be attributed to the difference in size of the BL-QMR block iterate with the size of the seed for our methods.

ITERATIVE REGULARIZATION AND MINRES*

MISHA KILMER[†] AND G. W. STEWART[‡]

Abstract. In this paper we present three theorems which give insight into the regularizing properties of MINRES. While our theory does not completely characterize the regularizing behavior of the algorithm, it provides a partial explanation of the observed behavior of the method. Unlike traditional attempts to explain the regularizing properties of Krylov subspace methods, our approach focuses on convergence properties of the residual rather than on convergence analysis of the harmonic Ritz values. The import of our analysis is illustrated by two examples. In particular, our theoretical and numerical results support the following important observation: in some circumstances the dimension of the optimal Krylov subspace can be much smaller than the number of the components of the truncated spectral solution that must be computed to attain comparable accuracy.

Key words. regularization, ill-posed problem, MINRES, iterative regularization

AMS subject classification. 65F10

PII. S0895479898348623

1. Introduction. The discretization of a compact self-adjoint operator equation with errors in the right-hand side results in a linear system whose exact solution bears no relation to the solution of the original error-free system. Specifically, in the spectral domain—that is, in the coordinate system of the eigenvectors of the matrix—the exact linear system can be written in the form

$$\Lambda x = b,$$

where

$$\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n), \quad 1 = \lambda_1 > \dots > \lambda_n > 0.$$

Note that we assume that the system is positive definite and has been scaled so that $\lambda_1 = 1$. To the extent that the quantities in this equation track the corresponding quantities in the original operator, they have the following properties:

- (1) If the operator is smooth, the eigenvalues λ_i of the discrete operator will eventually decay rapidly to zero.
- (2) If the solution of the original problem is square integrable, then the components ξ_i of x decay to zero.
- (3) Since the components β_i of the right-hand side satisfy $\beta_i = \xi_i \lambda_i$, they decay faster than either the components of the solution or the eigenvalues of the operator.

The system with error is

$$\Lambda \tilde{x} = b + e \equiv \tilde{b}.$$

If we model the error as white noise, then we can append the following condition to the above list.

- (4) The components ϵ_i of e are random variables with mean zero and standard deviation ϵ .

The components of the solution for the perturbed right-hand side are

$$(1.1) \quad \tilde{\xi}_i = \frac{\beta_i + \epsilon_i}{\lambda_i}.$$

Since the β_i decay rapidly, they soon fall below the error level. The subsequent components of the solution are effectively random variables with standard deviation ϵ/λ_i . The division by λ_i magnifies the originally small error so that it dominates the solution.

As long as the β_i are larger than the errors ϵ_i , the $\tilde{\xi}_i$ contain useful information. The process of extracting this information is called *regularization*. There are many regularization schemes. A natural one is to stop computing components of x when the β_i get near the error level. We will call this procedure *truncated spectral regularization*.¹

In this paper we will be concerned with regularization based on the iterative method MINRES [9]. The method can be described briefly as follows. Let

$$K_k = (\tilde{b} \ \Lambda \tilde{b} \ \cdots \ \Lambda^{k-1} \tilde{b})$$

be the k th *Krylov matrix*. Then we seek an approximation to x in the form

$$x_k = K_k a_k,$$

where a_k is determined so that

$$\rho_k^2 \equiv \|\tilde{b} - \Lambda x_k\|^2 = \min.$$

Here $\|\cdot\|$ denotes the usual Euclidean norm.

The residual $r_k = \tilde{b} - \Lambda x_k$ has an alternate expression that is used in the analysis of the algorithm. Given a vector $a_k = (\alpha_1, \dots, \alpha_k)^T$, let a polynomial p be defined by

$$p(t) = 1 - \alpha_1 t - \alpha_2 t^2 - \cdots - \alpha_k t^k.$$

Then the residual $r_k = \tilde{b} - \Lambda K_k a_k$ can be written in the form $r_k = p_k(\Lambda) \tilde{b}$, where p_k is the polynomial associated with a_k . Since MINRES minimizes $\|r_k\|$, we have

$$(1.2) \quad \rho_k \equiv \|r_k\| = \min_{\substack{\deg(p_k)=k \\ p_k(0)=1}} \|p(\Lambda) \tilde{b}\|.$$

Because the i th component of the residual is the value of a polynomial at λ_i , we will often call it the value of the residual at λ_i .

It has been widely observed that up to a certain index k_0 the MINRES solutions x_k are increasingly accurate approximates to the exact solution x , after which their accuracy rapidly deteriorates. Thus if we can determine k_0 (a difficult problem), MINRES can be used as a regularization method. What seems less well known is that

¹In the nonsymmetric case this process is also known as truncated SVD regularization (see [7] and the references therein).

in some circumstances the critical index k_0 can be quite small — much smaller than the number of components of the truncated spectral solution that must be computed to attain the same accuracy.²

In this paper we give three theorems that help explain the regularizing properties of MINRES. The phrase “help explain” is a deliberate warning to the reader not to expect a complete analysis. The theorems do not say that MINRES has to behave in a particular way. Nonetheless, they give considerable insight into the method.

There is a vast body of literature on regularization, much of which is devoted to determining the asymptotic behavior of the error in the optimally regularized solution as the error in the right-hand side approaches zero. (This literature has been admirably surveyed by Engl, Hanke, and Neubauer [4].) There is also a body of literature for well-posed problems in which the asymptotic convergence of Krylov methods like MINRES are analyzed (see, for example, the recent book by Greenbaum [5]). Our approach, which consists of leaving the error in b fixed and determining how the solution behaves as the regularization parameter varies, is essentially nonasymptotic and fits in neither of these categories. On the other hand, our work is closely related to analyses that attempt to find the optimal value of the regularization parameter. (For a survey of this literature see Hansen [8].)

In the next section we give a toy example that will be used to illustrate the subsequent results. We will also describe in a general way what is happening. The next three sections are devoted to establishing our three results. In section 6 we apply our results to another example. The paper concludes with a discussion of the results and suggestions for future work.

A little informal terminology will help in our discussions. We will call the part of the spectrum for which the β_i are little affected by the error the *initial part* of the spectrum. We will call the part where they are fully contaminated the *terminal part* of the spectrum. The part of the spectrum lying between will be called the *intermediate part* or the *transitional part*.

2. An example. In this section we will introduce a simple-minded example from image processing. Let $\underline{x}(t)$ represent an “image” on $[0, 1]$, and consider the Gaussian blurring operator

$$\underline{b}(t) = \int_0^1 \underline{x}(s) e^{-\left(\frac{s-t}{\sigma}\right)^2} ds.$$

We will discretize this operator by choosing an integer n and setting

$$t_i = \frac{i-1}{n}, \quad i = 1, \dots, n+1,$$

and generating a matrix K whose elements are

$$\kappa_{ij} = e^{-\left(\frac{t_j - t_i}{\sigma}\right)^2}.$$

The resulting matrix is then scaled so that its dominant eigenvalue is one. Although this problem is highly simplified, its regularization properties are typical of more realistic problems.

In the following experiments, we took $n = 40$ and $\epsilon = 0.1$. Our function was $\underline{x}(t) = 1 + t + t^2$, and it was discretized by evaluating it at the points t_i to give the components x_i of x . The vector b was generated in the form Ax . Figure 2.1 is a plot

²Martin Hanke has also observed this phenomenon [6].

FIG. 2.1. $x(t)$ (solid) and $b(t)$ (dashed).FIG. 2.2. ξ_i (solid), λ_i (dotted), and $\beta_i, \tilde{\beta}_i$ (dashed).

of $\underline{x}(t)$ and $\underline{b}(t)$. The divergence at the ends of the intervals is due to the fact that at those points the part of the blurring distribution that lies outside $[0, 1]$ becomes significant.

Figure 2.2 shows the vectors b , \tilde{b} , and x after they have been transformed to the spectral coordinates. Note that for $i > 15$ values $\tilde{\beta}_i$ are significantly contaminated with error. The plot also shows the eigenvalues of A , which decrease slowly at first and then rapidly plunge to about 10^{-15} . This rapid decrease is typical of smooth operators.

Truncated spectral regularization and MINRES regularization behave quite differently for this problem. Figure 2.3 plots the norms of the errors at the k th step of each method. The error for truncated spectral regularization decreases slowly until $k = 15$, after which it increases rapidly. The error in the MINRES iterates decreases rapidly until $k = 5$ and then rises. Truncated spectral regularization produces a bet-

FIG. 2.3. Errors from spectral regularization (dashed) and MINRES regularization (solid).

FIG. 2.4. First five MINRES residuals and \tilde{b} (dashed line).

ter solution with about half the error but arrives at it more slowly.³ In fact, not until $k = 11$ does it produce a solution as accurate as the MINRES solution for $k = 5$.

It is informative to examine the behavior of the MINRES residuals. Figure 2.4 displays the magnitudes of the residuals at the eigenvalues λ_i as a function of i for the first five MINRES approximations along with the magnitudes of the components of \tilde{b} . It is seen that they decrease in the initial part of the spectrum. At other points in the spectrum, they change very little. The plot in Figure 2.5 shows the same thing in terms of the residual polynomials that satisfy (1.2).⁴ The polynomials are small in

³The relative quality of the solutions depends on the throw of the dice in constructing the random vector e . For ten other simulations the ratio of the minimum error for truncated spectral regularization to that for MINRES was the following: 0.80, 0.57, 0.76, 0.41, 1.14, 0.65, 0.67, 0.67, 0.82, 0.68. These numbers show the solutions to be usually comparable, with the MINRES solution actually better in a single case.

⁴The plots are not strictly the polynomials. The values between i and $i + 1$ were obtained by evaluating the polynomial at ten equally spaced points between λ_i and λ_{i+1} .

FIG. 2.5. *First five MINRES residual polynomials.*

the initial part of the spectrum and then rise swiftly to a value of one.

Stepping back from this example, we see that three factors are operating to give the fast regularization.

- (1) From (1.1) it follows that the residual cannot be reduced indefinitely without harming the solution.
- (2) The plot in Figure 2.4 shows that the residual decreases rapidly to a point where further reduction is harmful.
- (3) Notice in Figure 2.4 that the values of the first five residuals corresponding to terminal eigenvalues λ_i coincide with $\tilde{\beta}_i$. Equation (1.1) implies that if we reduce the residual at λ_i from $\tilde{\beta}_i$ to $\tilde{\beta}_i(1 - \alpha)$, where $0 < \alpha < 1$, then the corresponding component of the approximate solution is $\alpha\tilde{\beta}_i/\lambda_i$. Now in the terminal part of the spectrum $\tilde{\beta}_i \cong \epsilon_i$, and hence the component of the approximate solution is essentially $\alpha\epsilon_i/\lambda_i$. Because the terminal eigenvalues are extremely small compared to the error, even a very small reduction of the residual at a terminal eigenvalue must result in a large component in the approximate solution. Thus if MINRES is to produce an acceptably regularized solution, it must not reduce the residuals at the terminal part of the spectrum while it is still reducing the residuals at the initial part. As it turns out (see Figure 2.5), the first 5 residual polynomials for our running example are very near one on the terminal spectrum, so there is virtually no reduction of the residual there.

In the next three sections we will establish results that give quantitative substance to these observations.

3. The residual and the error. The first of our results concerns the relation between the size of the error in a purported solution and the size of the corresponding residual. We have already noted that if the residual is required to be too small, the error must be large. However, we can be more precise.

Specifically, let y be a purported solution with residual norm δ . There are many such solutions, and among them one must give minimum error; i.e., there must be a

vector y that solves the following problem. Given $\delta > 0$,

$$(3.1) \quad \begin{aligned} & \text{minimize } \|x - y\|^2 \\ & \text{subject to } \|\tilde{\beta} - \Lambda y\|^2 = \delta^2. \end{aligned}$$

The following theorem shows when the solution to this problem has a large error. Below we have assumed $\lambda_1 = 1$.

THEOREM 3.1. *If $\tau > -1$ is the solution of the equation*

$$(3.2) \quad \sum_i \frac{\epsilon_i^2}{(1 + \tau \lambda_i^2)^2} = \delta^2,$$

then

$$(3.3) \quad \eta_i = \xi_i + \frac{\tau \lambda_i \epsilon_i}{1 + \tau \lambda_i^2}$$

is a solution of (3.1). In this case

$$(3.4) \quad \|x - y\|^2 = \sum_i \left(\frac{\tau \lambda_i}{1 + \tau \lambda_i^2} \right)^2 \epsilon_i^2.$$

Proof. Consider the Lagrangian

$$\sum_i (\xi_i - \eta_i)^2 + \tau \left[\sum_i (\tilde{\beta}_i - \lambda_i \eta_i)^2 - \delta^2 \right],$$

where τ is the Lagrange multiplier. Differentiating with respect to η_i and setting the results to zero, we get

$$\xi_i - \eta_i + \tau \lambda_i (\tilde{\beta}_i - \lambda_i \eta_i) = 0.$$

Equation (3.3) follows on solving this equation for η_i and using the fact that $\tilde{\beta}_i = \lambda_i \xi_i + \epsilon_i$. Equation (3.2) defines the value of τ for which the solution satisfies the constraint. Finally, (3.4) follows by direct computation. \square

The best way to understand this theorem is to consider the solution y_τ generated as τ varies from -1 to ∞ . From (3.2) we see that the residual norm δ decreases monotonically from ∞ to 0. The error norm $\|x - y_\tau\|$ decreases from ∞ to 0 at $\tau = 0$, where $\delta = \|e\|$. Thereafter, small reductions in the residual cause large increases in the error. To see this, consider the term

$$\frac{\epsilon_i^2}{(1 + \tau \lambda_i^2)^2}$$

in (3.2). For this term to be reduced by a factor of four from its value ϵ_i^2 at $\tau = 0$, a very modest reduction in the total, we must have $\tau \lambda_i^2 = 1$. The corresponding term in the square of the error norm (3.4) is

$$\left(\frac{\tau \lambda_i \epsilon_i}{1 + \tau \lambda_i^2} \right)^2 = \frac{\epsilon_i^2}{4 \lambda_i^2},$$

which for small λ_i is large. It is worth noting that these observations depend only on Λ and e and not on x or b .

The above comments suggest that an attempt to reduce the residual norm below $\|e\|$ will increase the error in the solution. This is certainly true of our example, for which $\|e\| = 0.033$. The error turns around at $k = 5$. The residual norms are $\rho_4 = 0.055$, $\rho_5 = 0.039$, and $\rho_6 = 0.031$. Thereafter the error increases sharply, as it must (see Figure 2.3).

It is worth noting that Theorem 3.1 supports the discrepancy principle of Morozov, which says that a regularization parameter should be chosen to make the norm of the residual approximately the size of the norm of the error (see [4, section 4.3]). However, the rapid increase of the error when the residual becomes too small suggests that methods based on the discrepancy principle will be extremely sensitive to variations in the estimate of the error norm (see the experiments in section 7.7.1 of [8]).

4. Reduction of the residual. We now turn to the reduction of the residual. The usual analysis of MINRES is based on (1.2). Specifically, given any polynomial p_k of degree k satisfying $p_k(0) = 1$, we have

$$(4.1) \quad \|r_k\|^2 \leq \sum_{i=1}^n p_k(\lambda_i)^2 \tilde{\beta}_i^2.$$

One convergence result amounts to choosing a sequence of polynomials p_k such that

$$\lambda \in [\lambda_n, \lambda_1] \implies p_k(\lambda) \rightarrow 0.$$

The rate at which the p_k approach zero on $[\lambda_n, \lambda_1]$ is an upper bound on the convergence rate of MINRES.

The key to analyzing the regularizing properties of MINRES is to note that we are not interested in the convergence of the method on the terminal part of the spectrum. In fact (1.1) shows that MINRES *must not* converge there until after a reasonable regularized solution has been formed. We can therefore restrict our attention to an interval, say, $[\lambda_m, \lambda_1]$ in which the $\tilde{\beta}_i$ are relatively error free. Since the interval is farther removed from the origin, the convergence will be faster.⁵

The polynomial $p_{k,m}$ for this analysis is constructed in the usual way from the Chebychev polynomials $c_k(\tau)$. Specifically, let

$$(4.2) \quad s_m(t) = -\frac{2t - \lambda_1 - \lambda_m}{\lambda_1 - \lambda_m}$$

and set

$$(4.3) \quad p_{k,m}(t) = \frac{c_k[s_m(t)]}{c_k[s_m(0)]}.$$

By bounding the values of these polynomials we obtain the following theorem.

THEOREM 4.1. *Let $m > 1$ and set*

$$\kappa = \frac{\lambda_1}{\lambda_m}$$

⁵For the standard analysis see [5, Chapter 3]. In fact, one reviewer has pointed out that Björck and Eldén [2] used polynomials of this kind to construct regularizing iterative methods. Here, on the other hand, we use them to analyze the regularizing properties of a particular iterative method.

and

$$\tilde{b}_m = (\tilde{\beta}_1, \dots, \tilde{\beta}_m)^T.$$

Then

$$(4.4) \quad \begin{aligned} \|r_k\|^2 &\leq \|p_{k,m}(\Lambda)\tilde{b}\|^2 \\ &\leq 4 \left(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1} \right)^{2k} \|\tilde{b}_m\|^2 \\ &\quad + \sum_{i=m+1}^n \left(1 - 2 \frac{\lambda_i}{(\sqrt{\lambda_1} + \sqrt{\lambda_i})^2} \right)^{2k} \tilde{\beta}_i^2. \end{aligned}$$

The proof of this theorem is highly technical and will be found in the appendix. The first term in (4.4) is of the same form as the bound from the usual analysis of MINRES mentioned above. However, for that bound κ is λ_1/λ_n , which is larger than λ_1/λ_m and implies slower convergence. The first factor in the remaining terms is essentially one for small eigenvalues. However, for eigenvalues near λ_m it has a reducing effect on the corresponding part of the residual.

The bound is too crude to use in applications, but it provides insight into the way MINRES converges. In our running example, when m is small, κ is near one, and the polynomials $p_{k,m}$ rapidly reduce the residual on $\lambda_1, \dots, \lambda_m$. But this is precisely the place where there is a large residual to reduce. Since the reduction by $p_{k,m}$ bounds the MINRES reduction, we conclude that initially MINRES will rapidly reduce the residual.

But the bound implies more. As k increases, for fixed m , $p_{k,m}$ will reach a point of diminishing returns when there is not enough residual to reduce. This can be seen by looking at the upper bound in (4.4). Consider m fixed at 4. Since κ is effectively 1, the first term becomes insignificant for $k \geq 2$, and we have a tight bound on the residual for $k = 2$. Yet as k increases and the residual continues to be reduced, the bound stagnates because the second term decreases slowly. However, if we increase m a little, the first term remains small while the second term becomes smaller (since there are fewer indices over which to sum). Thus with increasing k one should increase m to get the smallest possible upper bound. The following table shows that this is precisely what happens in our example.

k	1	2	3	4	5
m	2	4	5	6	7
$\ p_{k,m}(\Lambda)\tilde{b}\ $	8.8e-01	2.8e-01	1.3e-01	7.1e-02	4.7e-02
$\max_{[\lambda_m, \lambda_1]} p_{k,m}$	8.0e-02	2.9e-02	1.0e-02	6.1e-03	5.2e-03
ρ_k	8.7e-01	2.5e-01	1.0e-01	5.5e-02	3.9e-02

For each value of k , the value of m for which $p_{k,m}$ minimizes the residual $\|p_{k,m}(\Lambda)\tilde{b}\|$ was determined. As the table shows, the value of m increases with k . This increase is accompanied by a modest decrease in the size of $p_{k,m}$ on $[\lambda_m, \lambda_1]$. Note that by holding m fixed one can obtain a dramatic decrease in the size of $p_{k,m}$ over $[\lambda_m, \lambda_1]$, but this strategy is not as effective at reducing the bound on the residual norm as the strategy of increasing m and putting up with a modest decrease in $p_{k,m}$. For example, if m is fixed at two, then $\max_{[\lambda_2, \lambda_1]} p_{5,2} = 1.5e-09$, but the residual norm is only $8.9e-02$.

The last line in the table shows the MINRES residual norms. They are well approximated by the values in the third line, which suggests that MINRES is following a similar strategy. Figure 2.5 supports our contention that MINRES reduces the residual by increasing the interval in which the polynomial is small.

5. Nonreduction of the residual. Let $\alpha \in [0, 1]$, and suppose we wish to reduce the residual at λ_i from $\tilde{\beta}_i$ to $\tilde{\beta}_i(1 - \alpha)$. We have already noted that the corresponding component of \tilde{x} is then

$$\tilde{\xi}_i = \frac{\alpha \tilde{\beta}_i}{\lambda_i}.$$

If λ_i is small, then $\tilde{\xi}_i$ is large and the solution will be unsatisfactory. Thus while MINRES is producing a regularized solution, it must not reduce the residuals on the terminal part of the spectrum. From Figure 2.5 we see that this is precisely what is happening in our example. The residual polynomials are effectively one at small λ_i .

The reason MINRES behaves in this manner is that if any polynomial is small at a small eigenvalue, it must be very large at the initial eigenvalues, say $\lambda_1, \dots, \lambda_m$. Specifically, we have the following theorem.

THEOREM 5.1. *Let $p_{k,m}$ be defined by (4.3). If p is any polynomial of degree k satisfying $p(0) = 1$, $p(\lambda_i) = 1 - \alpha$ for some $i > m$, and*

$$(5.1) \quad \frac{p_{k-1,m}(\lambda_i)\lambda_i}{p_{k-1,m}(\lambda_i) - 1 + \alpha} < \lambda_m,$$

then there is a point $t_{\text{big}} \in [\lambda_m, \lambda_1]$ such that

$$(5.2) \quad |p(t_{\text{big}})| \geq \left| 1 - \frac{p_{k-1,m}(\lambda_i) - 1 + \alpha}{p_{k-1,m}(\lambda_i)} \frac{\lambda_m}{\lambda_i} \right| |p_{k-1,m}(\lambda_m)|.$$

Proof. The proof is a variant of the standard proof of the theorem of de laVallée Poussin [1, p. 191]. Consider the polynomial

$$q(t) = \left[1 - \frac{p_{k-1,m}(\lambda_i) - 1 + \alpha}{p_{k-1,m}(\lambda_i)} \frac{t}{\lambda_i} \right] p_{k-1,m}(t).$$

This polynomial satisfies the conditions $p(0) = 1$ and $p(\lambda_i) = 1 - \alpha$. If, in addition, (5.1) is satisfied, the root of the linear term in brackets is less than λ_m , and the polynomial $q(t)$ alternates in sign at k points

$$\lambda_m = t_1, t_2, \dots, t_k = 1$$

on the interval $[\lambda_m, \lambda_1]$.

Now let p also satisfy the conditions of the theorem. We claim that $|p(t_i)| \geq |q(t_i)|$ for at least one t_i . For if not, the polynomial $p - q$ alternates in sign at the t_i and hence has $k - 1$ zeros in the interval $[\lambda_m, \lambda_1]$. But by the conditions of the theorem $p - q$ is zero at zero and λ_i . Hence $p - q$ is a polynomial of degree not greater than k with $k + 1$ zeros and must be identically zero — a contradiction.

Because the values of $|p_{k-1,m}(t_i)|$ are equal, the absolute value of $q(t_i)$ is smallest at λ_m , and evaluating $|q(\lambda_m)|$ gives the lower bound (5.2). \square

Note that when i is large the condition (5.1) is not very restrictive. For in that case, the right-hand side is near λ_i/α , which cannot approach λ_m unless α is very small.

The import of this theorem is that the cost of reducing the residual at the small eigenvalues is to make the polynomial large on an interval containing the initial eigenvalues. This is because the factor λ_m/λ_i in (5.2) becomes enormous for i large. For

FIG. 6.1. *Eigenvalues (solid line) and components of b (dashed line).*

example, Theorem 5.1 implies that if $m = 8$ and $k = 5$ in our running example, then to get a reduction of .9 ($\alpha = .1$) in the residual at $\lambda_{25} = 6.8\text{e-}6$, the absolute value of the residual polynomial will have to be greater than 71 at some point in $[\lambda_8, \lambda_1]$. Such a large polynomial is more likely to cause a residual magnification than a residual reduction in $[\lambda_8, \lambda_1]$. This likelihood is increased by the fact that for our example the roots of p_k are spread out over $[\lambda_m, \lambda_1]$, where $m > k$, and the zeros of p_k cannot be near all m of these eigenvalues.

On the other hand, in our example, suppose we wish to reduce the residual at λ_{15} from β_{15} to $\beta_{15}(1 - \alpha)$ for $\alpha = 0.11$. The lower bound (5.2) for the residual polynomial is 0.0086. The maximum value of the residual polynomial in $[\lambda_8, \lambda_1]$ is, in fact, 0.037, which is insufficiently greater than 0.0086 to render the reduction at λ_{15} harmless. Once again, the dispersal of the roots of $p_{k,m}$ has a beneficial effect — this time allowing a modest decrease in the residual at the intermediate eigenvalues.

In the last section we observed that MINRES eschews a quick reduction of the residual polynomials over a limited range in favor of expanding the range in which they are moderately small. The theory of this section shows that the deferred reduction has another benefit: it gives the algorithm an opportunity to reduce the residual by a modest amount on the intermediate eigenvalues.

6. Another example. To confirm our analysis of MINRES, we consider a two dimensional blurring operator. Specifically, the original matrix A is the Kronecker product $T \otimes T$, where T is a symmetric Toeplitz matrix whose first row is given by

$$t_{1k} = e^{-0.1(1-k)^2}, \quad k = 1, \dots, 32.$$

Figure 6.1 exhibits the first 200 eigenvalues of the matrix and the absolute values components of b in the spectral coordinate system. The error e consists of white noise scaled so that $\|e\|/\|b\| = 0.01$.

Figure 6.2 plots the errors from spectral regularization and MINRES. The contrast is dramatic. The MINRES iteration reduces the error to a minimum of 195 in four iterations. Spectral regularization requires the first 100 components of the solution be computed to reduce the error to a minimum of 192. (However, the plot shows that acceptable accuracy is attained for, say, 30 components.)

FIG. 6.2. Errors from spectral regularization (dashed line) and MINRES regularization (solid line).

The analysis of section 3 suggests that the solution will deteriorate when the residual norm becomes less than the error norm. In fact, the fourth, fifth, and sixth residual norms are 8.66, 7.86, and 7.52. This should be compared with the error norm 7.78.

From the comments in section 4 we would expect that residual polynomials would reduce the error by spreading their roots over a number of eigenvalues rather than by approximating specific eigenvalues. The roots for the first five residual polynomials are given below.

(1)	9.3e-01				
(2)	9.8e-01	7.3e-01			
(3)	9.9e-01	8.1e-01	5.7e-01		
(4)	9.9e-01	8.7e-01	6.9e-01	3.6e-01	
(5)	1.0e+00	9.0e-01	7.4e-01	5.4e-01	2.2e-01

The largest root is converging to one, which in our normalization is an eigenvalue of A . But otherwise, the roots are dispersed. For example, the smallest root of p_4 is 0.36, which corresponds to λ_{34} .

7. Conclusions. In the introduction to this paper we emphasized that this work would not provide a complete analysis of MINRES as a regularization technique. We can analyze MINRES applied to well-posed problems because asymptotic bounds become applicable long before a solution of the desired accuracy is attained. On the other hand, for ill-posed problems in our examples, MINRES does not have a chance to settle down before the optimal solution is obtained. In effect, we are analyzing the early transient behavior of the algorithm — always a difficult problem.

In spite of not concluding with a general theorem, our analysis sheds considerable light on the behavior of MINRES as a regularizer. Theorem 3.1 is a very general result about ill-posed problems. It suggests that attempting to reduce the residual norm below the error norm will result in a worsened solution. As we have already noted, the theorem can be taken as a justification of the Morozov discrepancy principle.

We have mentioned that the bound (4.4) on the residual norm is too crude to be used in practical applications. Nonetheless, it is good enough to suggest the strategy that MINRES uses to obtain rapid reduction of the residual norm. The free parameter m in the bound is essentially a measure of the spread of the zeros of the residual polynomial. As we have seen, the bound is optimized by keeping m greater than the iteration number k . This suggests that MINRES will attempt to minimize the residual by spreading the roots of its residual polynomials over a larger number of eigenvalues. Our numerical examples support this conjecture.

Finally, Theorem 5.1 shows us why MINRES does not tend to reduce the residual at a small eigenvalue while homing in on the regularized solution. Essentially, a small value of the residual polynomial at a small eigenvalue causes the polynomial to be large on the larger eigenvalues—just where it is most desirable to obtain a decrease in the residuals.

For definiteness, we have restricted ourselves to MINRES applied to a positive definite system. Obviously, some of our results apply to other systems and methods—e.g., least squares regularization of overdetermined systems. Such generalizations, however, will be subject for future work.

8. Appendix. *Proof of Theorem 4.1.* Let $c_k(\tau)$ denote the Chebychev polynomial of degree k and define $s_m(t)$ and $p_{k,m}(t)$ as in (4.2) and (4.3), respectively. Now $p_{k,m}$ is a polynomial of degree k satisfying $p_{k,m}(0) = 1$, and therefore from (4.1), we have

$$(8.1) \quad \|r^{(k)}\|_2^2 \leq \sum_{i=1}^n p_{k,m}^2(\lambda_i) \tilde{\beta}_i = \|p_{k,m}(\Lambda) \tilde{b}\|_2^2.$$

When $i \leq m$, $c_k^2(s_m(\lambda_i)) \leq 1$. Moreover, one can show that the denominator of $p_{k,m}$, which is independent of i , is bounded above [10]:

$$(8.2) \quad \left| \frac{1}{c_k\left(\frac{\lambda_1 + \lambda_m}{\lambda_1 - \lambda_m}\right)} \right| \leq 2 \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^k.$$

Thus, it remains to determine an upper bound for the values $c_k(s_m(\lambda_i))$, $i > m$.

For notational convenience, we fix i , let $d = \frac{\lambda_i}{\lambda_1}$, and note that since $\kappa = \frac{\lambda_1}{\lambda_m}$, $\frac{\lambda_i}{\lambda_m} = d\kappa$. Using this notation, we write $s_{m,i} \equiv s_m(\lambda_i) = \left(\frac{\kappa+1-2d\kappa}{\kappa-1}\right)$.

Now $c_k(s) = \cosh(k \cosh^{-1} s)$. We use the formulas

$$(8.3) \quad \cosh x = \frac{e^x + e^{-x}}{2}$$

and

$$(8.4) \quad \ln z = \cosh^{-1} \left(\frac{z + z^{-1}}{2} \right) \quad \text{when } x = \ln z$$

to determine our upper bound as outlined below. We note that this type of proof technique was used at least as early as the 1960s (see [3]).

- (1) Find a z such that $\left(\frac{z+z^{-1}}{2}\right) = s_{m,i}, i > m$.
- (2) Use z and (8.3) to determine $c_k(s_{m,i}), i > m$.
- (3) Find an upper bound for $c_k^2(s_{m,i}), i > m$.
- (4) Use this bound and (8.2) to deduce an upper bound for $p_{k,m}^2(s_{m,i}) i > m$.
- (5) Use the above information to obtain the upper bound on the right-hand side of (8.1).

Step 1. We first set

$$\frac{z + z^{-1}}{2} = s_{m,i}$$

to obtain

$$z^2 - 2s_{m,i}z + 1 = 0.$$

Since this is a quadratic equation, z is given by

$$\begin{aligned} z &= \frac{2s_{m,i} \pm \sqrt{4s_{m,i}^2 - 4}}{2} \\ &= \left(\frac{\kappa + 1 - 2d\kappa}{\kappa - 1} \right) \pm \sqrt{\left(\frac{\kappa + 1 - 2d\kappa}{\kappa - 1} \right)^2 - 1} \\ &= \frac{1}{\kappa - 1} \left(\kappa + 1 - 2d\kappa \pm 2\sqrt{(\kappa - \kappa d)(1 - \kappa d)} \right) \\ &= \frac{(\sqrt{\kappa - \kappa d} \pm \sqrt{1 - \kappa d})^2}{\kappa - 1}. \end{aligned}$$

(8.5)

For convenience, we take z to be

$$z = \frac{(\sqrt{\kappa - \kappa d} + \sqrt{1 - \kappa d})^2}{\kappa - 1}. \quad (8.6)$$

Step 2. Now $c_k(s_{m,i}) = \cosh(k \ln z) = \cosh(\ln z^k)$. Using (8.3), we obtain

$$\begin{aligned} c_k(s_{m,i}) &= \frac{z^k + z^{-k}}{2} \\ &= \frac{z^{2k} + 1}{2z^k}. \end{aligned}$$

(8.7)

Step 3. Therefore,

$$c_k^2(s_{m,i}) = \frac{1}{4} \left(z^{2k} + \frac{1}{z^{2k}} + 2 \right).$$

(8.8)

To get an upper bound on $c_k^2(s_{m,i})$, let us first try to get an upper bound on $\frac{1}{z^{2k}}$ by getting a lower bound on z . Observe that the numerator of z in (8.6) is bounded below by $\kappa - d\kappa$, so our lower bound for z is $\frac{\kappa - d\kappa}{\kappa - 1}$. Since $d\kappa \leq 1$, we therefore obtain

$$\frac{1}{z} \leq \frac{\kappa - 1}{\kappa - d\kappa} \leq 1,$$

and so $\frac{1}{z^{2k}} \leq 1$.

Next, we have the following expression for z^{2k} :

$$z^{2k} = \left(\frac{\kappa + 1 + 2((\kappa - d\kappa)(1 - d\kappa))^{1/2} - 2d\kappa}{\kappa - 1} \right)^{2k}.$$

Therefore, we have the following bound on $c_k^2(s_{m,i})$:

$$(8.9) \quad c_k^2(s_{m,i}) \leq \frac{1}{4} \left(3 + \left(\frac{\kappa + 1 + 2((\kappa - d\kappa)(1 - d\kappa))^{1/2} - 2d\kappa}{\kappa - 1} \right)^{2k} \right).$$

Step 4. Now we may use (8.2) and (8.9) to determine an upper bound on $p_{k,m}^2(s_{m,i})$ for $i > m$:

$$p_{k,m}^2(s_{m,i}) \leq \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^{2k} \left(3 + \left(\frac{\kappa + 1 + 2((\kappa - d\kappa)(1 - d\kappa))^{1/2} - 2d\kappa}{\kappa - 1} \right)^{2k} \right).$$

Using $\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1} = \frac{\kappa-1}{\kappa+2\sqrt{\kappa}+1}$, we cancel like terms on the right-hand side above and factor out $\sqrt{\kappa}$ from the radical to obtain

$$p_{k,m}^2(s_{m,i}) \leq 3 \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^{2k} + \left(\frac{\kappa + 1 + 2\sqrt{\kappa} \left(\left(1 - \frac{\lambda_i}{\lambda_1}\right) \left(1 - \frac{\lambda_i}{\lambda_m}\right) \right)^{1/2} - 2\frac{\lambda_i}{\lambda_m}}{\kappa + 1 + 2\sqrt{\kappa}} \right)^{2k}.$$

The second term of the right-hand side above can be bounded above by

$$\left(1 - \frac{2\frac{\lambda_i}{\lambda_m}}{\kappa + 1 + 2\sqrt{\kappa}} \right)^{2k} = \left(1 - 2\frac{\lambda_i}{\lambda_1 + \lambda_m + 2\sqrt{\lambda_1\lambda_m}} \right)^{2k}.$$

Thus,

$$(8.10) \quad p_{k,m}^2(s_{m,i}) \leq 3 \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^{2k} + \left(1 - 2\frac{\lambda_i}{\lambda_1 + \lambda_m + 2\sqrt{\lambda_1\lambda_m}} \right)^{2k}.$$

Step 5. From (8.2) when $i \leq m$,

$$p_{k,m}^2(s_{m,i}) \leq \left(\frac{l}{c_k(s_{m,i})} \right)^2 \leq 4 \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^{2k}.$$

Breaking up the sum over the first m and last $n - m$ terms from (8.1) and (8.10), we observe

$$\|r_k\|_2^2 \leq 4 \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1} \right)^{2k} \|\tilde{b}_m\|_2^2 + \sum_{i=m+1}^n \left(1 - 2\frac{\lambda_i}{(\sqrt{\lambda_1} + \sqrt{\lambda_m})^2} \right)^{2k} \tilde{\beta}_i^2.$$

9. Acknowledgments. We wish to thank Per Christian Hansen and Dianne O’Leary for their useful comments on the first draft of this paper.

CHOOSING REGULARIZATION PARAMETERS IN ITERATIVE METHODS FOR ILL-POSED PROBLEMS*

MISHA E. KILMER[†] AND DIANNE P. O'LEARY[‡]

Abstract. Numerical solution of ill-posed problems is often accomplished by discretization (projection onto a finite dimensional subspace) followed by regularization. If the discrete problem has high dimension, though, typically we compute an approximate solution by projecting the discrete problem onto an even smaller dimensional space, via iterative methods based on Krylov subspaces. In this work we present a common framework for efficient algorithms that regularize after this second projection rather than before it. We show that determining regularization parameters based on the final projected problem rather than on the original discretization has firmer justification and often involves less computational expense. We prove some results on the approximate equivalence of this approach to other forms of regularization, and we present numerical examples.

Key words. ill-posed problems, regularization, discrepancy principle, iterative methods, L-curve, Tikhonov, truncated singular value decomposition, projection, Krylov subspace

1. Introduction. Linear, discrete ill-posed problems of the form

$$(1.1) \quad \min_x \|Ax - b\|_2$$

arise, for example, from the discretization of first-kind Fredholm integral equations and occur in a variety of applications. We shall assume that the full-rank matrix A is $m \times n$ with $m \geq n$. In discrete ill-posed problems, A is ill-conditioned and there is often no gap in the singular value spectrum. Typically, the right-hand side b contains noise due to measurement and/or approximation error. This noise, in combination with the ill-conditioning of A , means that the exact solution of (1.1) has little relationship to the noise-free solution and is worthless.

Instead, we use a *regularization* method to determine a solution that approximates the noise-free solution. We replace the original operator by a better conditioned but related one in order to diminish the effects of noise in the data. Sometimes this regularized problem is too large to solve exactly. In that case, we typically project the problem onto an even smaller dimensional space, perhaps via iterative methods based on Krylov subspaces. Sometimes this projection provides enough regularization to produce a good approximate solution, but often (see, for example, [28, 15]) additional regularization is needed.

A fundamental decision to be made in such cases is whether to regularize before or after the projection. *One subtle issue is that the regularization parameter that is optimal for the discretized problem may not be optimal for the lower-dimensional problem actually solved by the iteration*, and this leads to the research discussed in this paper.

At first glance, there can appear to be a lot of work associated with the selection of a good regularization parameter, and many algorithms proposed in the literature are needlessly complicated, repeating a Krylov iteration multiple times. By regularizing after projection by the iterative method, so that we are regularizing the lower dimensional problem that is actually being solved, this difficulty vanishes.

The purpose of this paper is to present a common framework for parameter selection techniques applied to the problem resulting from iterative methods such as Krylov subspace techniques. We show that by determining regularization parameters based on the final projected problem rather than on the original discretization, we can better approximate the optimal parameter and reduce the cost of solution.

Our paper is organized as follows. In section 2 we survey some methods for choosing the corresponding regularization parameters. In section 3, we show how any standard parameter selection technique for the original problem can be applied instead to a projected problem obtained from an iterative method, greatly reducing the cost without much degradation in the solution. We give experimental results in section 4 and conclusions in section 5.

In the following we shall assume that $b = b_{true} + e$, where b_{true} denotes the unperturbed data vector and e denotes zero-mean white noise. We will also assume that b_{true} satisfies the discrete Picard condition; that is, the spectral coefficients of b_{true} decay faster, on average, than the singular values.

Let $\hat{U}\Sigma\hat{V}^*$ denote the singular value decomposition (SVD) of A , where the columns of \hat{U} and \hat{V} are the singular vectors, and the singular values are ordered as $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_n$. Then the solution (1.1) is given by

$$(1.2) \quad x = \sum_{i=1}^n \frac{\hat{u}_i^* b}{\sigma_i} \hat{v}_i = \sum_{i=1}^n \left(\frac{\hat{u}_i^* b_{true}}{\sigma_i} + \frac{\hat{u}_i^* e}{\sigma_i} \right) \hat{v}_i.$$

As a consequence of the white noise assumption, $|\hat{u}_i^* e|$ is roughly constant for all i , while the discrete Picard condition guarantees that $|\hat{u}_i^* b_{true}|$ decreases with i faster than σ_i does. The matrix A is ill-conditioned, so small singular values magnify the corresponding coefficients $\hat{u}_i^* e$ in the second sum, and it is this large contribution of noise that renders the exact solution x defined in (1.2) worthless. The following four classes of regularization methods try in different ways to lessen the contribution of noise. For further information on these methods, see, for example, [19, 15].

In **Tikhonov regularization**, (1.1) is replaced by

$$(1.3) \quad \min_x \|Ax - b\|_2^2 + \lambda^2 \|Lx\|_2^2,$$

where λ is a positive scalar regularization parameter, and we choose L to be the identity matrix I . Solving (1.3) is equivalent to solving

$$(1.4) \quad (A^*A + \lambda^2 I)x_\lambda = A^*b.$$

In analogy with (1.2) we have

$$(1.5) \quad x_\lambda = \sum_{i=1}^n \left(\frac{\sigma_i \hat{u}_i^* b_{true}}{\sigma_i^2 + \lambda^2} + \frac{\sigma_i \hat{u}_i^* e}{\sigma_i^2 + \lambda^2} \right) \hat{v}_i.$$

In **truncated SVD** we compute the regularized solution by truncating the expansion in (1.2) as

$$(1.6) \quad x_\ell = \sum_{i=1}^{\ell} \frac{\hat{u}_i^* b}{\sigma_i} \hat{v}_i.$$

Here the regularization parameter is ℓ , the number of terms retained in the sum. Rust [33] introduced a related truncation strategy, including in the sum (1.2) only those terms corresponding to a spectral coefficient $\hat{u}_i^* b$ whose magnitude is greater than or equal to some tolerance ρ , which can be regarded as the regularization parameter.

Solving (1.4) or (1.6) can be impractical if n is large, but fortunately, regularization can be achieved through **projection** onto a k -dimensional subspace; see, for example, [9]. The truncated SVD (TSVD) is one example, but projection is often achieved through the use of iterative methods such as conjugate gradients, GMRES, QMR, and other Krylov subspace methods [28, 1]. Krylov subspace algorithms tend to produce, at early iterations, solutions that resemble x_{true} more than later iterates. Therefore, the choice of the regularization parameter k , the stopping point for the iteration and the dimension of the subspace, is very important.

Another important family of regularization methods, termed **hybrid methods** [19, 15], was introduced by O'Leary and Simmons [28]. These methods combine a projection method with a direct regularization method such as TSVD or Tikhonov regularization. Since the dimension k is usually small relative to n , regularization of the restricted problem is much less expensive, but the end results can be very similar to those achieved by applying the same direct regularization technique to the original problem; see section 3.5.

2. Existing parameter selection methods. In this section, we discuss three parameter selection techniques that have been proposed in the literature. They differ in the amount of a priori information required as well as in the decision criteria.

The discrepancy principle [26] says that if δ is the expected value of $\|e\|_2$, then the regularization parameter should be chosen so that the norm of the residual corresponding to the regularized solution x_{reg} is $\tau\delta$; that is,

$$(2.1) \quad \|Ax_{reg} - b\|_2 = \tau\delta,$$

where $\tau > 1$ is some predetermined real number. Note that as $\delta \rightarrow 0$, $x_{reg} \rightarrow x_{true}$. Other methods based on knowledge of the variance are given, for example, in [3, 13, 7].

Generalized cross-validation (GCV) [11] does not depend on a priori knowledge about the noise variance. We find the parameter λ that minimizes the GCV functional

$$(2.2) \quad G(\lambda) = \frac{\|(I - AA_\lambda^\sharp)b\|_2^2}{(\text{trace}(I - AA_\lambda^\sharp))^2},$$

where A_λ^\sharp denotes the matrix that maps the right-hand side b onto the regularized solution x_λ . In Tikhonov regularization, for example, A_λ^\sharp is $(A^*A + \lambda^2 I)^{-1}A^*$.

The L-curve, the plot of the norm of the regularized solution versus the corresponding residual norm for each of a set of regularization parameter values, was introduced by Lawson and popularized by Hansen [17, 25]. Intuitively, the best regularization parameter should lie on the corner of the L-curve, since for values higher than this, the residual increases without reducing the norm of the solution much, while for values smaller than this, the norm of the solution increases rapidly without much decrease in residual. In practice, only a few points on the L-curve are computed and the corner is located by estimating the point of maximum curvature [20].

The appropriate choice of regularization parameter—especially for projection algorithms—is a difficult problem, and each method has severe flaws. The discrepancy principle is convergent as the noise goes to zero, but it relies on information that

TABLE 2.1

Summary of additional flops needed to compute the regularization parameter for each of four regularization methods with various parameter selection techniques. Notation: q is the cost of multiplication of a vector by A ; p is the number of discrete parameters that must be tried; k is the dimension of the projection; m and n are problem dimensions.

	Basic cost	Added cost		
		Disc.	GCV	L-curve
Tikhonov	$O(mn^2)$	$O(p(m+n))$	$O(p(n+m))$	$O(p(m+n))$
TSVD	$O(mn^2)$	$O(m)$	$O(m)$	$O(m+n)$
Rust's TSVD	$O(mn^2)$	$O(m \log m)$	$O(m \log m)$	$O(m \log m)$
Projection	$O(qk)$	0	$O(q)$	$O(q)$

is often unavailable or erroneous. Even with a correct estimate of the variance, the solutions tend to be oversmoothed [21, p. 96]. (See also the discussion in section 6.1 of [17].) One noted difficulty with GCV is that G can have a very flat minimum, making it difficult to determine the optimal λ numerically [37]. The L-curve is usually more tractable numerically, but its limiting properties are nonideal. The solution estimates fail to converge to the true solution as $n \rightarrow \infty$ [38] or as the error norm goes to zero [8]. All methods that assume no knowledge of the error norm—including GCV—have this latter property [8].

For further discussion and references about parameter choice methods, see [7, 19]. The cost of these methods is tabulated in Table 2.1.

2.1. Previous work on parameter choice for hybrid methods. At first glance, it appears that for Tikhonov regularization, multiple systems of the form (1.4) must be solved in order to evaluate candidate values of λ for the discrepancy principle or the L-curve.

Chan and Ng [5] note that the systems involve matrices $C(\lambda) = A^*A + \lambda I$, which they solve using a Galerkin projection method on a sequence of “seed” systems. Although economical in storage, this is unnecessarily expensive in time because they do not exploit the fact that for each fixed k , the Krylov subspace $\mathcal{K}_k(A^*b, C(\lambda))$ is the same for all values of λ .

Frommer and Maass [10] propose two algorithms for approximating the λ that satisfies the discrepancy principle (2.1). The first is a “truncated conjugate gradient (CG)” approach, solving k systems of the form (1.4), truncating the iterative process early for large λ , and using previous solutions as starting guesses for later problems. Like Chan and Ng, this algorithm does not exploit the redundant Krylov subspaces. In the second method, however, they update the CG iterates for all k systems simultaneously, stopping their “shifted CG” algorithm when $\|Ax_\lambda - b\|_2 \leq \tau\delta$ for one of their λ values. The methods we propose in section 3 will usually require less work than the shifted CG algorithm because of less overhead.

Calvetti, Golub, and Reichel [4] use upper and lower bounds on the L-curve, generated by the matrices $C(\lambda)$ using a Lanczos bidiagonalization process, to approximate the best parameter for Tikhonov regularization before projection.

Kaufman and Neumaier [22] suggest an envelope guided conjugate gradient approach for the Tikhonov L-curve problem. Their method is necessarily somewhat more expensive than ours because they maintain nonnegativity constraints on the variables.

Substantial work has also been done on TSVD regularization of the projected problems. Björck, Grimme, and van Dooren [2] use GCV to determine the truncation point for the projected SVD. Their emphasis is on maintaining an accurate factor-

ization when many iterations are needed, using full reorthogonalization and implicit restart strategies. O'Leary and Simmons [28] take the viewpoint that the problem should be preconditioned appropriately so that a massive number of iterations is unnecessary. That viewpoint is echoed in this current work, so we implicitly assume that the problem has been preconditioned [28] so that $A = M^{-1}\hat{A}$ and $b = M^{-1}\hat{b}$, where \hat{A} and \hat{b} are the original data and M is a preconditioning matrix. See [16, 27, 24, 23] for preconditioners appropriate for certain types of ill-posed problems.

3. Regularizing the projected problem. In this section we categorize a dozen approaches to regularization of the projected problem that arise from using Krylov methods, giving enough detail to make the costs apparent and to show that the ideas are easy to program. Many Krylov methods have been proposed; for ease of exposition we focus on just one of these: the LSQR algorithm of Paige and Saunders [30].

LSQR iteratively computes a bidiagonalization related to that introduced by Golub and Kahan [12]. After k iterations, it has effectively computed three matrices: an upper-bidiagonal matrix B_k and two matrices $U_k \equiv [u_1, \dots, u_k]$ and $V_k \equiv [v_1, \dots, v_k]$, with orthonormal columns, related by

$$(3.1) \quad b = \beta_1 u_1 = \beta_1 U_{k+1} e_1,$$

$$(3.2) \quad AV_k = U_{k+1} B_k,$$

$$(3.3) \quad A^T U_{k+1} = V_k B_k^T + \alpha_{k+1} v_{k+1} e_{k+1}^T,$$

where e_i denotes the i th unit vector.

In numeric computations, the columns of U_k and V_k can fail to be orthonormal. This has never given us convergence difficulties, but if it becomes troublesome, there are well-known techniques to handle it [31, 32, 36, 6].

Now suppose we want to solve

$$(3.4) \quad \min_{x \in \mathcal{S}} \|b - Ax\|_2,$$

where \mathcal{S} denotes the k -dimensional subspace spanned by the first k vectors v_i . The solution we seek is of the form $x^{(k)} = V_k y^{(k)}$ for some vector $y^{(k)}$ of length k . Define $r^{(k)} = b - Ax^{(k)}$ to be the corresponding residual and observe that

$$\begin{aligned} r^{(k)} &= \beta_1 u_1 - AV_k y^{(k)} \\ &= U_{k+1} (\beta_1 e_1 - B_k y^{(k)}). \end{aligned}$$

Since U_{k+1} has, in exact arithmetic, orthonormal columns, the projected problem we wish to solve is

$$(3.5) \quad \min_{y^{(k)}} \|\beta_1 e_1 - B_k y^{(k)}\|_2.$$

Solving this minimization problem is mathematically equivalent to solving the normal equations involving the bidiagonal matrix

$$(3.6) \quad B_k^* B_k y^{(k)} = \beta_1 B_k^* e_1,$$

although more stable means are used in practice. Typically k is small, so reorthogonalization to combat round-off error might or might not be necessary. The matrix B_k may be ill-conditioned because some of its singular values approximate some of the small singular values of A . Therefore, solving the projected problem might not yield

TABLE 3.1

TABLE 3.3

Summary of storage, not including storage for the matrix, for projection plus inner regularization approach and various parameter selection techniques. Here p denotes the number of discrete parameters tried. Each of these regularization methods also requires us to save the basis V or else regenerate it in order to reconstruct x .

Projection plus –	Disc.	GCV	L-curve
Tikhonov	$O(1)$	$O(p)$	$O(p)$
TSVD	$O(1)$	$O(k)$	$O(k)$
Rust's TSVD	$O(k)$	$O(k + p)$	$O(k + p)$

a good solution $y^{(k)}$, but we can use any of the methods of section 2 to regularize this projected problem; we discuss options in detail below.

If we used the algorithm GMRES [35] instead of LSQR, we would derive similar relations. Here, though, the U and V matrices are identical and the B matrix is upper Hessenberg rather than bidiagonal. Conjugate gradients would yield similar relationships.

For cost comparisons for these methods, see Tables 2.1 and 3.1. Storage comparisons are given in Tables 3.2 and 3.3.

3.1. Regularization by projection. As mentioned earlier, if we terminate the iteration after k steps, we have projected the solution onto a k -dimensional subspace and this has a regularizing effect that is sometimes sufficient. Determining the best value of k can be accomplished, for instance, by one of our three methods of parameter choice. Efficient implementation relies on LSQR recurrences for determining $\|r^{(k)}\|$ and $\|x^{(k)}\|$ cheaply, without computing either $r^{(k)}$ or $x^{(k)}$ [30, 34].

For the **discrepancy principle**, we stop the iteration for the smallest value of k for which $\|r_k\| \leq \tau\delta$.

To apply **GCV**, we note that in LSQR (see section 3.1), the operator AA^\sharp is given by $U_{k+1}B_kB_k^\dagger U_{k+1}^*$, where B_k^\dagger is the pseudoinverse of B_k . Thus from (2.2), the

GCV functional is [19]

$$G(k) = \frac{\|r^{(k)}\|_2^2}{(m-k)^2}.$$

We note that there are in fact two distinct definitions for A^\sharp and hence two definitions for the denominator in $G(k)$; for small enough k , the two are comparable, and the definition we use here is less expensive to calculate [19, section 7.4].

To determine the **L-curve** associated with LSQR, values of $\|r^{(k)}\|_2$ and $\|x^{(k)}\|_2$ are needed for several values of k . In using this method or GCV, one must go a few iterations beyond the optimal k in order to verify the optimum [20].

3.2. Regularization by projection plus TSVD. If projection alone does not regularize, then we can compute the TSVD regularized solution to the projected problem (3.6). We need the SVD of the $(k+1) \times k$ matrix B_k . This requires $O(k^3)$ operations but can also be computed from the SVD of B_{k-1} in $O(k^2)$ operations [14].

Clearly, we still need to use some type of parameter selection technique to find a good value of $\ell(k)$. First, notice that it is easy to compute the norms of the residual and the solution resulting from retaining only the ℓ largest singular values. If ξ_{jk} is the component of e_1 in the direction of the j th left singular vector of B_k , and if γ_j is the j th singular value (ordered largest to smallest), then the residual and solution 2-norms are

$$(3.7) \quad \|r_\ell^{(k)}\| = \beta_1 \left(\sum_{j=\ell(k)+1}^{k+1} \xi_{jk}^2 \right)^{1/2} \quad \text{and} \quad \|x_\ell^{(k)}\| = \beta_1 \left(\sum_{j=1}^{\ell(k)} \left(\frac{\xi_{jk}}{\gamma_j} \right)^2 \right)^{1/2}.$$

Using this fact, we can use any of our three sample methods.

For the **discrepancy principle** we choose $\ell(k)$ to be the smallest value for which $\|r_\ell^{(k)}\| \leq \tau\delta$, if such a value exists. As k increases, the number of neglected singular values will be monotonically nondecreasing (exact arithmetic).

The **GCV** functional for the k th projected problem is obtained by substituting B_k for A and B_k^\sharp for A^\sharp , and substituting the expression of the residual in (3.7) for the numerator in (2.2):

$$G_k(\ell) = \frac{\beta_1^2 \sum_{j=\ell+1}^{k+1} \xi_{jk}^2}{(k-\ell+1)^2}.$$

We now have many **L-curves**, one for each value of k . The coordinate values in (3.7) form the discrete L-curve for a given k , from which the desired value of $\ell(k)$ can be chosen without forming the approximate solutions or residuals.

3.3. Regularization by projection plus Rust's TSVD. As in standard TSVD, to use Rust's version of TSVD for regularization of the projected problem requires computing the SVD of the $(k+1) \times k$ matrix B_k . Using the previous notation, Rust's strategy is to set

$$y_\rho^{(k)} = \sum_{j \in \mathcal{I}_\rho^{(k)}} \frac{\xi_{jk}}{\gamma_j} q_j^{(k)},$$

where $q_j^{(k)}$ are the right singular vectors of B_k and $\mathcal{I}_\rho^{(k)} = \{i < k+1 : |\xi_{ik}| > \rho\}$. We focus on three ways to determine ρ .

For the **discrepancy principle**, the norm of the residual of the regularized solution is given by $\|r_\rho^{(k)}\|_2 = \beta_1 (\sum_{j \notin \mathcal{I}_\rho^{(k)}} \xi_{jk}^2)^{1/2}$. According to the discrepancy principle, we must choose ρ so that the residual is less than $\tau\delta$. In practice, this would require that the residual be evaluated by sorting the values $|\xi_{ik}|$ and adding terms in that order until the residual norm is less than $\tau\delta$.

For **GCV**, let $\text{card}(\mathcal{I}_\rho^{(k)})$ denote the cardinality of the set $\mathcal{I}_\rho^{(k)}$. From (2.2), it is easy to show that the GCV functional corresponding to the projected problem for this regularization technique is given by

$$G_k(\rho) = \frac{\beta_1^2 \sum_{j \in \mathcal{I}_\rho^{(k)}} \xi_{jk}^2}{(k+1 - \text{card}(\mathcal{I}_\rho^{(k)}))^2}.$$

In practice, for each k we first sort the values $|\xi_{ik}|, i = 1, \dots, k$, from smallest to largest. Then we define k discrete values ρ_j to be equal to these values with ρ_1 being the smallest. We set $\rho_0 = 0$. Note that because the values of $\rho_j, j = 1, \dots, k$, are the sorted magnitudes of the SVD expansion coefficients, we have

$$G_k(\rho_j) = \frac{\beta_1^2 (|\xi_{(k+1),k}|^2 + \sum_{i=1}^j \rho_i^2)}{(j+1)^2}, \quad j = 0, \dots, k.$$

Finally, we take the regularization parameter to be the ρ_j for which $G_k(\rho_j)$ is a minimum.

As with standard TSVD, we now have one **L-curve** for each value of k . For fixed k , if we define the $\rho_j, j = 0, \dots, k$, as we did for GCV above and we reorder the γ_i in the same way that the $|\xi_{ik}|$ were reordered when sorted, then we have

$$\|x_{\rho_j}^{(k)}\|_2^2 = \beta_1^2 \sum_{i=j+1}^k \left(\frac{\rho_i}{\gamma_i} \right)^2; \quad \|r_{\rho_j}^{(k)}\|_2^2 = \beta_1^2 \left(|\xi_{(k+1),k}|^2 + \sum_{i=1}^j \rho_i^2 \right), \quad j = 0, \dots, k.$$

When these solution and residual norms are plotted against each other as functions of ρ , the value of ρ_j corresponding to the corner is selected as the regularization parameter.

3.4. Regularization by projection plus Tikhonov. Finally, let us consider using Tikhonov regularization to regularize the projected problem (3.5) for some integer k . Thus, for a given regularization parameter λ , we would like to solve

$$(3.8) \quad \min_y \|\beta_1 e_1 - B_k y\|_2^2 + \lambda^2 \|y\|_2^2.$$

The solution $y_\lambda^{(k)}$ satisfies

$$(3.9) \quad (V_k^* A^* A V_k + \lambda^2 I) y_\lambda^{(k)} = V_k^* A^* b.$$

We need to address how to choose a suitable value of λ .

For the **discrepancy principle**, note that in exact arithmetic, we have

$$(3.10) \quad r_\lambda^{(k)} = b - A x_\lambda^{(k)} = U_{k+1}^* (\beta_1 e_1 - B_k y_\lambda^{(k)}).$$

Hence $\|B_k y_\lambda^{(k)} - \beta_1 e_1\|_2 = \|r_\lambda^{(k)}\|_2$. Therefore, to use the discrepancy principle requires that we choose λ so that $\|r_\lambda^{(k)}\|_2 \leq \tau\delta$ with p discrete trial values λ_j . For a given k ,

we take λ to be the largest value λ_j for which $\|r_\lambda^{(k)}\|_2 < \tau\delta$, if it exists; if not, we increase k and test again.

For **GCV**, let us define $(B_k)_\lambda^\dagger$ to be the operator mapping the right-hand side of the projected problem onto the regularized solution of the projected problem:

$$(B_k)_\lambda^\dagger = (B_k^* B_k + \lambda^2 I)^{-1} B_k^*.$$

Given the SVD of B_k as above, the denominator in the GCV functional defined for the projected problem (refer to (2.2)) is

$$\left(k + 1 - \sum_{j=1}^k \frac{\gamma_j^2}{\gamma_j^2 + \lambda^2} \right)^2.$$

The numerator is simply $\|r_\lambda^{(k)}\|_2^2$. For values of $k \ll n$, it is feasible to compute the singular values of B_k .

The **L-curve** is comprised of the points $(\|B_k y_\lambda^{(k)} - \beta_1 e_1\|_2, \|y_\lambda^{(k)}\|_2)$. But using (3.10) and the orthonormality of the columns of V_k , we see these points are precisely $(\|r_\lambda^{(k)}\|_2, \|x_\lambda^{(k)}\|_2)$. For p discrete values of λ , $\lambda_i, 1 \leq i \leq p$, the quantities $\|r_{\lambda_i}^{(k)}\|_2$ and $\|x_{\lambda_i}^{(k)}\|_2$ can be obtained by updating their respective estimates at the $(k-1)$ st iteration.¹

3.5. Correspondence between direct regularization and projection plus regularization. In this section, we demonstrate why the projection plus regularization approaches can be expected to yield regularized solutions nearly equivalent to the direct regularization counterpart. The following theorem, a simple corollary of the invariance of Krylov sequences under shifts, establishes the desired result for the case of Tikhonov vs. projection plus Tikhonov.

THEOREM 3.1. *Fix $\lambda > 0$ and define $x_\lambda^{(k)}$ to be the k th iterate of conjugate gradients applied to the Tikhonov problem*

$$(A^* A + \lambda^2 I)x = A^* b.$$

Let $y_\lambda^{(k)}$ be the exact solution to the regularized projected problem

$$(B_k^* B_k + \lambda^2 I)y = B_k^*(\beta_1 e_1),$$

where B_k, V_k are derived from the original problem $A^ A = A^* b$, and set $z_\lambda^{(k)} = V_k y_\lambda^{(k)}$. Then $z_\lambda^{(k)} = x_\lambda^{(k)}$.*

Proof. See [15, p. 301]. \square

Let us compare TSVD regularization applied to the original problem to the projection plus TSVD approach. Direct computation convinces us that the two methods compute the same regularized solution if $k = n$ and arithmetic is exact. An approximate result holds in exact arithmetic when we take k iterations, with $\ell \leq k \leq n$. Let the SVD of B_k be denoted by $B_k = Z_k \Gamma_k Q_k^T$, and define the $s \times \ell$ matrix $W_{s,\ell}$ as

$$W_{s,\ell} = \begin{bmatrix} I \\ 0 \end{bmatrix}.$$

¹The technical details of the approach are found in [29, pp. 197–198], from which we obtain $\|r_\lambda^{(k)}\| = \sqrt{\|\bar{r}_\lambda^{(k)}\|^2 - \lambda^2 \|x_\lambda^{(k)}\|^2}$. The implementation details for estimating $\|x_\lambda^{(k)}\|$ and $\|\bar{r}_\lambda^{(k)}\|$ were taken from the Paige and Saunders algorithm at <http://www.netlib.org/linalg/lsqqr>.

Then the regularized solution obtained from the TSVD regularization of the projected problem is

$$x_{reg}^{(k)} = V_k(Q_k W_{k,\ell} \Gamma_{k,1}^{-1} W_{k+1,\ell}^T Z_k^T U_k^T b),$$

where $\Gamma_{k,1}$ denotes the leading $\ell \times \ell$ principal submatrix of Γ_k . If k is taken to be sufficiently larger than ℓ so that $V_k Q_k W_{k,\ell} \approx \hat{V} W_{n,\ell}$, $W_{k+1,\ell}^T Z_k^T U_{k+1}^T \approx W_{n,\ell}^T \hat{U}^T$, and $\Gamma_{k,1} \approx \Sigma_1$ with Σ_1 the leading principal submatrix of Σ , then we expect $x_{reg}^{(k)}$ to be a good approximation to x_ℓ . This is made more precise in the following theorem.

THEOREM 3.2. *Let $k \geq \ell$ such that*

$$(V_k Q_k W_{k,\ell}) = \hat{V}_1 + E_1 \quad \text{with } \|E_1\| \leq \delta_1 \ll 1,$$

$$(U_{k+1} Z_k W_{k+1,\ell}) = \hat{U}_1 + E_2 \quad \text{with } \|E_2\| \leq \delta_2 \ll 1,$$

where \hat{V}_1 and \hat{U}_1 contain the first ℓ columns of \hat{V} and \hat{U} , respectively. Let $D = \text{diag}(d_1, \dots, d_\ell)$ satisfy

$$\Gamma_{k,1} = \Sigma_1 + D \quad \text{with } |d_i| \leq \delta_3 \ll 1.$$

Then

$$\|x_{reg}^{(k)} - x_\ell\| \leq \max_{1 \leq i \leq \ell} \frac{1}{\sigma_i + d_i} \left(\frac{\delta_3}{\sigma_\ell} + 3 \max(\delta_1, \delta_2) \right) \|b\|.$$

Proof. Using the representations $x_\ell = \hat{V}_1 \Sigma_1^{-1} \hat{U}_1^T b$ and $x_{reg}^{(k)} = (\hat{V}_1 + E_1) \Gamma_{k,1}^{-1} (\hat{U}_1^T + E_2^T) b$, we obtain

$$\|x_{reg}^{(k)} - x_\ell\| \leq (\|\Gamma_{k,1}^{-1} - \Sigma_1^{-1}\| + \|\Gamma_{k,1}^{-1}\| \|E_2\| + \|E_1\| \|\Gamma_{k,1}^{-1}\| + \|E_1\| \|\Gamma_{k,1}^{-1}\| \|E_2\|) \|b\|,$$

and the conclusion follows from bounding each term. \square

Note that typically $\sigma_\ell \gg \sigma_n$ so that $1/\sigma_\ell$ is not too large. The bound says that the better LSQR captures the first ℓ singular values and vectors, the more we are assured the solution obtained by projection plus TSVD is close to the TSVD regularized solution to the original problem. For some results relating to the value of k necessary for the hypothesis of the theorem to hold, refer to the theory of Kaniel-Paige and Saad [31, section 12.4]. There is no universal recipe, but if k is large enough that the projected problem satisfies the discrete Picard condition, then this is some indication that the approximability property holds.

4. Numerical results. In this section, we present three numerical examples. All experiments were carried out using Matlab with IEEE double precision floating point arithmetic. Where noted, we made use of certain routines in Hansen's Regularization Tools [18]. Since the exact, noise-free solutions were known in these examples, we evaluated the methods using the relative, 2-norm difference between the regularized solutions and the exact solutions. When we applied Rust's method to the original problem, the ρ_i were taken to be the magnitudes of the spectral coefficients of b sorted in increasing order.

TABLE 4.1

Example 1: comparison of $\|x_{true} - x_{reg}\|_2 / \|x_{true}\|_2$ for each of four regularization methods on the original problem, where the regularization method was chosen using methods indicated. The parameter values selected for each method are indicated in parentheses.

	Disc.		GCV		L-curve		Optimal	
Tikhonov	(1.6E-1)	2.2E-2	(8.0E-2)	2.2E-2	(4.0E-2)	4.3E-2	(1.3E-1)	2.1E-2
TSVD	(6)	1.1E-1	(9)	1.6E-2	(10)	1.6E-2	(9)	1.6E-2
Rust's TSVD	(1.6E-2)	2.5E-2	(5.3E-5)	2.2E+4	(1.6E-2)	2.5E-2	(1.6E-2)	2.5E-2
Projection	(5)	2.5E-2	(5)	2.5E-2	(10)	2.2E-2	(9)	2.2E-2

4.1. Example 1. The 200×200 matrix A and true solution x_{true} for this example were generated using the function `phillips` in Hansen's Regularization Tools. We generated $b_{true} = Ax_{true}$ and then computed the noisy vector b as $b + e$, where e was generated using the Matlab `randn` function and was scaled so that the noise level, $\frac{\|e\|}{\|b_{true}\|}$, was 5×10^{-3} . The condition number of A was on the order of 4×10^7 .

Table 4.1 displays the values of the regularization parameters chosen when the original problem was solved using one of the three parameter selection techniques together with one of the four regularization methods. We set $\tau\delta$ for the discrepancy principle to be $8E-2$, close to the value $\|e\|_2 = 7.65E-2$.

The last column in the table gives the value of the parameter that yielded a regularized solution with minimum relative error. Several values of λ were tested: $\log_{10} \lambda = -4, -3.9, \dots, 0$. The relative error values for regularized solutions corresponding to the parameters are also presented in this table. The GCV and L-curve parameters for projection were determined after 15 iterations. Note that using GCV to determine a regularization parameter for Rust's TSVD resulted in an extremely noisy solution with huge error.

The corners of the L-curves for the Tikhonov, projection, and TSVD methods were determined using Hansen's `lcorner` function, with the modification that sometimes points not strictly on the portion of the curve that was L-shaped (that is, points with very large residual or very small residual) were not considered (otherwise, a false corner resulted); this was most often a concern with the TSVD method. Since the corner was so clearly defined for Rust's method but the function had trouble automatically finding the corner, the corner was picked manually.

Next, we projected using LSQR and then regularized the projected problem with one of the other three regularization methods together with one of the three parameter selection techniques. Results at iterations 10 and 25 are given in Tables 4.2 and 4.3, respectively. As before, the `lcorner` routine was used to determine the corners of the respective L-curves, with the modifications as mentioned above.

Comparing Tables 4.1 and 4.2, we observe that using either the discrepancy principle or the L-curve, 10 steps of projection plus Tikhonov gives results as good as or much better than if those techniques had been used with Tikhonov on the original problem. A similar statement can be made for projection plus Rust's TSVD when any of the 3 selection methods are used and for projection plus TSVD when the discrepancy principle is used. After 25 iterations, the errors for projection plus Tikhonov or Rust's TSVD closely resemble the errors in Table 4.1 with one exception. We note that at 25 iterations, the parameters chosen for projection plus Tikhonov by the discrepancy principle or the L-curve method and their corresponding errors are identical to those chosen for the original problem.

In fact, the L-curve, GCV, and discrepancy methods applied to the projected

TABLE 4.2

Example 1, iteration 10: comparison of $\|x_{true} - x_{reg}\|_2 / \|x_{true}\|_2$ for projection plus Tikhonov, TSVD, and Rust's TSVD. The parameter values for each method are indicated in parentheses.

Tikhonov	(1.6E-1)	2.1E-2	(2.5E-2)	2.5E-2	(2.0E-4)	2.2E-2	(2.0E-2)	2.0E-2
TSVD	(7)	2.5E-2	(7)	2.5E-2	(10)	2.2E-2	(10)	2.2E-2
Rust's TSVD	(9.7E-3)	2.5E-2	(9.7E-3)	2.5E-2	(5.5E-4)	2.2E-2	(9.1E-3)	2.1E-2

TABLE 4.3

Example 1, iteration 25: comparison of $\|x_{true} - x_{reg}\|_2 / \|x_{true}\|_2$ for projection plus Tikhonov, TSVD, and Rust's TSVD. The parameter values are given in parentheses.

	Disc.		GCV		L-curve		Optimal	
Tikhonov	(1.6E-1)	2.2E-2	(2.0E-1)	2.3E-2	(4.0E-2)	4.3E-2	(1.3E-1)	2.1E-2
TSVD	(17)	2.5E-2	(17)	2.5E-2	(21)	2.4E-2	(19)	1.6E-2
Rust's TSVD	(2.0E-2)	2.5E-2	(2.0E-2)	2.5E-2	(1.5E-2)	2.5E-2	(1.5E-2)	2.5E-2

problem with Tikhonov regularization consistently chose the same parameter for future iterations (see Figure 4.1, for instance), and correspondingly the errors remain constant; however, the results at earlier iterations are actually better than after the parameter on the projected problem has converged to the L-curve parameter on the original. For the projection plus TSVD, both the discrepancy principle and GCV method yielded parameters for which the solutions had similar errors from one iteration to the next for at least the first 80 iterations (see the top of Figure 4.2); the L-curve behaved slightly less consistently for iterations beyond about 50. Discrepancy and GCV when applied to projection plus Rust's TSVD also gave consistent solutions for about 40 iterations, after which the GCV solutions began to grow very large in error, much like GCV applied to the original problem (refer to the bottom of Figure 4.2).

4.2. Example 2. The 3969×3969 matrix A for this example was a symmetric, block Toeplitz matrix with Toeplitz blocks formed according to $A = T \otimes T$. Here T is a symmetric, banded Toeplitz matrix with entries $T_{i,j} = t_{i-j}$; the nonzero entries in the first row were $t_k = (\sin(k/B)/(k/B))^2$, $0 \leq k \leq 4$, $B = .8$. The singular values of this matrix range from 5.7 to 8.6×10^{-8} but do not decay very quickly, and the matrix has a condition number of about 7×10^7 . x was obtained by stacking by columns the 63×63 image that was zero except for a rectangle with value 1 from rows 20 to 49, columns 4 to 24, and another rectangle with value .8 at rows 23 to 53, columns 29 to 52. We generated $b_{true} = Ax_{true}$ and then computed the noisy vector b as $b + e$, where e was generated using the Matlab `randn` function and was scaled so that the noise level, $\frac{\|e\|}{\|b_{true}\|}$, was 2×10^{-3} .

We generated our discrete λ_i using $\log_{10} \lambda = -4, -4.9, \dots, 0$. The norm of the noise vector was $3.66E-1$, so we took $\tau\delta = 4.00E-1$ for the discrepancy principle.

In this example, when no preconditioning was used, it took 90 iterations for LSQR to reach a minimum relative error of $7.93E-2$. Likewise, the dimension k of the projected problem had to be at least 90 to obtain good results with the projection-plus-regularization approaches and even larger for the parameter selection techniques to work well on the projected problem. Therefore, for the projection based techniques, we chose to work with a left preconditioned system (refer to the discussion at the end of section 2.1). Our preconditioner was chosen as in [23] where the parameter defining the preconditioner was taken to be $m = 2080$. Results for right preconditioning were

FIG. 4.1. Example 1. Top: λ_k as selected by L-curve method; bottom: relative error for corresponding solution. The solid line indicates the optimal value on the original problem, and the dashed line indicates value selected by L-curve on the original problem.

FIG. 4.2. Example 1. Relative error between computed and exact solutions for projection plus TSVD (top) and projection plus Rust's TSVD (bottom) when the parameters for the projected problem are selected by either the discrepancy principle (*) or GCV method (o).

similar, although the errors were not quite as small. On other examples, though, we found that right preconditioning by this type of preconditioner was only effective in certain instances, even when left preconditioning was effective.²

The results of the resulting regularization for the original problem parameters are given in Table 4.4. We note that GCV with Rust's TSVD was ineffective. Also, after 50 iterations on the left preconditioned system, the GCV functional for projection was still decreasing, so the value in Table 4.4 corresponds to the value after 50 iterations. The L-curve parameter in the table was determined after 20 iterations.

Although we projected using LSQR, we note that since the matrix and preconditioner were symmetric, we could have used MINRES as in [23]. The results in each case at iterations 10, 20, and 40 are given in Tables 4.5, 4.6, and 4.7, respectively, and we summarize results up to 60 iterations in the discussion below.

Again, we used the `lcorner` routine to determine the corners of the respective L-curves, with the modification that for 20 iterations and beyond for TSVD, we first removed points on the curve with residual norm greater than 10 to avoid detecting a false corner.

²In the language of [23], right preconditioning worked well only when K was a very good approximation to C so that right preconditioning did not mix noise into early iterates; left preconditioning was not nearly as sensitive to the approximation on the transition and noise subspaces.

TABLE 4.4

Discrepancy and GCV consistently chose the same regularization parameter and hence gave the same error for projection plus Tikhonov for 10 to 60 iterations. From the tables, we see that these are not the same parameters as those chosen when applied to the original problem and that, in fact, the solutions for projection plus Tikhonov have smaller error. The errors for the solutions obtained using any of the 3 parameter selection methods applied to find ℓ for projection plus TSVD were also consistent for 10 to 60 iterations, as alluded to in the tables. Figure 4.3 shows the errors from iterations 5 to 60 for projection plus Tikhonov and projection plus TSVD when GCV is used. For Rust's TSVD, the L-curve and discrepancy rules are fairly consistent at picking parameters that give solutions with similar error from iteration to iteration. We note that GCV for Rust's TSVD picked parameters giving solutions with reasonably small errors, even though GCV for Rust's TSVD on the original problem failed, giving a solution with huge error. A similar statement can be made for the L-curve with projection plus Tikhonov.

Summarizing, we observe two phenomena. First, the parameters selected to regularize the projected problem can be different from those chosen on the original problem but still yield solutions of better or comparable error. Second, as this and the previous

Rust's TSVD	(3.0E-1) 7.4E+2	(1.8E-1) 1.2E+4	(3.7) 4.6E-1	(3.9E-1) 4.6E-1
Projection	(9) 4.0E-1	(23) 4.3E-1	(16) 4.0E-1	(12) 3.9E-1

example show, loss of orthogonality does not seem to hamper the parameter selection process, at least not for a reasonable number of iterations. This may be due to the fact that the parameter selection methods are applied directly to the projected problem: for example, the denominator of our GCV function for projection plus TSVD is different from the denominator of the GCV function given in [2, (3.8)].

4.3. Example 3. Our final example is from the field of computed tomography. In this example, the true vector x corresponded to the 20×20 image created with the `phantom.m` function. The matrix A was the corresponding 561×400 Radon transform matrix where it is understood that the data was taken at angles from 0 to 179 degrees in increments of 11 degrees. The matrix itself was computed (albeit naively) in Matlab column by column using successive applications of `radon.m` on images of point sources. The singular values fall off very slowly at first (the first 260 of the 400 singular values range between 18 and about 1) after which they fall off rapidly, resulting in a condition number for A of about 10^7 .

Since the norm of the noise vector was about 3.44, we took the tolerance for the discrepancy principle to be 3. The discrete values λ_i used for Tikhonov regularization were 51 evenly log-spaced points between 10^{-4} and 10^1 . The results computed using discrepancy, GCV, and L-curve methods for Tikhonov, TSVD, Rust's TSVD, and projection on the original problem are given in Table 4.8.

Table 4.9 gives the results after 10 iterations of LSQR. Notice that the errors for the projection plus Tikhonov solutions via GCV and L-curve are slightly better than the corresponding error for Tikhonov without projection at only 10 iterations. Also interesting is the fact that at 10 iterations the discrepancy and GCV methods for projection plus Rust's TSVD give solutions with reasonable errors, whereas these techniques give solutions with very large errors when applied to the original problem.

TABLE 4.9

Example 3, iteration 10: comparison of $\|x_{true} - x_{reg}\|_2 / \|x_{true}\|_2$ for projection plus Tikhonov, TSVD, and Rust's TSVD. Parameter values are given in parentheses.

	Disc.		GCV		L-curve		Optimal	
Tikhonov	(1.0)	4.0E-1	(2.2)	4.0E-1	(1.6E-4)	3.9E-1	(4.0E-1)	4.0E-1
TSVD	(10)	3.9E-1	(1)	8.6E-1	(5)	8.3E-1	(10)	3.9E-1
Rust's TSVD	(1.0)	3.9E-1	(1.5)	4.0E-1	(2.2)	4.0E-1	(0.0)	3.9E-1

TABLE 4.10

Example 3, iteration 40: comparison of $\|x_{true} - x_{reg}\|_2 / \|x_{true}\|_2$ for projection plus Tikhonov, TSVD, and Rust's TSVD. Parameter values are given in parentheses.

	Disc.		GCV		L-curve		Optimal	
Tikhonov	(1.0)	3.9E-1	(1.2)	4.1E-1	(5.0E-1)	4.1E-1	(7.9E-1)	3.9E-1
TSVD	(37)	4.0E-1	(15)	7.8E-1	(39)	4.1E-1	(38)	4.0E-1
Rust's TSVD	(6.0E-1)	4.2E-1	(1.2)	4.1E-1	(2.7E-1)	4.1E-1	(6.6E-1)	4.0E-1

FIG. 4.4. Example 3. Top: Value of ρ_k selected by GCV for projection plus Rust's TSVD; Bottom: Relative error of the corresponding solutions.

Table 4.10 shows the parameters and the errors after 40 iterations. From these results, we see that the L-curve for projection plus Tikhonov eventually gives the same regularization parameter and same solution error as when applied to the larger problem, and we observed this to be true for several iterations beyond 40. Again, we see that discrepancy and GCV used with projection plus Rust's TSVD is effective, whereas they are ineffective when used on the original problem; we observed this behavior well beyond 40 iterations (see Figure 4.4).

5. Conclusions. In this work we have given a common framework for methods based on regularizing a projected problem. We have shown that determining regularization parameters based on the final projected problem rather than on the original discretization has firmer mathematical justification and often involves less computational expense. We presented results that in fact the regularized solution obtained by backprojecting the TSVD or Tikhonov solution to the projected problem is almost equivalent to applying TSVD or Tikhonov to the original problem, where “almost” depends on the size of k . The examples indicate the practicality of the method and illustrate that our regularized solutions are usually as good as those computed using the original system, and they can be computed in a fraction of the time, using a fraction of the storage. We note that similar approaches are valid using other Krylov subspace methods for computing the projected problem.

In this work, we did not address potential problems from loss of orthogonality as the iterations progress. In this discussion, we did, however, assume that either k was naturally very small compared to n or that preconditioning had been applied to enforce this condition. Possibly for this reason, we found that for modest k , round-off did not appear to degrade either the LSQR estimates of the residual and solution norms or the computed regularized solution in the following sense: the regularization parameters chosen via the projection-regularization and the corresponding regularized solutions were comparable to those chosen and generated for the original discretized problem. Another possible reason for the success of our approach is that we chose parameters for the projected problem directly, rather than for the backprojected, larger problem. In our experiments, we found that the parameters selected usually leveled out after a few iterations. The stagnation of the parameters themselves may suggest when k is large enough.

For the Tikhonov approach in this paper, we have assumed that the regularization operator L was the identity or was related to the preconditioning operator; this allowed us to efficiently compute $\|r_\lambda^{(k)}\|$ and $\|x_\lambda^{(k)}\|$ for multiple values of λ efficiently for each k . If L is not the identity but is invertible, we can first implicitly transform the problem to “standard form” [19]. With $\bar{A} = AL^{-1}$, $\bar{x} = Lx$, we can solve the equivalent system

$$\min_{\bar{x}} = \|\bar{A}\bar{x} - b\|_2^2 + \lambda^2 \|\bar{x}\|_2^2.$$

Then the projection plus regularization schemes may be applied to this transformed problem. Clearly the projection based schemes will be useful as long as solving systems involving L can be done efficiently.

A Unified Discipline of Subsurface Sensing and Imaging Systems

M. B. Silevitch, S. W. McKnight, and C. Rappaport
Center for Subsurface Sensing and Imaging Systems (CenSSIS)
Northeastern University, Boston, MA 02115

Abstract

Subsurface sensing and imaging seeks to locate and identify objects or conditions underneath an obscuring media by monitoring a probe or wave outside the surface. Many of the mathematical and physical models used in this process are common to underground and underwater environmental exploration, medical imaging, and three-dimensional microscopies, allowing a common framework of physic-based signal processing (PBSP) to be applied. The basis for a unified discipline of subsurface sensing and imaging can be identified from a few general subsurface *information extraction strategies*. These strategies and their related families of PBSP algorithms can be used to guide a systems-oriented approach to subsurface solutions.

1. The Need for a Unified Discipline

The problem of imaging under a surface arises in a wide variety of contexts, and these problems are among the most difficult and intractable system challenges known. Place one hundred plastic landmines on top of a cleared field and they can be safely removed in hours by trained workers. Bury them under one centimeter of soil, and you have a problem that has been the subject of intensive research for over half a century and remains far from solved. State-of-the-art inductive sensors in the hands of an experienced operator can detect non-metallic mines from the signal received from the firing pin and other small metal parts. In typical operation, however, over 300

false alarms are recorded for every mine identified, each requiring lengthy and delicate examination. In the end, operational mine detection systems have little, if any, advantage over probing each square centimeter of the ground with a titanium rod, a process that can clear a field at a rate of 1 meter by 25 meters of ground per person per day. No one has any idea how the three million landmines buried in Bosnia or the 10 million in Cambodia can be removed at any reasonable cost.¹

De-mining, in common with nearly all subsurface sensing and imaging problems, is an *information* problem. If we could see precisely where the mines were buried, world-wide humanitarian de-mining could be achieved with available physical resources. Yet in an Information Age, when the cost of computation and communications is reduced by a sizable fraction each year, the full potential of applying our exponentially expanding information technology sector to subsurface problems has not been realized because of lack of equivalent progress in subsurface detection and identification.

In addition to the technical problems of probes and processing that we will discuss below, we identify two major systems obstacles to progress in subsurface sensing and imaging:

- 1) the problems of sensor design, modeling, image processing, and recognition have been compartmentalized, viewed as separate disciplines rather than as integrated parts of a *system* optimization problem.

- 2) the subsurface problems in different media and different length scales are commonly viewed as unrelated problems and addressed with *ad hoc* solutions. Lessons learned in one subsurface technology are rarely applied to other problems, and no overarching theory exists to identify fundamental limitations, predict what can be detected and the optimal way to do it.

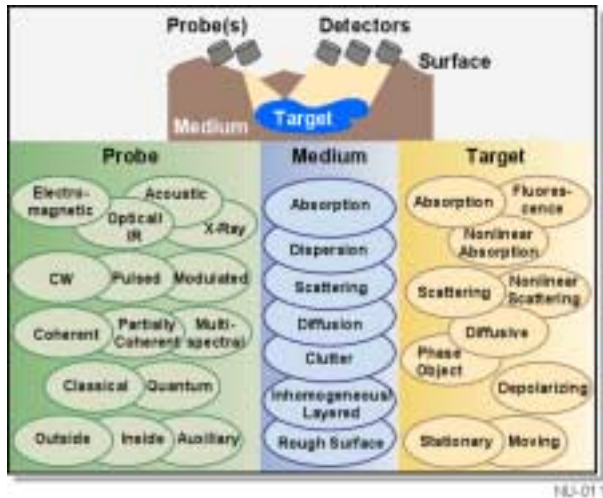

Figure 1. Subsurface problems can be classified on the basis of the probe-medium-target interactions.

Figure 2. A unified physics-based approach can unite subsurface problems from many domains at different length scales.

The subsurface sensing and imaging problem is to extract information about a subsurface target from scattered and distorted waves received above the surface. Imaging techniques, whether ultrasound sensors in tissue or electromagnetic probes in soil, can be described by the properties of probe wave, the wave propagation characteristics of the medium and surface, and the nature of target/probe interaction as shown in Figure 1. The framework of Figure 1 describes not only underground imaging, but also underwater imaging, medical imaging inside the body, and 3D biological microscopies inside a cell or collection of cells. A unified theory of subsurface sensing and imaging, as illustrated in Figure 2, should encompass all of these applications and permit progress in one domain to be transparently applied in other domains with similar elements in the taxonomy of Figure 1.

For example, diffusive wave optical imaging for medical diagnosis and crosswell electromagnetic induction tomography for geophysical exploration both involve extracting an image of, or

information about, anomalous regions (e.g., diabetic lesions under the skin or oil-bearing rock formations under the ground; see Figure 3). Although the problems occur on vastly different length scales, both require solution of the frequency-domain diffusion equation in the presence of an inhomogeneous, layered medium, and a need to filter large data sets from multiple transmitters and receivers that are, nevertheless, sparse compared to the information set sought. Attacking these two problems within the same framework allows the synergy of the two solutions to be exploited. Thus, even the critical differences between the two problems (lossy vs. lossless propagation, Poisson vs. Gaussian noise statistics, the diffusion equation as a limit of the radiative transfer equation vs. the diffusion equation derived by neglecting the displacement current in Maxwell's Equations) become a basis for more complete understanding of the unified problem, rather than just an obstacle to applying the same specialized algorithm to each problem.

2. Physics-Based Signal Processing

It is rarely the case that we cannot get any information from the subsurface region. The concealing media, while not transparent, can usually be penetrated to a considerable depth by a

Figure 3. The physical/mathematical framework of diverse problems can be very similar.

variety of acoustic and electromagnetic wave probes. The problem is that the target signal is distorted by complex absorption, dispersion, diffraction, and refraction of the wave through the media and obscured by surface reflection, subsurface clutter, and scattered energy from unknown inhomogenities on many scales. The signal received, y , depends on the target

information x and various signal-dependent clutter and nuisance parameters z through the function C which describes the physics of the probe-wave generation, propagation, and target and clutter interaction:

$$y = C(x, z) + n \quad (1)$$

The inverse problem of un-encoding the signature of the target object x from the received signal y in the presence of unpredictable clutter signals due to z and noise, n , is the challenge of subsurface sensing and imaging.

Since the mapping from the target to the sensor depends on unknown information about the subsurface media and target, the inversion from the scattered wave to the target properties is a nonlinear mathematical problem^{2,3}. The use of appropriate physical models of the probe/surface/media/target/ receiver interaction (C in Equation 1) to assist in the solution of that inverse problem is what is referred to as physics-based signal processing (PBSP). PBSP has been identified in a seminal 1998 review article as a key to progress in image formation in complex media.⁴. Physics-based reasoning through the entire image understanding process and goal-directed processing is the most direct path to produce algorithms which are robust to modeling errors and generate accurate reconstructions of the critical information.

The fundamental problem of subsurface sensing and imaging is to differentiate the target of interest from the background scattered return and irrelevant clutter: to distinguish a landmine from the ground-surface and volume-inhomogeneity reflections, roots, stones, or shell-casings, for example. In the pulse-reflection ground-penetrating radar (GPR) simulation in Figure 4 the signal from the plastic cylinder in the lower figure is obscured by the rough-surface reflection in the upper

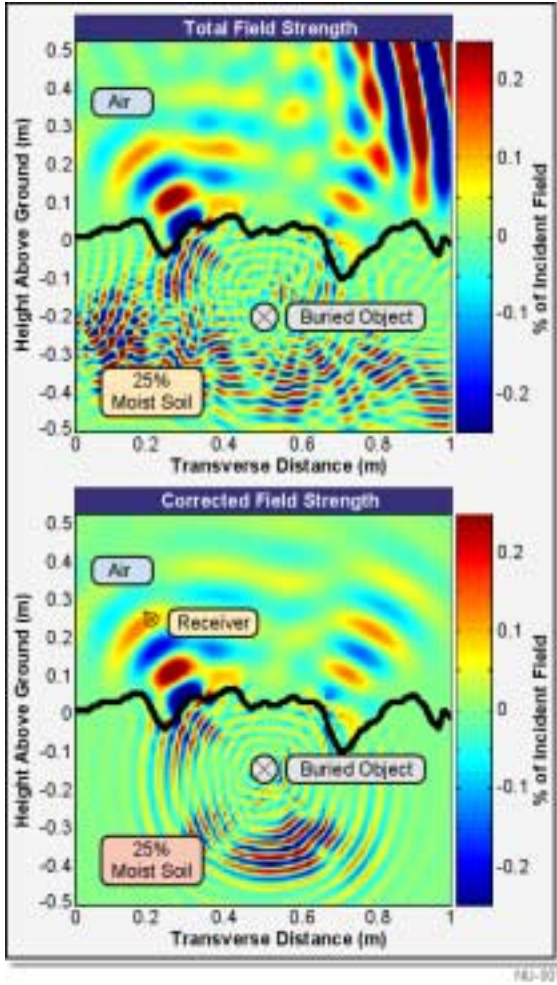

Figure 4. Clutter from rough-surface reflection in the top frame obscures the signature of the buried object in the bottom frame in this pulse GPR simulation.

figure. The task is to extract the signal from the complex scattered field of random surface irregularities. In principle, if the surface profile and the soil dielectric properties were precisely known, one could subtract the calculated background from the received signal to extract the target signature, but a full 3D calculation of the scattered field for a single pulse could take on the order of 10 hours on a 450 MHz desktop Pentium computer.

One of the primary methods of differentiating a target from clutter is through resolution of the target *shape*. Problems where the target distinguishing features are comparable to the clutter size, such as demining, are among the

most challenging subsurface problems that exist. Since resolution in the far-field is limited to order of the wavelength, it is desirable to use probes with wavelengths smaller than the size of identifying features. Unfortunately in most subsurface modalities, absorption increases with increasing frequency (smaller wavelengths). For example, the attenuation of medical ultrasound increases at the rate of 1dB/cm for every megahertz of frequency. Arterial plaque, which can be resolved by inserting catheters containing 30 MHz ($\lambda = 50 \mu\text{m}$) ultrasonic probes, cannot be noninvasively

imaged from outside the body because the attenuation is too severe (about 30 dB per centimeter of depth at 30 MHz). This range/resolution trade-off is a fundamental limitation on many subsurface modalities including underground seismic imaging and underwater sonar imaging.

Alternatively, probes which are sensitive to target *material properties*, such as to material optical response (color), conductivity, permittivity, or magnetic susceptibility, can offer advantages for target differentiation. For example, medical imaging probes such as magnetic resonance imaging or nuclear medicine molecular tags which are sensitive to target chemistry can be used to differentiate targets on the basis of *physiology* (functioning) instead of *anatomy* (structure). Imaging the subtle physiological differences between cancerous cells and normal cells would be a medical breakthrough.

Nonlinear material properties are used for subsurface discrimination in two-photon microscopy^{5,6,7} or ultrasonic harmonic imaging. Harmonic imaging can yield diagnostically useful information on the 25% to 30% of the population that cannot be imaged well by ultrasound due to high clutter levels, distortions, and artifacts. Although harmonic imaging is already commercially available, the physical mechanisms behind it are poorly understood.

Quantitative subsurface imaging, for example measuring low concentrations of contaminants in ground water or determining oxygenation levels in a neo-natal brain, demands a challenging combination of spatial and material differentiation. To image an intensive quantity, such as percent of contaminants, requires 1) a sensing strategy with sufficient material sensitivity to differentiate to the desired measurement precision, and 2) the ability to localize the anomaly to a meaningful region. In this case the target/background differentiation includes the necessity to distinguish, for example,

a ground-water plume with 5% contaminants from an uncontaminated background and also, if a measurement precision of $\pm 5\%$ is desired, from a plume with 10% contaminants. The ability to differentiate such subtle differences in the presence of unknown subsurface inhomogeneity tests the limits of subsurface imaging.

3. Information Extraction Strategies

Despite the bewildering variety of imaging modalities and techniques covered in the Figure 1 taxonomy, subsurface problems can be organized into a relatively small number of *information extraction strategies* which use similar algorithmic tools. Three broad information extraction strategies are discussed here.

Localized probing and mosaicking (LPM) concentrates the probe wave on a local subsurface region by focusing or time-gating and then assembles these individual pieces of information into an information mosaic. Common to these techniques are problems of concentration, aberration, and registration which may use tools as simple as a lens or as complex as three-dimensional image matching and reconstruction. For example, medical reflection ultrasound and confocal microscopy both collect scattered energy from a subsurface target voxel. In both cases, precise focusing assumes a uniform homogeneous wave velocity, rarely the case in subsurface imaging, and resulting aberrations impede accurate imaging. LPM techniques are subject to obstruction by opaque objects (e.g., bones), and

because reflection geometries are sensitive to high spatial frequencies (interfaces) LPM techniques are poor at detecting low-contrast or phase-only objects. One approach to increasing LPM resolution is to produce a localized modification of the object under study, *e.g.*, by introducing a controlled magnetic field gradient in magnetic resonance imaging (MRI) or through radioactive molecular tags in nuclear medicine.

Wide-scan, high resolution LPM imaging usually requires mosaicking of multiple frames. Figure 5 shows an image of an ocean-floor hydrothermal vent assembled in this way by our Woods Hole Oceanographic Institution collaborators. Errors in image registration and

Figure 5. High-resolution underwater optical image of an ocean-floor thermal vent is assembled by 3D photo-mosaicking techniques. (Photo courtesy of Wood Hole Oceanographic Institution.)

composition techniques contribute to errors on the scale of meters in the large-scale representation of imaged objects, reducing their utility in quantitative oceanography. The use of high-resolution sonar maps to register the optical images is a multi-modality path to the desired capability for high-resolution mapping of hundreds of thousands of square meters with an accuracy of centimeters.

In contrast to LPM where the sensor information is spatially isolated, in *multi-view tomography* (MVT) correlated information from multiple sensors is combined mathematically to create a virtual map of the physical properties of

the target. These systems all involve mathematical inversion of integral equations through linearization, regularization, and integral transforms. Examples include x-ray CAT scanning, diffraction tomography, and synthetic aperture radar.

If multiple view angles are possible, MVT techniques can image obstructed/occluded objects and yield quantitative maps of wave velocity as well as absorption, allowing imaging of phase-only objects. For wavelengths that are short compared to feature dimensions, as in CAT scans^{8,9}, Radon convolution-backprojection algorithms combined with Fast Fourier Transforms (FFT) was first used to achieve 3D feature imaging in the 1970's.

Diffraction tomography¹⁰ is the technique of image reconstruction and resolution enhancement by multiple-view imaging when the wavelength is comparable to feature size. The development of the theory of diffraction tomography by the linearization and Fast Fourier Transform (FFT) inversion of the wave diffraction equations using the filtered back-propagation algorithm was pioneered in the early 1980s.^{11,12} Diffraction tomography has been successfully applied for seismic imaging of near-surface objects, including fossil dinosaur bones¹³ and to ultrasonic imaging^{14,15,16,17}, Applications of diffraction tomography with limited or obstructed field-of-view or with higher-order, non-linear models are at the forefront of the state-of-the-art.

When the wavelength is long compared to feature size, *near-field* tomographic techniques can still yield useful information in geophysical, industrial, or medical applications. In Electrical Resistance Tomography and Electromagnetic Induction Tomography, quasi-static probes and models are used to image contaminants in soil and groundwater and leaks from storage tanks on scales much smaller than the electromagnetic wavelength.^{18,19} Capacitance Tomography is used to image the permittivity

of multiphase pipeline flow components for industrial process control.²⁰ Applications in medical imaging include Electrical Impedance Tomography²¹ and Cardiac Electrical Imaging^{22,23,24}. Figure 6 shows the electric potential on the

heart imaged from the measured potential on the torso by Cardiac Electrical Imaging. The potential

Figure 6. In Cardiac Electrical Imaging (CEI), near-field MVT inversion yields the electric potential on the heart from measured voltages on the torso.

benefits of the enhanced information gained by this technique over standard electrocardiograms (ECGs) are enormous. ECGs have a rate of false diagnosis of myocardial infarctions (Aheart attacks®) as high as 30% which results in unnecessary health-care costs in the U.S. estimated at \$4 billion per year²⁵, while up to 25% of actual heart attacks go unnoticed until evidence of cardiac damage is detected in annual checkups.

Multi-spectral discrimination (MSD) adds the element of frequency discrimination to the spatial resolution sought by LPM and MVT giving a 4-dimensional map (3-space plus frequency) of the object. Combinations of MSD with LPM are common (a color photograph or hyperspectral image are examples). Joint methods for MSD and MVT have received little attention. MSD information extraction methods focus on material dispersion, parameter estimation, image registration, and fusion. Multi-sensor fusion can be viewed as an MSD problem involving, in some cases, probes that differ in modality (acoustic and optical, for example) as well as frequency.

For example, the work^{26,27} illustrated in Figure 7 shows that subtractive imaging at two nearby optical wavelengths can map specific chemical concentrations, such as oxygenated /deoxygenated

hemoglobin (Hb).^{28,29,30} This use of optical spectroscopy to detect chemical indicators of physiological function *in vivo* is promising for diagnostic discrimination. The rich spectral interaction of IR-VIS-UV light with biological molecules, however, causes absorption and strong scattering in tissue^{31,32,33} and makes the localization of emergent light difficult. Light will propagate through a hand, but the strong scattering does not allow imaging of the bone structure. Diffusive Wave Imaging^{34,35} in strongly scattering media is the focus of much current research, including optical coherence tomography^{36,37,38} and *dual-wave* acousto-phonic imaging³⁹ which seek to improve spatial resolution from centimeters to millimeters for precise quantitative diagnosis.

Satellite hyperspectral imaging of the Caribbean Basin has been used to determine the health of coral reef ecosystems and measure coastal erosion⁴⁰. Reflected light is strongly scattered in the water column, by the ocean surface, and by the atmosphere, distorting the spectral information as well as the position of underwater objects. This problem is similar to medical diffusive imaging except on a length scale that differs by orders of magnitude.

The physics of both are modeled by the radiative transfer equation (RTE).⁴¹ However, in diffusive medical imaging, the ratio of absorbed to scattered light is assumed to be small leading to the diffusion equation, while in ocean scattering Beer's law is often applied by assuming the ratio is large. In reality, the physical situation in both cases may be intermediate, and there is a need for more rigorous forward models and more robust

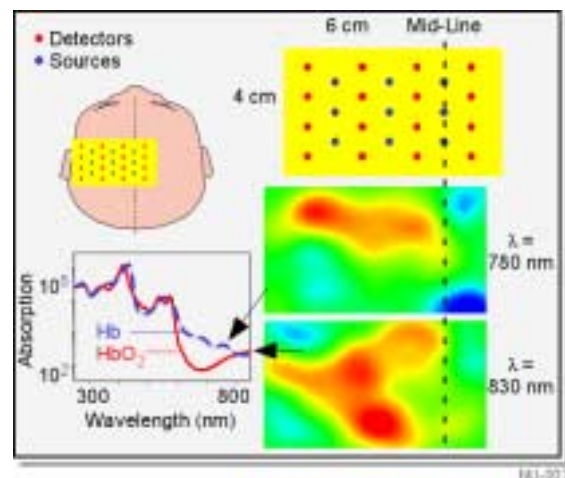

Figure 7 MSD analysis of diffusive optical waves images areas of activity (high blood oxygenation levels) in infant brain.

inversion algorithms. Current spatial resolution from space-based platforms is approximately 1 meter; processing techniques that take advantage of accurate physical models may improve the resolution limit to 10 centimeters.

4. A Systems Approach to Subsurface Sensing and Imaging

Progress in subsurface sensing and imaging approaches within these information extraction strategies has been documented in the feature articles in a recent issue of Science ("Imaging: New Eyes on Hidden Worlds")⁴². Key elements in these advances include the increase in computation power, the application of new mathematical algorithms and advanced sensing strategies, the exploitation of wave coherence, and the fusion of multiple sensing modalities (e.g., microwave and infrared) to extract increasingly detailed information from physical systems.

Still, the need for new technologies is clear. The General Accounting Office has stated, "the dimensions and potential costs of cleaning up our environment are so great that, without innovative technologies, we may find the solution cost prohibitive and impacting on our ability to address other national needs." By using current technologies, the costs of remediating Superfund and Resource Conservation and Recovery Act sites, Federal facilities, and other known hazardous waste sites may total \$750 billion over the next 30 years⁴³. Humanitarian de-mining remains an unsolved problem. No current imaging technique can adequately detect precancerous cell masses in soft tissue or

noninvasively diagnose arteriosclerosis, and there is no way to collect and correlate the images from different modalities to automatically identify incipient health problems.

The path to the solution of these important societal problems lies through the application of the unified framework of subsurface sensing and

imaging to create “end-to-end” systems solutions as shown in Figure 8. A general information

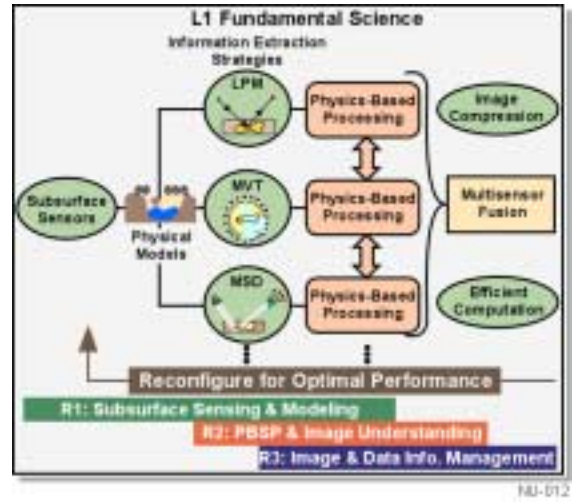

Figure 8. Application of a unified framework of subsurface sensing and imaging will allow the creation of “end-to-end” optimized system solutions.

extraction strategy is based on the common model in Equation 1. This model encompasses all traditional tomographic (MVT) problems: electrical impedance tomography, diffraction tomography, diffuse wave imaging, and the deconvolution and focusing problems associated with LPM and MSD methods such as optical microscopy systems and hyperspectral sensors.

We observe that the number of information extraction strategies is small compared to the number of individual modalities, and there is sufficient commonality in the underlying physical and mathematical structures to develop a unified framework for PBSP techniques. This framework incorporates the relevant physics of wave propagation plus techniques for capturing the effects of random fluctuations in background properties, unknown interfaces, and discrete background clutter.

The end-to-end integration of subsurface sensing mechanisms with advanced algorithms fostered by a unified approach enhances subsurface sensing systems in two ways. First, the physics-based processing and recognition/decision algorithms can exploit the *a priori* knowledge implicit in a deep

understanding of the physics of the wave probe and sensors. Second, the approach to problems from the front-end to final product permits optimization of the entire system--all the way to the sensor modality and configuration--based on the ultimate system objective.

5. Research Needs and Barriers to Progress

Fundamental research on several overlapping levels is necessary to create the desired system solutions of Figure 8. Subsurface Sensing and Modeling research (R1) seeks to elucidate the nature of the physical model contained in C in Equation 1. This includes investigations of fundamental wave interactions in the subsurface media and targets, particularly for non-linear and dual-wave (*e.g.*, acousto-photonic) probes where propagation and scattering mechanisms are poorly understood. Forward modeling plays an important role here. Given a sensor system, the computational model provides the mathematical description of the physics of the device/wave/media/target/receiver interaction problem. We can have reasonable confidence that the physics of the wave interactions is understood only when good agreement can be achieved between a physical model and the sensor data. This forward model then becomes the first step in the inversion process, and may be used repeatedly in iterative reconstructions.

PBSP and Image Understanding (R2) research uses the model C developed from R1 in PBSP algorithms to find x from y . This is the inverse problem which is the core of subsurface sensing and imaging. The difficulties with accurate reconstruction of the required information in x arise from many sources: sparse, limited data collected at surface boundaries, sensor uncertainties, clutter, and the complex nature of the operator C .

To gather enough information to identify subsurface objects in cluttered and noisy environments, large amounts of data may need to be collected from multiple diverse sensors. This can lead to severe computation and data handling tasks. Research in Image and Data Information Management (R3) is needed to develop compression and computation capabilities to link distributed sensors and to implement complex R2 algorithms in near-real-time, allowing sensor reconfiguration to optimize performance.

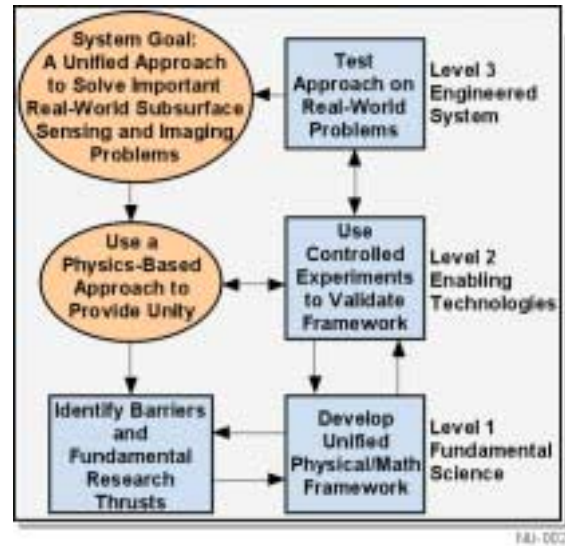

Figure 9. The unified framework enables a top-down approach to sensing and imaging systems solutions.

The path from these fundamental research thrusts to advanced sensing and imaging solutions to societal needs requires a model for goal-directed research and engineering development. In Figure 9 we present one such model based on the National Science Foundation’s Engineering Research Centers Program.⁴⁴ In a top-down focus, we begin with a broad system goal: to create a unified discipline of subsurface sensing and imaging to solve important societal problems. Applying the unified approach of Figure 8 based on the common wave-physics elements, we identify barriers to our goal and select fundamental research thrusts (R1-R3) to address these barriers. The Level 1 fundamental science develops a unified physical/mathematical framework for subsurface sensing and imaging.

At Level 2, experimental testbeds are used to validate the unified framework on well-characterized “ground-truth” scenarios. On this level, the research breakthroughs will be verified

with real data. This will require the development of widely accessible experimental testbeds with reconfigurable sensors in a number of subsurface sensing scenarios. In addition standards for data and metadata need to be developed so that algorithms can be tested in diverse domains at different length scales. As the unified framework is developed and verified it will be used to revise the barriers and research efforts. The verified framework is applied to real-world problems at Level 3, completing the system goal.

Beginning from the unified framework developed in this paper as a first step, we can identify some present barriers to advanced civil-environmental and biomedical detection systems. The major barriers lie both in unsolved fundamental research problems and in lack of adequate technology tools. These barriers are:

Barrier 1: Fundamental knowledge is lacking about nonlinear interactions, dual-wave sensing mechanisms, and coherent imaging in scattering media. While linear acoustic and electromagnetic interactions can be modeled and characterized by well-understood linear response functions, advanced imaging techniques using non-linear or dual-wave (*e.g.*, acoustic/optical) probes require fundamental investigations to determine appropriate physical models.

Barrier 2: The present formulation of coherent inverse scattering is inadequate to quantitatively image objects in highly-scattering random inhomogeneous and cluttered environments. In these situations the non-linear character of the inverse problem defeats tomographic reconstruction and adequate alternatives do not yet exist.

Barrier 3: Recognition strategies for obscured and limited-view subsurface applications are not well developed, and we have no theory for combining different sensor inputs to optimize the information obtained.

Barrier 4: Forward modeling of large complex scattering geometries is too slow for real-time inverse-processing applications. Progress is required in both efficient approximate forward solvers and in hardware/software implementation of processing.

Barrier 5: There are few test facilities with sufficient flexibility and sensor reconfigurability to permit the optimization of sensor modality/configuration and processing strategies based on recognition and decision objectives.

Barrier 6: Techniques for rapid processing, cataloging, storage and retrieval of large image databases are not sufficiently developed. Data and metadata standards will need be instituted so that processing algorithms can be routinely tested on experimental results from diverse experimental domains.

5. Conclusion

The pieces are in place for a major advance in the field of sensing and imaging. The development of a common framework and unified discipline of subsurface sensing and imaging promises to allow the field to emerge as a co-pillar of the Information Age, along with computation and communications. We can look forward to systems-level advances such as integrated, field-tested, algorithmic and computational tools for the entire range of subsurface problems, and standards and criteria for the use of multiple sensing modalities to achieve subsurface sensing system goals. These, in turn, will open the door for the next generation of systems for environmental sensing underground

or under the water, medical imaging and automatic diagnosis inside the body, and biological microscopy to reveal fundamental processes inside living cells.

Laser-Induced Acoustic Imaging of Buried Objects

S. W. McKnight, C. A. DiMarzio, W. Li, and J. Stott

Center for Subsurface Sensing and Imaging Systems

Northeastern University, Boston, MA 02115

Abstract

A 100 mJ, 100ns pulsed CO₂ laser incident on the surface of soil is used as a localized acoustic source for the detection and imaging of underground objects. The acoustic pulse produced by the impulsive heating of the soil surface due to the absorbed 10.6 μm radiation is detected with an acoustic transducer suspended over the surface. Application of a Fourier domain filter enables the separation of the direct acoustic return from the faint echo from an object buried 3-25mm below the surface. Scanning of the laser pulses across the position of a buried object allows the resolution of the shape and the depth of the buried object. The application of this technique to image buried landmines is demonstrated in trials at an outdoor test track.

Keywords: Laser, acoustic, landmine, detection

The detection, location, and ultimate removal of landmines is a challenging and important task. Mines with low metal content pose severe difficulties for the standard electromagnetic induction techniques¹. Often, 300 or more false alarms are observed for every actual landmine detected. A major goal of any new mine-detection technology, then, is to reduce the false alarm

rate of existing techniques. Any technology which provides information on the shape, size, and composition of buried objects may prove useful in this regard. Acoustic detection is attractive in principle because of the large acoustic mismatch between porous soil and solid metallic or non-metallic objects, but difficult to achieve in practice because of the need to couple acoustic energy into and out of the soil^{2,3,4,5}. A laser-induced acoustic imaging system is proposed, and experiments are reported here to validate the technique.

The photo-acoustic effect has been used to produce acoustic pulses for liquid drop studies and materials characterization^{6,7,8}. A short pulse of laser light is absorbed at the surface of the solid or liquid target, resulting in immediate heating and expansion of the material. Provided that the duration of the pulse is shorter than the time required for thermal diffusion to reduce the temperature, the resultant heating will cause expansion, and thus generation of a broad-band acoustic wave. For application to mine detection, the laser pulse would be directed at the surface of the ground over the suspected location of the landmine. The laser-generated acoustic wave reflects and refracts upon encountering buried objects or interfaces. An acoustic receiver placed above the ground will detect the acoustic wave from the surface, and at a later time, will detect the reflection from a buried object, if present⁹.

To test this concept, a pulsed, TEA, carbon-dioxide laser (LSI 150, by Laser Science, Inc.) was used to induce acoustic signals in a box of sand with various buried objects.¹⁰ The laser pulse energy was over 100 mJ, with a typical gain-switched spike about 100 ns long, followed by a tail of several microseconds. The sandbox was moved as shown in the inset in Figure 1 on a grid pattern to produce a raster scan, and the echo at each location was recorded with an acoustic receiver in the air above and an oscilloscope connected to a personal computer.

Two different detectors were used in these measurements. The measurements reported in

the lab used a generic piezoelectric transducer potted in an epoxy cylinder approximately 4cm long by 2cm in diameter. The resonant response of this detector created a high gain signal sharply peaked around 30 kHz. The field trial measurement used a Radio Shack 33-1073A audio microphone with an approximately flat response below 15 kHz. The microphone had a higher sensitivity, but also was much more susceptible to low-frequency noise. The lower frequency microphone also lead to noticeably lower acoustic resolution. The detectors were positioned between 2 and 10cm above the surface of the ground, directly above the laser impact site.

Two typical time histories are shown in Figure 1, one with an ice-hockey puck, sliced in half, buried one centimeter below the surface and one with no buried object. The dominant feature is the ringing of the transducer at approximately 29 kHz, stimulated primarily by the reflection from the air-sand interface, and so the two signals look very similar. The challenge then is to extract the small echo caused by the buried object from the larger surface signal. If the soil surface is level, the laser spot and microphone will remain at the same relative positions, and subtraction of a background signal from a target-free region of ground will reveal the anomaly created by the echo from the subsurface object, albeit strongly modulated by the detector ringing. If the ground is non-uniform, amplitude and phase differences between the target and background time traces will defeat the cancellation by subtraction of the time-domain signals.

Alternatively the signals may be Fourier transformed, the detector response estimated from the no-target signal and removed by a deconvolution. Deconvolution is implemented by dividing the received signal by the no-target signal in the Fourier domain. The problem with this approach is the singularities created at frequencies where the detector response went to zero. To take out these singularities, a deconvolution based on a Weiner filter¹¹ was used.

Under the assumption that the signal consists of the impulse response of the transducer

convolved with a temporal description of the reflectivity as a function of depth, the Fourier transform of the signal, $Y(\omega)$ is the product of the transfer function $H(\omega)$ and the desired reflectivity function $X(\omega)$, plus a noise term, $N(\omega)$.

$$Y=HX+N \quad (1)$$

Straightforward deconvolution would magnify the noise at frequencies where H approaches zero. Instead, the Weiner filter produces an estimate, \hat{X} , of the signal as

$$\hat{X}=Y\frac{H^*}{HH^*+\epsilon} \quad (3)$$

where ϵ is a constant chosen empirically through trial and error. If the magnitude of the transfer function is large, the result is:

$$\hat{X}\approx\frac{Y}{H} \quad (4)$$

which implements a deconvolution, while for small magnitudes of H ,

$$\hat{X}\approx Y\frac{H^*}{\epsilon}$$

which implements a matched filter. The function H can be determined from the Fourier transform of a pulse where the laser is not near the target.

The constant parameter ϵ is chosen by examining the Fourier transform of the data and selecting a value that was equivalent to the signal level at a cut-off frequency about 50 kHz. The data above the cut-off frequency was discarded since the piezoelectric transducer response was

reduced by a factor of 40 from the peak response near 30 kHz. In practice, the selection of the high-frequency cut-off and the value of ϵ did not make a large difference in the quality of the deconvolution.

To test the ability to distinguish depth, the puck was tilted as shown in the Figure 1 inset, and the sand box was moved in the x-direction with respect to the fixed laser and detector so that the laser spot passed directly over the center of the puck. The vertical slices (constant position) through the resulting data processed through the Weiner filter, shown in Figure 2, clearly demonstrated the ability to resolve depth and to effectively filter the signal even under an uneven surface. At our measured speed of sound in dry sand of about 300 m/s, the time delays in Figure 2 correspond to a distance under the surface of between 0.3 to 1.2 cm, consistent with the tilt of the target puck.

A half-hockey puck was buried horizontally less than 1 cm below the surface and horizontal (constant time delay) slices were also developed to show the strength of the signal at each individual depth as the target was scanned in an x-y plane. Each such slice imaged the surface of the puck at a given depth. All the slices between time delays of 45-60 μ s (depth from 0.7-0.9 cm) were summed to produce the projection shown in Figure 3. The outline of the puck is shown by the dashed line to illustrate that the shape is also quite well resolved in two dimensions.

At the 29-kHz resonant frequency of the transducer the acoustic wavelength in dry sand is about 1 cm, and we have measured an pressure-field absorption length ($1/\alpha$) close to 30cm (assuming $1/r$ spreading). Experiments conducted with a microphone with a response from 0-15 kHz produced noticeably poorer resolution. At higher frequencies it is anticipated that resolution will improve and absorption will increase, with an optimal frequency at some yet-to-be-determined value.

To evaluate the usefulness of this technique for application to demining, we conducted a field test of the system at an outdoor test facility. The test track is a 25 x 3 meter section of screened loam traversed by an instrument cart on rails. The laser and electronics were mounted on the cart and pushed over the location of a known mine simulant, a 5.6 cm-diameter plastic M-14 antipersonnel mine with the charge replaced with inert silicone filler and buried 2.5 cm below the surface. The laser was focused with a lens to a spot size about 5mm in diameter and the detector, an audio microphone, was mounted on the cart about 2 cm from the ground surface near the incident laser spot. The cart was moved so the laser pulse crossed the center of the known mine location and stopped every 1.3 centimeter so the acoustic signals from eight laser pulses could be recorded and averaged.

To allow for variations in the ground surface that affected the intensity of the acoustic signal, the signals were Fourier transformed and normalized before applying the Weiner filter. The filtered signal is shown in Figure 4 as a function of laser position with respect to the known position of the mine simulant as indicated. The trace indicates a clear anomaly at a position between about 20 and 30 cm corresponding to the position of the buried mine. The return from the mine at about 0.2 ms time delay is weak, but the modification of the acoustic signal from the plastic mine and the disturbed soil with respect to the undisturbed soil creates a pronounced ringing in the filtered signal that extends for almost a millisecond after the initial pulse.

The Weiner filter was not as successful in reconstructing the impulse echo as in the laboratory test, perhaps due to the limited dynamic range of the sampling oscilloscope, and the image is larger than the diameter of the M-14 simulant, possibly as a result of the imaging of the disturbed soil caused by the simulant emplacement, or the lower resolution of the microphone frequency range. Nevertheless, the existence of an acoustic anomaly at the position of the buried mine simulant is evident in Figure 4.

Additional information could be obtained if multiple acoustic sensors are used, for example, through the use of a multiple-beam laser vibrometer, scanned with the incident laser beam. The shape information attainable with laser-induced acoustic imaging, combined with additional information, has the potential to reduce the false-alarm rate associated with landmine detection.

Acknowledgments

The authors are grateful to Robin Cleveland, Ron Roy, and Jim Sabatier for their insights into acoustic propagation in granular media, to Gerry Sauermann and Dan Hogenboom for assistance in the design and implementation of the experiments, and to Eric Miller for suggestions on the signal processing. This work was supported in part by the Army Research Office Demining MURI under Grant DAAG55-97-1-0013 and by the Engineering Research Centers Program of the National Science Foundation under award number EEC-9986821.

Abstract

Simulation code was developed to model monostatic or bistatic radar returns from terrain and discrete objects within the radar's field of view, including subsurface scattering due to complex permittivity inhomogeneities and buried objects, using Born approximations. This code is applied to simulation of return from a mine-like dielectric cylinder buried a few inches below the surface. Clutter sources included are: scattering from the rough surface above the mine and subsurface random permittivity inhomogeneities. Simulated images of received power from a subsurface region are obtained with and without the mine and the results will be compared with experimentally-obtained images of the region. Depth resolution of a few inches is obtained by using a focused linear array of 4 transmitters and a linear array of 4 receivers identical to and parallel to the transmitter array. The illuminated subsurface volume is between the two arrays. The detector scans the volume by varying relative delays between array elements such that, at a given time instant t_1 the signals arrive at a point p_1 and returns from p_1 arrive at the 4 receivers with equal delays. Superposition of received signals at time t_1 favors returns from a small volume around p_1 . At time t_2 all energy is similarly focussed on a different point p_2 . The process continues until the entire volume has been scanned and an image of the region has been generated. Sensitivity to mine dimensions, composition and burial depth and soil parameters is demonstrated.

1 INTRODUCTION

This paper describes a frequency domain simulation of a GPR scenario involving a bistatic focused array radar system attempting to detect and locate a mine in the presence of clutter. The clutter sources are: the rough surface at the air-soil interface above the mine and a random distribution of complex permittivity throughout the subsurface region containing the mine.

In the next section we briefly discuss the modeling of the propagation of the transmitted wave into the soil, its reflection from the interface and scattering from underground objects and regions of deviation of permittivity from its mean value.

In the section following that we describe the focused array scheme and the way in which we have attempted to simulate its application to the mine detection and location scenario of interest in this investigation.

Finally, some results of the simulation are presented in the form of 3- D plots of the amplitude of the received signal against depth and horizontal distance along the array axis. These plots, in showing the distribution of received radar signal energy within the region containing the mine, seem to demonstrate that the mine signals exceed the component of clutter due to subsurface permittivity inhomogeneities. However, the clutter component due to surface reflections is comparable to or larger than the mine signal; hence the latter can not be seen except through time delay resolution.

Some interpretations of the results and some conclusions are presented in the last two sections of the paper. Also discussed are both ongoing and planned enhancements and modifications designed to improve the accuracy of the modeling on which the simulation code is based.

There is a large literature on the modeling of scattering from rough surfaces [1, 2, 3] and volume scattering due to permittivity inhomogeneities [4, 5]. The simulation code used in this study is based on established theoretical models detailed in the cited references. In using these models in the context of this study, we adapted them to the simulation format, i.e. the scattering algorithm is always applied to a small surface element or a small volume element and the incidence and scattering angles for that element depend on the relative positions and orientations of transmitter, receiver and element. Hence, regardless of the specific scattering model used, the code must produce a complex bistatic scattering matrix for arbitrary incidence and scattering angles.

2 SUMMARY OF BACKGROUND ANALYSIS

The theoretical background for the simulation algorithms dealing with received radar signals from earth surface terrain and discrete objects above the surface is given in [6]. The extension to include signals from below the surface [7, 8] will be summarized below.

The algorithm for computation of the received signal voltage in a single receiver at point 2 due to scattering from a small volume centered at point p irradiated by a transmitter at point 1, is based on the vector Born approximation. The geometry is illustrated in Figure 1(a). The 2- D grid of earth surface elements in the x - y plane, numbered 3 to $N+2$, is shown in (b). To include subsurface scattering, this grid is extended to 3- D , where the third dimension is depth $-z$, as illustrated in (c).

Given M depth layers, the volume elements ("cells") in the first (top) layer are numbered $N + 3$ to $2N + 2$, the next layer $2N + 3$ to $3N + 2$ etc. until the deepest layer to be covered by the simulation is reached, its cells being numbered $MN + 3$ to $(M + 1)N + 2$.

Figure 1: Illustration of problem geometry and 3-D grid

In the generic simulation code described in [6], the single scattering specialization of the received signal voltage is the coherent superposition of the singly-scattered returns from all of the numbered cells. For GPR cases, there are N surface scattering processes and MN volume scattering processes.

The \mathbf{E} -field vector of the transmitted wave at a surface cell q is

$$\mathbf{E}_q = \hat{\Theta}_{1q} E_{\Theta_{1q}} + \hat{\phi}_{1q} E_{\phi_{1q}} \quad (1)$$

where $\hat{\Theta}_{1q}$, $\hat{\phi}_{1q}$ are unit base vectors in the spherical coordinate frame $(r_{1q}, \Theta_{1q}, \phi_{1q})$, centered at 1, and where

$$E_{\Theta_{1q}, \phi_{1q}} = \left[\sqrt{(P_T/4\pi) G_{T0} |f_T(\Theta_{1q}, \phi_{1q})|^2} \right]_{v, h} \exp(-jk_0 r_{1q}) / r_{1q} \quad (2)$$

In (2), P_T , G_{T0} and $f_T(\Theta, \phi)$ are respectively the peak transmitted power, peak antenna gain and complex voltage radiation pattern of the transmitter for vertical ("v") or horizontal ("h") polarization. These polarization directions are defined with respect to the transmitter's local coordinates.

Assuming the air-soil boundary to be horizontal on average and the soil medium to be a LHI half-space on average, the mean \mathbf{E} -field at the center of volume cell p due to downward propagation from surface cell q is (in vector-matrix form)

$$\mathbf{E}(\mathbf{r}_{qp}) = [T_{01}] \cdot \mathbf{E}(\mathbf{r}_{oq}) \exp(-j\mathbf{k}_1 \cdot \mathbf{r}_{qp}) \quad (3)$$

where the tangent plane approximation is used to determine the field just below the surface at q , $[T_{01}]$ is the 3 by 3 matrix of transmission coefficients for downward propagation from air into the soil medium at the point q , and the Stratton-Chu integral [9] evaluated by stationary phase is used to obtain the field at p , thereby excluding wave fields from other surface cells. In (3), \mathbf{k}_1 is the propagation vector for the soil medium, $\mathbf{E}(\mathbf{r}_{qp})$ and $\mathbf{E}(\mathbf{r}_{oq})$ are the field vectors at points p and q respectively, and \mathbf{r}_{qp} and \mathbf{r}_{oq} are respectively the vectors from q to p and from the origin to q .

The "forward path" portion of the computation is the coherent superposition of the fields as given by (3) over all surface cells q and all subsurface volume cells p , resulting in a field vector in every volume cell along the propagation path from a surface cell illuminated by the transmitted wave.

The next phase of the algorithm is the "return path" portion of the computation, whose inputs are the fields given by (3) for all cells p . The first order field vector just below a surface cell q' at position $\mathbf{r} = \mathbf{r}_{oq'}$ due to upward propagation from all volume cells p centered at points $\mathbf{r}' = \mathbf{r}_{op}$, based on the vector Born approximation, is given by

$$\mathbf{E}(\mathbf{r}) = -k_0^2 \int \int \int dx' dy' dz' \bar{G}(\mathbf{r}/\mathbf{r}') \cdot \mathbf{E}(\mathbf{r}') (\Delta \in (\mathbf{r}')) \quad (4)$$

where $\Delta \in (\mathbf{r}')$ is the deviation of complex permittivity from its mean value at \mathbf{r}' , $\mathbf{E}(\mathbf{r}')$ is the field calculated by (3), $\bar{G}(\mathbf{r}/\mathbf{r}')$ is the dyadic Green's function, and in the necessarily digitized algorithm to implement (4), $\mathbf{r}' = \mathbf{r}_{op} = (x', y', z')$ is the vector from the origin to p .

The field vector just above q' is given by

$$\tilde{\mathbf{E}}(\mathbf{r}_{oq'}) = [T_{10}] \cdot \mathbf{E}(\mathbf{r}_{oq'}) \quad (5)$$

where the field components on the right-hand side are those on the left-hand side of (4) and $[T_{10}]$ is the matrix of transmission coefficients for upward propagation from the soil medium back into air.

Again using Stratton Chu, this time to evaluate the field at the receiver due to propagation from q' , we obtain

$$\mathbf{E}(\mathbf{r}_{q'2}) = (K \exp(-jk_0 r_{q'2})/r_{q'2}) [S(\mathbf{r}_{q'2}/\mathbf{r}_{oq'})] \tilde{\mathbf{E}}(\mathbf{r}_{oq'}) \quad (6)$$

where $\mathbf{r}_{q'2}$ and $\mathbf{r}_{oq'}$ represent the vector from q' to the receiver at point 2 and the vector from the origin to the point q' respectively, $\tilde{\mathbf{E}}(\mathbf{r}_{oq'})$ and $\mathbf{E}(\mathbf{r}_{q'2})$ are respectively the field on the left side of (5) and that at the receiver, $[S(\mathbf{r}_{q'2}/\mathbf{r}_{oq'})]$ is a surface scattering matrix derived from Stratton Chu (including the coherent part from the flat mean horizontal surface and the incoherent part due to the surface roughness) and K is a constant given by

$$K = \sqrt{A_{e0} |f_R(\Theta_{2q'}, \phi_{2q'})|^2 \sigma_0 / 4\pi}$$

where A_{e0} is the receiver's peak effective aperture area, $f_R(\Theta, \phi)$ is the receiving antenna's complex voltage receptivity pattern and σ_0 is the peak value of the bistatic scattering cross-section, to whose square root the elements of $[S]$ are normalized. The angles $\Theta_{2q'}$ and $\phi_{2q'}$ are in the receiver's

coordinate frame. They correspond to v and h polarizations with respect to the receiver's coordinate frame, in general different from their counterparts in the transmitter's frame.

Finally we obtain the v and h voltages in the receiver by taking projections of the field vector as given by (6) onto the receiver's aperture plane in the directions along that plane corresponding to those polarizations.

Superposing the computations in (1) through (6) over all MN volume cells and further superposing scatterings from the N surface cells, we obtain the return from the 2- D surface grid and the 3- D volume grid directly below it.

3 THE FOCUSED ARRAY GPR SYSTEM

The focused array scheme [10], shown in Figure 2, is based on two parallel linear arrays, one of them an array of four transmitters parallel to a horizontal axis which we label x . The second array, that of four receivers, is also parallel to the x axis and separated from the transmitter array by a distance $2Y$ in the y direction. The y axis is set midway between the two arrays. In both arrays, the x -separation distance between elements is X ; hence the length of each array is $3X$. The x -origin is at the center of the array. All array elements are at height Z and they are designed to be identical. We can infer from all this that transmitter T_1 is at position $(-1.5X, -Y, Z)$, T_2 at $(-.5X, -Y, Z)$, T_3 at $(.5X, -Y, Z)$ and T_4 at $(1.5X, -Y, Z)$. Corresponding receiver positions are R_1 at $(-1.5X, Y, Z)$, R_2 at $(-.5X, Y, Z)$, R_3 at $(.5X, Y, Z)$ and R_4 at $(1.5X, Y, Z)$. The current values of these parameters are: $X = 10''$, $Y = 5''$, $Z = 15''$.

Figure 2: Geometry of Focused Array System

The vehicle-mounted mine detection assembly is moved in the y direction. Every three seconds it scans a specified subsurface volume directly below the pair of arrays, as shown in Figure 2. The volume scanned is envisioned as a rectangular 3-D grid of volume elements containing 16, 1 and 64 in the x , y and z directions respectively. To focus on a particular volume cell centered at point p , pulses are triggered at transmitters T_1 , T_2 , T_3 and T_4 at time instants t_1 , t_2 , t_3 and t_4 respectively in such a manner that they arrive at p at precisely the same time. (Ideally these pulses are conceived as impulse waveforms so that it is possible to define their times of arrival exactly.) The receiver R_1 sees the superposition of the signals from p due to all four transmitters at a time instant $t_{1'}$. R_2 , R_3 and R_4 see the superposition of signals from p at $t_{2'}$, $t_{3'}$ and $t_{4'}$ respectively. The received pulses that the timing algorithm indicates to be from p are then delayed in each receiver such that the effective arrival times for the pulses from p are exactly the same for all four receivers (i.e. the induced delay in R_2 is $t_{1'} - t_{2'}$, that in R_3 is $t_{1'} - t_{3'}$ and that in R_4 is $t_{1'} - t_{4'}$). Then the artificially delayed signals from p are superposed, resulting in a total signal from p consisting of a sum of sixteen signals whose path delays are all equal, i.e. a sharply focused return from p in the ideal case where the transmitted signals are impulses. The sixteen returns from other points within the grid arrive with different delays and hence should be weaker than the signal from p .

The scanning process performed by the system consists of application of the timing protocol as described above to each cell in the grid during the three second scan period, searching for especially strong signals from a particular region of the grid, indicating the presence of a mine.

The task of computing the radar return from all of the cells in the subsurface grid for all sixteen transmitter-receiver position pairs is straightforward for our simulation software. To execute that phase of the simulation we choose the subsurface grid of numbered cells, as described in Section 2, to closely match the grid defined by the timing algorithm in the actual system. This cannot be done exactly without incorporating that algorithm into the simulation code. It is done approximately, maintaining the feature that the numbered grid cells in the code used to compute the radar signals are all of the same size. The vertical dimensions of the cells of the scanned grid in the system itself are different, being dependent on the timing protocol. Because of refraction at the interface and the phase velocity difference between soil and air, equal time delays obviously do not correspond to equal depths and hence the vertical dimension of a grid cell is depth-dependent.

The horizontal dimensions of the grid cells used in the radar signal computations are roughly the same as those of the scanning grid. There are 16 cells in the x -direction each 2" wide and 1 cell in the y direction, of dimension 5". There are 64 cells in the z direction, each of dimension .1875", thus covering depths from zero down to 12". The total coverage region of the computation grid is about the same as that of the scanning grid, from $x = -16''$ to $+16''$, from $y = -2.5''$ to $y = +2.5''$ and from $z = 0$ to $z = -12''$.

The computation of the returns from all 16 surface cells and 1024 volume cells for each pair of transmitter-receiver positions includes the evaluation of the electrical path length τ for each return, using an algorithm based on

$$\tau = (1/c) [(r_{1q} + r_{q'2}) + (c/v)(r_{qp} + r_{pq'})] \quad (7)$$

where c and v are phase velocities in free space and the medium respectively and r_{jk} is the distance between points j and k .

In the system used in the field, the probing signal is a 500 picosecond "time domain" pulse. Our simulation code is designed for frequency domain modeling. The program can model the transmitted pulse spectrum, compute the scattering at sampled frequencies throughout the signal band and IFT the resulting set of frequency samples of the return to construct the received signal pulse. This would be the ideal way to apply the code to this problem. However, that process is very CPU time-intensive and hence was not invoked for this first investigation. The simulations were all executed at 1 GHz.

4 RESULTS

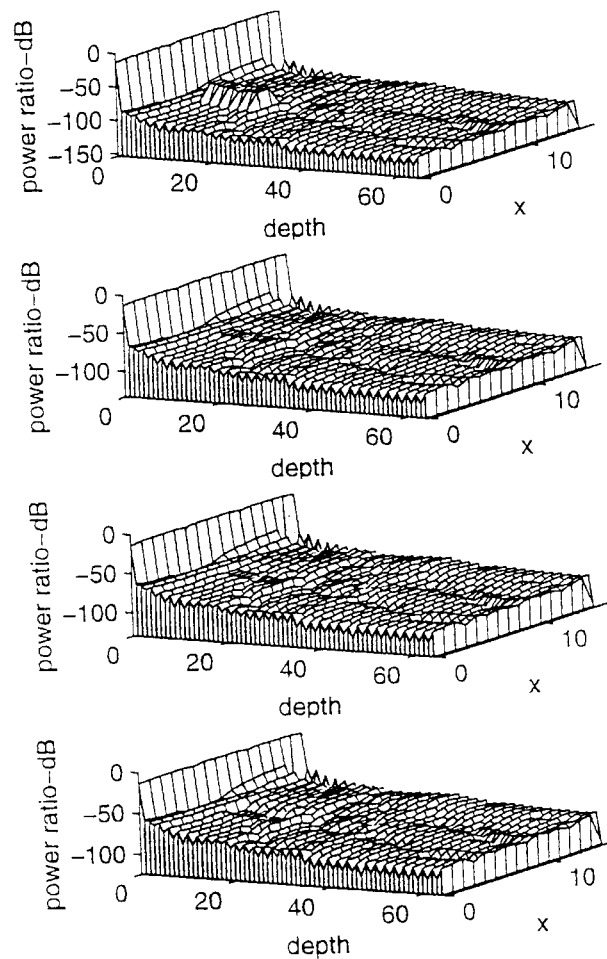

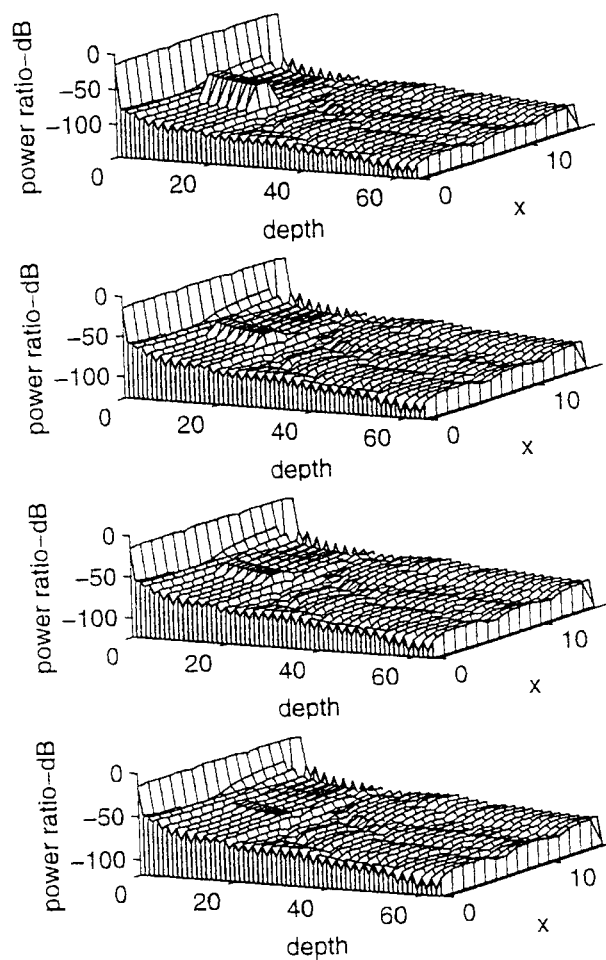

The results to be shown below were obtained by computing the returns from the subsurface grid described in Section 3 for each of the sixteen transmitter-receiver position pairs, then superposing the sixteen amplitudes of returns from each of the 1040 grid cells. This is not an exact simulation of the focused array system's scanning procedure. However, it captures the essential feature of its operation, the superposition of returns from a small volume at various look angles synchronized in time delay so that the return from that region is enhanced relative to that from other regions. The time synchronization can also be achieved in our code by equalizing path delays for all 16 $T - R$ pairs and superposing the resulting returns coherently. In some respects that is closer to the system's true operation than summation of amplitudes. However, it also retains phase differences due to causes other than path delay, so that all 16 sets of returns from the same cell are not really in phase. That detracts from the desired effect and doesn't happen in the actual system, so it would not be a realistic simulation.

The output plots shown here are not in the same format as the experimental results obtained with the time domain system. The latter are acquired by averaging returns from volume cells similar to those generated in our simulation; hence, they contain much less information. An output format like the one we are using allows us to examine in detail the spatial distribution of radar energy to be expected from the illuminated underground region as predicted by our model.

On all of the output plots, the x-axis is along the array axis and is calibrated in cell index numbers in the x-direction, each cell being 2 inches wide in that direction. Thus the x-axis region covered is between $-16''$ and $+16''$. The other horizontal axis is that depth, calibrated in vertical cell index numbers, where each cell is .1875 inches deep, which implies that 64 cells cover depths from 0 to 12 inches. The cell whose vertical index number is 1 is that for the surface return, which is assumed to be resolved by the timing algorithm from the returns from the first depth layer (vertical cell index number 2); hence, the results show the surface return as separated from the underground volume grid returns. In the actual system, the surface return is separated from the total return because it would overwhelm the latter if it were included in the final output display. The ability to resolve surface return from underground returns is a requirement for the feasibility of subtracting it out.

Figures 3,4,5,6:CL,1%,10%,15%,30%

Figures 7,8,9,10:SS,1%,10%,15%,30%

% means percent clutter level
depth in units of 3/16"

x = array axis; in units 2"

CL - clay loam

SS - sandy soil

The vertical axis on the plots is the power received due to scattering from a single cell, where the amplitudes of the returns have been summed over all 16 T - R pairs and the sum has been divided by 16, i.e., the average amplitude (not the average power) has been computed, then squared and plotted in dB relative to the peak transmitted power.

The computed outputs are vpol and hpol components of the returns from all the cells, but the output plots show the square root of the sum of the squares of vpol and hpol returns, i.e., polarization information for each cell has been discarded and we show only the total power for both polarizations.

The source of the clutter model used here is a set of zero mean complex random numbers whose real and imaginary parts have a bivariate Gaussian PDF. The rms values are weighted with assigned fractions of the magnitude of relative complex permittivity of the soil medium. The weighted random numbers are entered into the code as the random variations about the mean of the complex relative permittivity of the underground volume cells. The assigned fractions, multiplied by 100, are designated as "percent clutter levels", e.g., a 1% level means a weighting fraction of .01.

In figure 3-6 and 7-10 respectively, plots are shown for clay loam soil (dielectric constant = 6.2, loss tangent = .145 at 1 GHz) and sandy soil (dielectric constant = 2.55, loss tangent = .03) [11, 12] for a cylindrical dielectric mine (dielectric constant = 3.00, loss tangent = .00033) buried 2" deep, whose vertical dimension and radius are 2" and 1.5" respectively. The surface clutter is shown in all of the plots. Figures 3-6 and 7-10 show how the mine signal becomes less discernible as the clutter level is increased, being clearly distinguishable from the clutter for a 1% clutter level for both soils, still visible at 10% and 15% for clay loam and below 10% for sandy soil. The reason for this difference in mine visibility in the two media is the difference between their dielectric constants relative to that of the mine. This difference is 3.2 for clay loam and -.45 for sandy soil. The ratios of mine contrast to rms clutter are 34 dB and 25 dB respectively for a 1% clutter level. For 10% clutter level, these ratios are 14.3 dB and 5 dB respectively, and they are 10.7 and 1.4 dB for a 15% clutter level. The mine contrast does not descend below the clutter (i.e., the ratio defined above = 0 dB) until the clutter level exceeds 51% in clay loam, but does so in sandy soil when the clutter level exceeds 17.6%.

5 CONCLUSIONS AND DISCUSSION OF CONTINUING WORK

At this stage of the work definitive conclusions about the realism of the results presented here would be premature, since we do not yet have comparisons with experimental results. However, some tentative observations can be made about the potential for use of this simulation code as a forward model for study of mine detection algorithms. The code is based on high frequency approximations and hence cannot be expected to produce images whose accuracy is competitive with purely numerical techniques. It is designed as a fast and easily implemented algorithm to simulate entire systems such as the focused array and to capture the essential features of the

returns from a subsurface region containing a mine.

Our 3-D plots show that the focusing scheme achieves the necessary spatial resolution to provide significant contrast between the region containing a mine and the remaining volume that contains only clutter. The mine image would be still sharper if we fully accounted for the time domain pulse spectrum, which is one of the planned improvements alluded to in the discussion below.

There are a number of ways in which the accuracy of the modeling used to obtain these results can be greatly improved. Work is currently in progress on generalizations accounting for the fact that mines buried only a few inches below the surface are actually in the near zone of points on the surface at frequencies from 0.7 GHz to 1.3 GHz. Hence, the interactions between points on the surface and those on the mine are not really far zone scattering processes. The code is being extended to include some near-zone effects for both forward and return paths. In this approach, the surface integrals are not evaluated by stationary phase; hence waves (not necessarily transverse) propagate in all directions between ground surface and subsurface points, not only in those directions dictated by Snell's law at the air-interface boundary. This generalization results in significantly greater accuracy but greatly increases CPU time. The tradeoff between speed and accuracy for this application will need to be evaluated ultimately by comparing the results with experimental data and determining whether the enhanced modeling accuracy has a significant positive effect on the comparison.

The same remarks would apply to other generalizations that are either in the process of being written or already exist as options in the code. Among these are the time domain modeling of the returns through frequency domain computation of the scattering over the spectrum of the transmitted waveform followed by inverse Fourier transformation, already feasible with the existing code but very CPU time-intensive. Other planned generalizations not yet fully implemented are: inclusion of a distribution of rocks as an additional clutter source, inclusion of higher order interactions between the mine and air-soil boundary, which may have a significant effect on the results for shallow mines, and finally: generalizations beyond the first order Born approximation [13], e.g., first order renormalization [13, 14] and possibly the extended Born approximation [15] (although the latter is most suitable for frequencies below 100MHz). These extensions would decrease the limitations in maximum allowable permittivity contrast between mine and soil that still preserve the validity of the analysis.

Signal processing methods for sub-surface detection

Harold Raemer and Eric Miller

ECE Department and Center for Electromagnetics Research,
Northeastern University, Boston, MA 02115

Sophisticated signal processing methods for the detection and localization of buried objects must be built around a scattering model describing the interaction of the probing energy with the medium parameters of interest (i.e., complex electrical permittivity). These algorithms can assume one of two forms. An imaging-type algorithm would use the forward model as part of an optimization routine to construct a pixel-by-pixel image or volumetric rendering of the subsurface permittivity. Alternatively, in the event that one's primary objective is the localization of known objects such as mines or buried drums of hazardous waste, one would make use of this forward model as part of a more structured object-detection algorithm. This class of algorithms typically employs methods such as template matching, matched filtering, or sequential hypothesis testing and is distinct from an imaging algorithm in that these unknown quantities are the number and spatial locations of the objects rather than a large number of pixel or voxel values.

The forward model to be used in this application is an extension of a simulation program developed by one of the authors, whose purpose was to model radar returns from the terrain surface and discrete objects in the radar's field of view for a wide variety of radar scenarios. The extension, discussed in a paper presented at AP-S/URSI in July 1996 (H.R. Raemer and R. Bilotta, "Simulation of imaging radar returns including underground volume scattering"), adds to the existing capabilities of this software the option of modeling the scattered returns due to a specified volume distribution of complex permittivity deviation from the mean value below the ground surface and spatially resolving these contributions. The simplest option uses the first-order Born approximation for vector fields, accounting for the effects of transmission through the air-earth interface. This can be used to model both subsurface clutter and returns from some buried objects. More advanced options include layered media and hence the effects of reflections from interfaces below the ground surface. Still more advanced options not yet fully implemented involve higher-order vector Born approximations. Some examples of the use of this forward model in the context of the signal processing algorithms referred to above are shown in the presentation. The basis of the simulated scenario is some SAR data on buried objects in desert terrain. The case studies include both buried objects and subsurface clutter due to random spatial variations of complex permittivity.

Effects of wavefield interactions on simulated GPR signals

by Harold Raemer, Carey Rappaport and Eric Miller
Northeastern University, Boston, MA, 02115

In previous papers by the authors (Proc. SPIE 3392, April, 1998, pp 754-765 and Proc. SPIE, April, 1999), work was reported on a frequency domain simulation of a bistatic GPR scenario in which dielectric objects, (e.g. mines) are buried a few inches below the ground surface. Received signals from the objects must compete with surface return, the direct signal, scattered signals from random permittivity fluctuations and clusters of rocks within the illuminated subsurface region. Near-field effects and the influence of surface roughness were partially accounted for in our earlier work. However, the reflections from the underside of the air-ground interface due to first-order scattering from the buried objects and permittivity inhomogeneities were neglected. In the present work, this effect is approximately accounted for in determination of the illumination on a subsurface scatterer. Since the distance between the underground scatterers and the interface are within a wavelength in the frequency region of interest (0.7 to 1.3 GHz), this interaction between them can significantly influence the received signal within specified delay gates from which the object's location is inferred in the signal processing. Simulated image plots of the illuminated subsurface region are shown with the above-mentioned effects included in the algorithm and compared with previous results in which these effects have been neglected.

ABSTRACT

THE CONICAL SPIRAL ANTENNA PROBE FOR UNDERGROUND OBJECT DETECTION

Harold Raemer and Carey Rappaport
Department of Electrical and Computer Engineering and
Center for Subsurface Sensing and Imaging Systems
Northeastern University, Boston, MA 02115

In underground object detection by ground penetrating radar, it is necessary to use an antenna with a bandwidth sufficiently large to accommodate wideband transmitted signals and wide receiver passbands. The high spatial resolution attainable with system bandwidths of the order of Gigahertz is limited by employment of antennas with insufficient bandwidths.

Recently the authors initiated an investigation of the use of a particular class of "frequency independent antenna", the conical spiral, in a GPR application. The antenna is used as a probe, thrust into the ground apex first at an angle of about 60 degrees from vertical and radiating primarily along the cone axis. This antenna offers promise of large bandwidth within the constraints of size and portability. The planned deployment method should provide significant enhancement of the information about nearby buried objects (e.g. mines) than the mechanical probes routinely used in mine detection work.

The basic reference sources are a series of papers published in the 1960's in AP Transactions by Rumsey, Dyson, Yeh, Mei and others, on the theory of frequency independent antennas in general and the conical spiral in particular, in free space. Our investigation extends this work to include the partial immersion of the antenna in a soil medium, the interactions between the antenna and the possibly rough air-ground interface and interactions between the antenna and the buried object that the radar is attempting to detect. The frequency range of interest is 500 MHz to 8GHz.

A MOM computation of the currents on a conical spiral antenna 52 cm. long and with a maximum diameter of 12 cm. immersed in dry sand, followed by evaluation of the near field pattern, was carried out by the authors and reported in a recent conference paper (SPIE Aerosense, Orlando, April, 2001). The present paper is a continuation of that work to include other soil media and to begin to address some of the effects of the air-soil interface and the buried object on the operation of the antenna.

Dear Ms. Kramer:

Enclosed is the revised manuscript of the paper "Near-Field and Timing Effects in Simulation of Focused Array Radar Signals from a Mine in Subsurface Clutter," by Harold Raemer, Carey Rappaport and Eric Miller, whose code number for the SPIE Conference in Orlando in April 1999 is 3710-135. In our recent telephone conversation, I informed you that significant revisions were being made and that I would send you a revised copy before the conference. Since the corrections were made on several pages (Pages 6, 8, 9, 10, 11, 12), please discard the paper you now have and replace it with the enclosed revised version. Thank you.

Sincerely,

Harold Raemer

Near-Field and Timing Effects in Simulation of Focused Array Radar Signals from a Mine in Subsurface Clutter

Presented at Radar 4, Proc. SPIE 3392, Orlando, FL, April, 1999.

Abstract

In a previous paper (Raemer, Rappaport and Miller, Proc. SPIE 3392, Orlando, FL, April 1998) we discussed a frequency-domain simulation of GPR returns from buried mines in clutter due to random permittivity inhomogeneities, using a focused array radar system (Rappaport and Reidy, SPIE 2747, Orlando, FL, April 1996, pp. 202-213). 3-D image plots of the illuminated volume resulting from this simulation were presented and showed that a mine buried a few inches deep in clay loam or sandy soil appears distinguishable from the clutter if the rms deviation of the permittivity from its mean is less than ten percent of the mean permittivity.

The simulation is designed to be a forward model for signal processing algorithms for mine detection and location. Hence, both accuracy and running speed are important considerations. The code discussed in our previous paper is very fast, but contains approximations that compromise the accuracy of the electromagnetic modeling. The recent work on which the present paper is based addresses improvements in accuracy, emphasizing inclusion of near-field effects and more accurate depiction of the timing algorithm that is the basis of the focused array system. The results obtained from the more accurate algorithms require more running time to obtain but are still sufficiently fast for use as a forward model for signal processing.

1 INTRODUCTION

This paper reports continuing work on the subject of a previous SPIE paper [1] on a frequency domain simulation of a GPR scenario involving a focused array system [2] attempting to detect and locate mines in the presence of clutter. The clutter sources are: the rough surface at the air-soil interface above the mines, a random distribution of complex permittivity throughout the subsurface region containing the mines and an aggregate of rocks in that same region.

The modeling of the propagation of the transmitted wave into the soil, its reflection at the interface and scattering from underground objects and permittivity fluctuations were discussed in [1], together with the focused array system and our method of simulating its use in the mine detection and location scenario of interest in this study.

In the work reported in [1] each ground-patch in the surface grid that covers the radar's field of view is assumed to be in the far-zone of both the transmitted and receiver and hence the field of the wave from transmitter to patch and that scattered from the patch toward the receiver have inverse distance dependence. The far-zone approximation also applies to the wave propagating downward from the patch to a volume element of the subsurface grid and that scattered upward from that element toward another surface patch from which it propagates toward the receiver. These may be valid approximations for the deeper regions of the subsurface coverage volume, but tend to become poorer for the more shallow regions, which are in the near-zones of the surface patches.

The objective of the major enhancement of the code for the present paper is to more accurately model the fields in the near zones of their sources. In the general expressions that describe a field from a source in an LHI medium (those specifically used in this study are the Stratton-Chu integral [3] and the Green's Function for the soil medium [4]) the factor $(\exp(-jkR)/R)F(R)$ always occurs. In this expression R is the distance between source and observation point, the real part of k is $2\pi/\lambda$, where λ is the wavelength, and $F(R)$ is a vector-phasor of the form

$$F(R) = c + (a/jkR) + b(1/jkR)^2 \quad (1)$$

where $|a|/|c|$ and $|b|/|c|$ are quantities of the order of unity (no greater than about 3).

The media assumed in this study are complex in general. The factor $|F(R)|$ is approximately unity in the far zone, where $|1/kR| \ll 1$, and hence the last two terms are negligible in (1). However, if we examine the wavelengths in the media assumed in this study at 1 GHz, and the distances between source and observation points where the most important effects occur, we find that these terms are not necessarily negligible and neglecting them can significantly reduce the accuracy of our simulation code.

Far zone analysis predicts only transverse waves. But longitudinal field components are always present in a general analysis. They are negligible in cases where $|F(R)|$ is approximately unity but begin to appear when $|1/kR|$ becomes large enough to compare significantly with 1, since they only exist in the terms proportional to $(1/jkR)^2$ and never in those proportional to $(1/jkR)$, the latter being the far zone terms.

At 1 GHz, the central frequency of the transmitted signal spectrum in this investigation, the free-space wavelength is 30 cm., or equivalently 11.8 inches. In the two media assumed in the study,

clay loam and dry sand, the wavelengths are about 12 cm. (4.7 ") and 19 cm. (7.5 ") respectively. For distances $R = 1$ inch and $f = 1\text{GHz}$, $|1/kR|$ is about .75 for clay loam and about 1.18 for dry sand. Thus for these media and a wide class of other soils whose constitutive parameters have the same orders of magnitude, the second and third terms of $F(R)$ in (1) may have magnitudes comparable to the first term and should not be neglected in the field computation code. This is particularly true for burial depths of the order of 4 inches or less, where the subsurface scattering points are in the near zone of the air-ground interface.

Consider the waves propagating from the transmitter to the ground surface and from ground to receiver. In this scenario the transmitter and receiver heights are 15 inches. The minimum value of R is 15 " and hence the largest value of $1/kR$, based on the free space wavelength of 11.8" at 1 GHz, is about 0.1. This means that the terms beyond the first in $F(R)$ can probably be neglected in most cases without much compromise in accuracy. In the original code, where all scatterers and receiving points were assumed to be in the far-zones of the sources, these terms were always neglected. In the work we are discussing here, no changes have been made in the portions of the code that model the propagation between transmitter and ground and between ground and receiver.

2 BACKGROUND ANALYSIS

The geometry of a subsurface scattering process was illustrated in Figure 1 in Section 2 of [1], which is repeated here as Figure 1.

Figure 1: Illustration of Problem Geometry.

Referring to that figure, transmitter and receiver are at points 1 and 2 respectively and the subsurface scatterer is at point p . The transmitted wave propagated downward toward p intersects the air-ground interface at point q . The wave propagating upward from p toward the receiver intersects the interface at q' .

The surface patch centered at q is small, allowing the incoming wave from point 1 to be approximated locally as a plane wave since the curvature of the phase-front is negligible within the patch. Its traversal of the boundary is treated at point q as if it were a plane wave incident on an infinite horizontal plane and is modeled accordingly. The vertical propagation plane of that wave is the x' , z' plane of a Cartesian coordinate system. The y' components of it's electric ("E") and magnetic ("H") fields immediately below the surface are:

$$E_{qv'}^- = T_{01}^{TE} E_{qv'}^+ \quad (2-a)$$

$$H_{qv'}^- = T_{01}^{TM} H_{qv'}^+ \quad (2-b)$$

where T_{01}^{TE} and T_{01}^{TM} are respectively the transverse electric and transverse magnetic downward transmission coefficients and the E^+ and H^+ on the right hand sides are those immediately above the surface. The arguments of E and H are the vectors from the origin of a global coordinate system to the center of the surface patch at point q .

Since there are many processes of the kind described here in each simulation run and they must be superposed, they must all be in the same coordinate frame. The global Cartesian frame used for this purpose has its x , y plane on the horizontal air-ground interface. Its x axis is at an angle ϕ_{1q} with respect to the x' axis of the primed system alluded to above. Obviously $z = z'$. The field vectors in the global frame are:

$$\mathbf{E}_q^- = \hat{x} \left[-Z_1 H_{qv'}^-, \cos \Theta_t \cos \phi_{1q} - E_{qv'}^-, \sin \phi_{1q} \right] \quad (3-a)$$

$$+ \hat{y} \left[-Z_1 H_{qv'}^-, \cos \Theta_t \sin \phi_{1q} + E_{qv'}^-, \cos \phi_{1q} \right] + \hat{z} \left[-(Z_0/\epsilon_{1R}) H_{qv'}^-, \sin \Theta_i \right]$$

$$\mathbf{H}_q^- = \hat{x} \left[Y_1 E_{qv'}^-, \cos \Theta_t \cos \phi_{1q} - H_{qv'}^-, \sin \phi_{1q} \right] \quad (3-b)$$

$$+ \hat{y} \left[Y_1 E_{qv'}^-, \cos \Theta_t \sin \phi_{1q} + H_{qv'}^-, \cos \phi_{1q} \right] + \hat{z} \left[Y_0 E_{qv'}^-, \sin \Theta_i \right]$$

where

$$\cos \Theta_t = \sqrt{1 - \frac{\sin^2 \Theta_i}{\nu_1^2}} = \frac{1}{\sqrt{\epsilon_{1R}}} \sqrt{\epsilon_{1R} - \sin^2 \Theta_i}$$

where Z_1 and Y_1 are respectively the complex wave impedance and admittance of the medium, \hat{x} , \hat{y} , \hat{z} are the unit base vectors along the global coordinate axes, Θ_i is the angle of incidence of the transmitted wave at q , ν_1 is the complex refractive index, equivalent to the square root of ϵ_{1R} the complex relative permittivity. Z_0 and Y_0 are wave impedance and admittance of free space, where $Z_1 = Z_0/\sqrt{\epsilon_{1R}}$ and $Y_1 = Y_0\sqrt{\epsilon_{1R}}$.

After evaluation of \mathbf{E}_q^- and \mathbf{H}_q^- , these field vectors are viewed as sources of waves propagating downward from point q . More precisely, the surface patch whose center is at q is treated as an

incremental element of the Stratton-Chu integral over the entire ground surface assumed to be illuminated by the transmitting antenna beam. Based on this, the electric field vector at an arbitrary point p within the underground volume is:

$$\mathbf{E}(\mathbf{r}_p) = \frac{1}{4\pi} \int_{\Delta S_q} \int d^2\mathbf{r}_q \left(\frac{e^{-jk_1 r_{qp}}}{r_{qp}} \right) \tilde{\mathbf{E}}(\mathbf{r}_p/\mathbf{r}_q) \quad (4)$$

where

$$\tilde{E}_x(\mathbf{r}_p/\mathbf{r}_q) = -j\omega\mu_0 H_y(\mathbf{r}_q) + d(\mathbf{r}_{qp}) [E_x(\mathbf{r}_q) \cos \Theta_{qp} + E_z(\mathbf{r}_q) \sin \Theta_{qp} \cos \phi_{qp}] \quad (4-a)$$

$$\tilde{E}_y(\mathbf{r}_p/\mathbf{r}_q) = j\omega\mu_0 H_x(\mathbf{r}_q) + d(\mathbf{r}_{qp}) [E_y(\mathbf{r}_q) \cos \Theta_{qp} + E_z(\mathbf{r}_q) \sin \Theta_{qp} \cos \phi_{qp}] \quad (4-b)$$

$$\tilde{E}_z(\mathbf{r}_p/\mathbf{r}_q) = d(\mathbf{r}_{qp}) [\sin \Theta_{qp} (E_x(\mathbf{r}_q) \cos \phi_{qp} + E_y(\mathbf{r}_q) \sin \phi_{qp}) + E_z(\mathbf{r}_q) \cos \Theta_{qp}] \quad (4-c)$$

and where

$d(\mathbf{r}_{qp}) = jk_1 \left(1 + \frac{1}{jk_1 r_{qp}} \right)$, ΔS_q is the area of the surface patch, (Θ_{qp}, ϕ_{qp}) are the spherical polar angles of point p as viewed from point q in the global coordinates and $d^2\mathbf{r}_q$ is a surface element on the patch.

The next phase of the computation is the vector Born scattering [5] from a small volume element centered at p . The general expression for this is given by Eq. (4) of [1], repeated below as Eq. (5).

$$\mathbf{E}(\mathbf{r}) = -k_1^2 \int \int \int d\mathbf{r}' \bar{\bar{G}}(\mathbf{r}/\mathbf{r}') \cdot \mathbf{E}(\mathbf{r}') (\Delta \in (\mathbf{r}')) \quad (5)$$

where $\Delta \in (\mathbf{r}')$ is the deviation of complex permittivity from its mean value at \mathbf{r}' , $\mathbf{E}(\mathbf{r}')$ is the field calculated by (3), $\bar{\bar{G}}(\mathbf{r}/\mathbf{r}')$ is the dyadic Green's function, and in the necessarily digitized algorithm to implement (5), $\mathbf{r}' = (x', y', z') = \mathbf{r}_{op}$ is the vector from the origin to a point within the volume cell centered at p .

The dyadic Green's function in (5) [6] is a symmetric 3×3 matrix given by

$$\bar{\bar{G}}(\mathbf{r}/\mathbf{r}') = -g(R) \begin{bmatrix} G_{11} & G_{12} & G_{13} \\ G_{12} & G_{22} & G_{23} \\ G_{13} & G_{23} & G_{33} \end{bmatrix} \quad (6)$$

where

$$\begin{aligned} g(R) &= e^{jk_1 R}/4\pi R \\ R &= |\mathbf{r} - \mathbf{r}'| \end{aligned}$$

and where the matrix elements are given generically by

$$G_{jk} = BU_j U_k - A\delta_{jk}$$

where δ_{jk} is the Kroneker delta (1 if $j = k$, 0 if $j \neq k$),

$$\begin{aligned} U_1 &= (x - x')/R \\ U_2 &= (y - y')/R \\ U_3 &= (z - z')/R \end{aligned}$$

$$A = \frac{1}{jk_1 R} + \left(\frac{1}{jk_1 R}\right)^2; \quad B = 1 + 3A$$

The observation point in (5) is specialized to the point q' as illustrated in Figure 1. Then counterparts of the steps implemented in modeling the downward boundary traversal at q are executed to model the upward boundary traversal at q' . First, we postulate another primed coordinate system whose x' , z' plane is the propagation plane from q' to the receiver at point 2. The y' component of the electric field immediately below the boundary at q' is obtained from (5) and is given by

$$E_{y'}^-(\mathbf{r}_{q'}) = -E_x^-(\mathbf{r}_{q'}) \sin \phi_{pq'} + E_y^-(\mathbf{r}_{q'}) \cos \phi_{pq'} \quad (7)$$

where $\phi_{pq'}$ is the azimuthal angle of the point q' relative to p in the global frame.

The y' component of the electric field immediately above the patch centered at q' is given by

$$E_{y'}^+(\mathbf{r}_{q'}) = T_{10}^{TE} E_{y'}^-(\mathbf{r}_{q'}) \quad (8)$$

where T_{10}^{TE} is the upward transmission coefficient for the TE mode.

To obtain the TM field above the boundary, we must first evaluate the y' component of the magnetic field immediately below the boundary. Again viewing the upward-propagating wave from p toward q' in the vicinity of q' as approximated by a plane wave, we can calculate the y' component of the magnetic field from the electric field given by (5). The result is

$$\begin{aligned} H_{y'}^-(\mathbf{r}_{q'}) = \\ Y_1 \left[E_x(\mathbf{r}_{q'}) \cos \Theta'_{pq'} \cos \phi_{pq'} + E_y(\mathbf{r}_{q'}) \cos \Theta'_{pq'} \cos \phi_{pq'} - E_z(\mathbf{r}_{q'}) \sin \Theta'_{pq'} \right] \end{aligned} \quad (9)$$

where $\Theta_{pq'}$ is the spherical polar angle of q' relative to p' in the global frame.

Next we calculate the y' component of the magnetic field immediately above q' from that immediately below q' , with the result

$$H_{y'}^+(\mathbf{r}_{q'}) = T_{10}^{TM} H_{y'}^-(\mathbf{r}_{q'}) \quad (10)$$

where T_{10}^{TM} is the upward transmission coefficient for the TM mode.

From (8) and (10), the Maxwell equations with the plane wave approximation and an expression for $(\hat{x}, \hat{y}, \hat{z})$, the unit base vectors in the global frame, in terms of $(\hat{x}', \hat{y}', \hat{z}')$, the unit base vectors in the primed coordinate system, we obtain the components of $\mathbf{E}^+(\mathbf{r}_{q'})$ and $\mathbf{H}^+(\mathbf{r}_{q'})$ in the global frame, given by

$$\begin{aligned} \mathbf{E}^+(\mathbf{r}_{q'}) = & \hat{x} \left[-E_{y'}^+(\mathbf{r}_{q'}) \sin \phi_{q'2} + Z_0 H_{y'}^+(\mathbf{r}_{q'}) \cos \Theta_{q'2} \cos \phi_{q'2} \right] \\ & + \hat{y} \left[E_{y'}^+(\mathbf{r}_{q'}) \cos \phi_{q'2} + Z_0 H_{y'}^+(\mathbf{r}_{q'}) \cos \Theta_{q'2} \sin \phi_{q'2} \right] \\ & + \hat{z} \left[-Z_0 H_{y'}^+(\mathbf{r}_{q'}) \sin \Theta_{q'2} \right] \end{aligned} \quad (11-a)$$

$$\begin{aligned} \mathbf{H}^+(\mathbf{r}_{q'}) = & \hat{x} \left[-H_{y'}^+(\mathbf{r}_{q'}) \sin \phi_{q'2} - Y_0 E_{y'}^+(\mathbf{r}_{q'}) \cos \Theta_{q'2} \cos \phi_{q'2} \right] \\ & + \hat{y} \left[H_{y'}^+(\mathbf{r}_{q'}) \cos \phi_{q'2} - Y_0 E_{y'}^+(\mathbf{r}_{q'}) \cos \Theta_{q'2} \sin \phi_{q'2} \right] \\ & + \hat{z} \left[Y_0 E_{y'}^+(\mathbf{r}_{q'}) \sin \Theta_{q'2} \right] \end{aligned} \quad (11-b)$$

where $\Theta_{q'2}$ and $\phi_{q'2}$ are the spherical coordinate angles of the receiver at point 2 relative to the point q' as origin.

The fields given by Eqs. (11-a, b) at the point q' act as sources for the wave propagating from q' toward the receiver.

The portions of the analysis not explicitly included in the discussion above are:

- (a) the process by which the field components $E_{y'}^+$ and $H_{y'}^+$ in Eqs. (2-a, b) are obtained from the fields generated at the transmitting antenna at point 1;
- (b) the determination of the fields at the receiver due to the wave propagating from q' ;
- (c) explicit indication of the transmission coefficients in Eqs. (2-a, b), (8) and (10);
- (d) evaluation of the surface integral indicated by (4);
- (e) simulation of the focused array system.

Items (a) and (b) are part of the radar simulation program that serves as a framework for the GPR code [7]. Bistatic radar returns from a grid of small ground surface patches are modeled in that program. It includes the effect of the antenna patterns for both transmitter and receiver and the direct signal from transmitter to receiver. The theoretical background for all of the received

signals from scattering regions on or above the ground (i.e. the direct signal and the ground-reflected signals) is covered in [7] and will not be given here, the focus of this paper being returns from below the ground surface, as illustrated in Figure 1. The enhancement of the original code to include subsurface returns begins with the transmitted wave field impinging on the surface patch centered at point q . That field is the source for both the wave scattered toward the receiver from that patch and the wave transmitted across the boundary toward the subsurface point p as described by Eqs. (2)-(11). The patch centered at point q' in Figure 1, which receives the subsurface wave scattered from p , also intercepts a wave from the transmitter and scatters it toward the receiver. All of these processes, executed thousands of times, are the constituents of the overall simulation program. Turning to Item (c), the transmission coefficients in Eqs. (2-a, b) are given by

$$T_{01}^{TE} = \frac{2 \cos \Theta_i}{\cos \Theta_i + \sqrt{\epsilon_{iR} - \sin^2 \Theta_i}} \quad (12-a)$$

$$T_{01}^{TM} = \frac{2\epsilon_{iR} \cos \Theta_i}{\epsilon_{iR} \cos \Theta_i + \sqrt{\epsilon_{iR} - \sin^2 \Theta_i}} \quad (12-b)$$

and those in (8) and (10) are

$$T_{10}^{TE} = \frac{2\sqrt{\epsilon_{iR}} \cos \Theta'_i}{\sqrt{\epsilon_{iR}} \cos \Theta'_i + \sqrt{1 - \epsilon_{iR} \sin^2 \Theta'_i}} \quad (13-a)$$

$$T_{10}^{TM} = \frac{2 \cos \Theta'_i}{\cos \Theta'_i + \sqrt{\epsilon_{iR}} \sqrt{1 - \epsilon_{iR} \sin^2 \Theta'_i}} \quad (13-b)$$

where Θ'_i is the angle of incidence for the wave propagating upward from p toward q' .

Item (d), the surface integration in (4), can be treated in one of two ways, and both options are available in the code. The option used in the computations done for this paper is a straightforward integration over the patch centered at q under the assumption that the field is constant over the patch surface and equal to its value at the center. The patches are small enough to use the standard approximation

$$\exp(-jk_1 r_{qp})/r_{qp} \simeq [\exp(-jk_1 r_{qp})/r_{qp}]_0 \exp(jk_1 \mathbf{r}'_q \cdot (\hat{\mathbf{r}}_{1q} + \hat{\mathbf{r}}_{qp})) \quad (14)$$

where subscript 0 indicates that the point q is at the patch center. This leads to a product of complex expressions for the x and y integrals, each of which degenerates into a sinc function in the limit of zero conductivity.

The other option is to find stationary phase points and to obtain the stationary phase approximation of the integral at only those points. The relative merit of these two approaches is the subject of continuing work but will not be discussed further here. Item (e), the operating principle of the focused array system, was covered in detail in [2] and further summarized in [1] and

will not be repeated here. To simulate the action of the focused array we are required to execute the computation of the received radar signals from the illuminated region 16 times, once for each transmitter-receiver position pair, and combine the outputs of each run of the code for every one of the illuminated volume cells, as explained in [1] (Section 3, "The focused array GPR system").

3 RESULTS AND CONCLUSIONS

The 3D plots in Figures 2 through 9 show outputs of simulations of received signals from a volume directly below the focused array. The horizontal locations of the four transmitters $T_k = 1, 2, 3, 4$ and the four receivers $R_k = 1, 2, 3, 4$ are shown in Figure 2 of [1]. This assembly moves along the y axis ("alongtrack" direction). The x axis ("crosstrack" direction) is parallel to transmitter and receiver array axes, which are at $y = -5''$ and $+5''$ respectively and both of which extend from $x = -15''$ to $x = +15''$ and are at heights of $15''$ above ground. This configuration corresponds roughly to a version of the focused array system used to obtain some of the experimental results we have received from Geo-Centers. The underground volume grid covered in these simulations extends from $-15''$ to $+15''$ in the crosstrack direction, from $-5''$ to $+5''$ in the along-track direction and from the ground surface to a depth of $8''$. Figures are plots of received power (in dB over a given reference level) from each small volume element in the grid, averaged over all 16 transmitter-receiver position pairs, vs. the depth and the crosstrack coordinate (where the latter is calibrated in inches from 0 to 30, rather than from -15 to $+15$, as depicted in Figure 2 of [1]). The scattering computations whose background theory was discussed in Section 2 were performed for each of 3072 volume elements of 1 inch dimension in all 3 directions. There are 32 x elements, 12 y elements and 8 depth elements. For each x and depth value, the received powers from all 12 y elements are summed to generate the total return from a single y element extending from $-5''$ to $+5''$. This refinement of the y scale for the computations addresses a problem that existed in the results presented in [1]. In those earlier simulations the grid used for the computations was the same as the grid used for the 3D output plots, which in turn is the same grid as used to collect experimental data as the moving detector assembly stops to examine a region directly below it (16, 1 and 64 in x , y and z directions respectively, totaling to 1024 elements). The physics of the scattering computations is less accurately depicted if the scatterer dimension in the y direction is 10 inches than if that dimension is only 1 inch. A better simulation of the scattering process is realized by computing the returns from 12 small elements and summing them to generate an output from a single element.

In all of the plots shown, the mine is a slightly lossy dielectric cylindrical object $3''$ high and $3''$ in diameter, with complex relative permittivity of TNT (3, $-.001$) at 1 GHz. Its burial depth is indicated on each figure. The rocks are slightly lossy dielectric spheres with radii between $.75''$ and $1.5''$, burial depth between $1.5''$ and $3''$ and distributed horizontally around the illuminated region, with dielectric constant between 2 and 5. The soil is clay loam or dry sand, with mean relative complex permittivity (6.2, -0.9) or (2.55, $-.077$) respectively at 1 GHz. The clutter from each element is modeled as a bivariate Gaussian distribution of the soil's complex permittivity around its mean. A given "percent clutter" is the ratio of average deviation to the mean value times 100.

Figures 2 and 3 show image plots for a mine buried 2" deep in clay loam soil for 1 and 10 percent level of permittivity fluctuation clutter respectively and Figures 4 and 5 are analogous plots for dry sand. There is no clutter due to rocks in any of these cases. With either soil type, the mine is easily discernible in 1 percent clutter and imperceptible in 10 percent clutter based on modeling not accounting for near field effects. Inclusion of these effects does alter the shapes of the image plots somewhat but does not greatly change the dependence of mine visibility on clutter level on these plots. The near field effects appear to influence the mine signals and clutter signals to about the same extent. In Figures 6 and 7, the effects of 10 rocks in the vicinity of the mine is shown for both soil types, where clutter due to permittivity fluctuations has been suppressed. Even in the absence of such clutter, and more prominently when both rocks and permittivity fluctuation clutter are present (Figures 8 and 9), there appears to be no way to distinguish a mine from one of the rocks with the spatial resolution in our output displays. That resolution is set to be comparable to that in the actual system as provided by the focused array principle in the crosstrack and depth directions, which partially offsets the delay resolution limitations of a 500 picosecond pulse. It would be feasible to improve the resolution in our displays by decreasing the size of the elements in the volume grid used for the output displays and thereby enable discrimination on the basis of shape, but that would reduce the realism of the model and therefore is not a permissible option.

4 CONTINUING WORK

In Section 5 of [1], we cited ongoing efforts to improve the realism and scope of the code. One task was inclusion of near-field effects, which is the major theme of this paper. Another was study of rocks as clutter sources, also included in this paper. Still not implemented are generalizations beyond the first order Born theory, especially effects of reflection of scattered waves from subsurface volume elements from the underside of the air-soil interface, resulting in second order contributions to the illumination of these elements. Another study, now in progress but not mentioned in [1], is the effect of local surface tilt due to large-scale roughness on scatterer locations indicated by the timing algorithm. This could be an important source of distortion of image plots of the return from the illuminated volume. In addition to carrying out the studies indicated above, we are reconstructing the output formats to simulate a scenario that matches the geometry consistent with minefield data received from Geo-Centers, a step required for comparisons with experimental results.

Dear Ms. Steger:

Enclosed is the manuscript for Paper 3752-54, which was officially due on June 21, 1999. In our telephone conversation last week, you agreed to extend the deadline to June 28, 1999. I believe you will receive this before that date.

Thank you for the extension.

Sincerely,

A handwritten signature in cursive script that reads 'Harold Raemer'.

Surface Roughness Effects in Simulation of Mine Signals
Using a Focused Array GPR System

by

Denver, CO, July, 1999.

Abstract

In two previous papers, the authors discussed a frequency-domain simulation of received signals in a focused array radar system (Rappaport and Reidy, SPIE 2747, April 1996, pp. 202-213) illuminating a swath of flat terrain with one or more small plastic mines buried a few inches below the surface and a clutter background consisting of returns from random permittivity fluctuations, aggregates of rocks and the ground surface (SPIE 3392, pp 754-765, April 1998 and "Near-field and timing effects in simulation of focused array radar signals from a mine in subsurface clutter", SPIE, April 1999). The second paper emphasizes generalization of the algorithm to take proper account of the fact that distances between participants in the scattering processes are within fractions of wavelengths, enhancing the importance of near field effects in the modeling.

In the present work, further generalizations are made which enhance the realism of the model. In particular, we investigate the role of surface height variations in changing the apparent propagation delay of the signal from a subsurface region. Since delay is the major discriminant in the processing of received signals in this system, this has a possibly significant effect on the simulated images. Still another generalization under investigation is that of inclusion of surface reflections from the interface's underside on the effective illumination of subsurface regions.

Simulated image plots will be shown and compared with some previous results in order to assess the effects of these enhancements in the model.

1 INTRODUCTION

In this paper we discuss further progress on a study reported in two previous SPIE papers by the authors [1, 2]. The objective of the study is to develop an effective simulation of the received signals in a focused array radar system [3] illuminating a swath of land terrain with small plastic mines buried within a few inches below the ground surface. The ultimate purpose of this simulation is to provide a forward model for evaluation of signal processing algorithms for improvement of detection of the mines in a clutter background. The clutter consists of random fluctuations of the complex permittivity of the soil, aggregates of rocks and returns from the ground surface.

Previous improvements in the accuracy of the modeling [2] were directed toward accounting for the fact that the buried mines, rocks and the permittivity fluctuations from which scattering occurs are within fractions of a wavelength from the ground surface. Hence, near field effects were addressed in [2].

In [2], the air-ground interface was assumed to be horizontal on the average, with the possibility of small-scale fluctuations around the average height.

In the present paper, both small scale and large scale height variations around the horizontal are allowed, with a significant effect on the timing algorithm on which the focused array system is based. Application of that algorithm, which is based on the assumption of a flat horizontal ground surface, results in a distortion of the spatial distribution of the illumination of the underground volume of interest and that of the returns from that volume if the true surface is rough.

2 BACKGROUND ANALYSIS

In Section 2 of [2], aided by a diagram in Figure 1 of [2], we described the background analysis for simulation of the propagation of a ray from a transmitter at point 1 to a subsurface point label p , via a refracting surface point q . The diagram of Figure 1 of [2] then shows a scattered wave from q propagating toward a different surface point q' , from which it propagates toward the receiver at point 2. In that diagram the ground surface is shown as nearly flat and horizontal with very small-scale height fluctuations.

In the code that generated the simulation discussed in [2], the refracting angles at points q and q' are based on the average surface height and are independent of the small-scale height fluctuations. The only assumed effect of these fluctuations is on the scattered wave from the ground surface to the receiver and they have no effect on the returns from the illuminated subsurface region.

Part (a) of Figure 1 in this paper is Figure 1 of [2]. Part (b) of Figure 1 illustrates the generalization that is the subject of the most recent work. The surface in Figure 1(b) is shown to have large-scale height variations on which are superposed small-scale variations like those shown in Part (a). The surface patches centered at q and q' now have an average tilt with respect to the horizontal. As in [2], the small-scale surface fluctuations on the now tilted patch have no effect on the refraction angles, which are based on the average height and tilt angles. However, they do have a significant effect on the surface return, whose ratio of incoherent-to-coherent scattering increases with the small-scale rms height variation.

This generalization complicates the geometry considerably and requires a re-definition of the primed coordinate system used in [1] and [2]. To explain this, some of the equations and associated text will be repeated below, beginning with Eqs. (1) and (2) of [1].

The E-field vector of the transmitted wave at a surface cell q is

$$\mathbf{E}_q = \hat{\Theta}_{1q} E_{\Theta_{1q}} + \hat{\Phi}_{1q} E_{\Phi_{1q}} \quad (1)$$

where $\hat{\Theta}_{1q}, \hat{\Phi}_{1q}$ are unit base vectors in the spherical coordinate frame $(r_{1q}, \Theta_{1q}, \Phi_{1q})$, centered at 1, and where

$$E_{\Theta_{1q}, \Phi_{1q}} = \left[\sqrt{(P_T/4\pi) G_{T0} |f_T(\Theta_{1q}, \Phi_{1q})|^2} \right]_{v, h} \exp(-jk_0 r_{1q})/r_{1q} \quad (2)$$

In (2), P_T, G_{T0} and $f_T(\Theta, \Phi)$ are respectively the peak transmitted power, peak antenna gain and complex voltage radiation pattern of the transmitter for vertical (“v”) or horizontal (“h”) polarization. These polarization directions are defined with respect to the transmitter’s local coordinates.

The magnetic field components of the transmitted wave at q , obtained from \mathbf{E}_q , are

$$H_{\Phi_{1q}} = -Y_0 E_{\Theta_{1q}}, \quad H_{\Theta_{1q}} = Y_0 E_{\Phi_{1q}} \quad (3)$$

where Y_0 is the wave admittance of free-space.

As in [2], we consider the surface patch centered at q to be small enough to allow the incoming wave to be approximated locally as if it were a plane wave incident on an infinite plane (i.e. the “tangent plane approximation.”) But the departure from the analysis in [2] occurs at this point, wherein the plane of the patch is tilted with respect to the horizontal direction. To determine the tilt angles, we first note that the unit normal to the patch at q , pointing into free space, is given by

$$\hat{n}_q = \frac{-(z_x)_q \hat{x} - (z_y)_q \hat{y} + \hat{z}}{\sqrt{1 + (z_x)_q^2 + (z_y)_q^2}} \quad (4)$$

where $(\hat{x}, \hat{y}, \hat{z})$ are the unit base vectors for the global coordinate system and $(z_x)_q$ and $(z_y)_q$ are the partial derivatives of the surface height with respect to x and y respectively at the point q , both assumed constant within the patch.

The orientation angles of the surface normal \hat{n} in the global frame are (Θ_n, Φ_n) , given at q by

$$\Theta_{nq} = \cos^{-1} \left(\frac{1}{\sqrt{1 + (z_x)_q^2 + (z_y)_q^2}} \right), \quad \Phi_{nq} = \cos^{-1} \left(\frac{-(z_x)_q}{\sqrt{(z_x)_q^2 + (z_y)_q^2}} \right) \quad (5)$$

A local coordinate system (x'_q, y'_q, z'_q) is constructed such that the z'_q axis is in the direction of the surface normal \hat{n}_q as given by (4) and the x'_q axis is along the projection of the incident wave’s propagation vector \mathbf{k}_i (from the transmitter at point 1 to q) onto the $(x'_q - y'_q)$ plane (Figure 2). The plane of propagation, no longer necessarily vertical as it was in [2], is the $x'_q - z'_q$ plane. The y'_q axis is normal to the plane of propagation. Thus the unit base vectors are given by

$$\hat{z}'_q = \hat{n}_q, \hat{y}'_q = \frac{\hat{n}_q \times \hat{k}_{1q}}{|\hat{n}_q \times \hat{k}_{1q}|}, \hat{x}'_q = \hat{y}'_q \times \hat{z}'_q \quad (6)$$

The angle of incidence Θ'_i in this local primed coordinate frame is given by

$$\Theta'_i = \cos^{-1}(-\hat{k}_{1q} \cdot \hat{n}_q) \quad (7a)$$

and it is evident from (6) and (7a) that

$$\sin \Theta'_i = |\hat{n}_q \times \hat{k}_{1q}| \quad (7b)$$

To calculate the TE and TM fields of the wave immediately below the boundary at the point q , we first find the y' components of those immediately above the boundary, which are given by

$$E_{qv'}^+ = \mathbf{E}_q \cdot \hat{y}'_q, \mathbf{H}_{qv'}^+ = \mathbf{H}_q \cdot \hat{y}'_q \quad (8)$$

where \mathbf{E}_q is obtained from (1) and (2), \mathbf{H}_q from (3) and \hat{y}' from (5) and (6). The fields immediately below the boundary are given by

$$E_{qv'_q}^- = T_{01}^{TE} E_{qv'_q}^+, \quad H_{qv'_q}^- = T_{01}^{TM} H_{qv'_q}^+ \quad (9)$$

where T_{01}^{TE} and T_{01}^{TM} are respectively the transverse electric and transverse magnetic downward transmission coefficients.

The field vectors at the point q immediately below the boundary act as sources of the wave propagating downward toward the subsurface point p . As in Eqs. (4) and (4-a, b, c) of [2], we use the Stratton Chu integral including near field terms to evaluate the fields at p , using the fields $\mathbf{E}_q^-, \mathbf{H}_q^-$ as the source fields on the bottom surface of the patch. The latter fields were given in the global coordinate frame by Eqs. (3-a, b) of [2], but are specialized there to the case of a flat horizontal patch. For the tilted patch, these equations are more complicated. In the primed (i.e. tilted) coordinated frame, they are

$$\begin{aligned} \mathbf{E}_q^- &= \hat{x}'_q \left[-Z_1 H_{qv'_q}^- \cos \Theta'_t \right] \\ &+ \hat{y}'_q \left[\mathbf{E}_{qv'_q}^- \right] + \hat{z}'_q \left[-(Z_0/\epsilon_{1R}) H_{qv'_q}^- \sin \Theta'_i \right] \end{aligned} \quad (10-a)$$

$$\begin{aligned} \mathbf{H}_q^- &= \hat{x}'_q \left[Y_1 E_{qv'_q}^- \cos \Theta'_t \right] \\ &+ \hat{y}'_q \left[H_{qv'_q}^- \right] + \hat{z}'_q \left[Y_0 E_{qv'_q}^- \sin \Theta'_i \right] \end{aligned} \quad (10-b)$$

where

$$\cos \Theta'_t = \sqrt{1 - \frac{\sin^2 \Theta'_i}{\nu_1^2}} = \frac{1}{\sqrt{\epsilon_{1R}}} \sqrt{\epsilon_{1R} - \sin^2 \Theta'_i}$$

where Z_1 and Y_1 are respectively the complex wave impedance and admittance of the medium, \hat{x}'_q , \hat{y}'_q , \hat{z}'_q are the unit base vectors along the tilted coordinate axes, Θ'_i is the angle of incidence of the transmitted wave at q , relative to the tilted plane of the patch, ν_1 is the complex refractive index, equivalent to the square root of ϵ_{1R} , the complex relative permittivity. Z_0 and Y_0 are wave impedance and admittance of free space, where $Z_1 = Z_0/\sqrt{\epsilon_{1R}}$ and $Y_1 = Y_0\sqrt{\epsilon_{1R}}$.

To determine \mathbf{E}_q^- and \mathbf{H}_q^- in the global coordinates from (10-a, b), a rotational transformation is required, i.e. in vector-matrix notation

$$[\mathbf{E}_q^-] = [B_q] [\mathbf{E}_q^-]' , [\mathbf{H}_q^-] = [B_q^-] [\mathbf{H}_q^-]' \quad (11-a)$$

where $[\mathbf{E}_q^-]$ and $[\mathbf{E}_q^-]'$ are the vectors of the electric field components in global and local coordinates respectively and $[\mathbf{H}_q^-]$ and $[\mathbf{H}_q^-]'$ have analogous meanings for magnetic fields and where

$$(B_q)_{jk} = \hat{\mathbf{u}}'_{qk} \cdot \hat{\mathbf{u}}_j \quad (11-b)$$

where $\hat{u}_{1,2,3} = \hat{x}, \hat{y}, \hat{z}$, $u'_{q1,2,3} = \hat{x}'_q, \hat{y}'_q, \hat{z}'_q$

and where the matrix elements, i.e. the scalar products $\hat{x}'_q \cdot \hat{x}$, $\hat{x}'_q \cdot \hat{y}$, $\hat{y}'_q \cdot \hat{z}$ etc. are given in the appendix in terms of (Θ_{nq}, ϕ_{nq}) , the orientation angles of the surface normal and the incidence angles (Θ_i, ϕ_i) in the global coordinates.

After the fields \mathbf{E}_q^- , \mathbf{H}_q^- have been evaluated in global coordinates, the fields at p are computed in global coordinates using Eqs. (4) and (4-a, b) of [2], which are not changed by our generalization and will not be repeated here. That step, when carried out in a loop over the entire grid of subsurface volume elements, constitutes the “forward path” computation, i.e. that of the illuminating fields within the entire subsurface region of interest.

These illuminating fields at each subsurface point are the incident wavefields for scattering from that point. We now focus attention to the “return path” computation, i.e. that of the received signal voltages due to the superposition of scattered wavefields from all of the subsurface points.

The first phase of that computation is to evaluate the wavefields at the surface point q' due to scattering from p . This is done in global coordinates in our code. The analysis behind the algorithm is based on Eqs. (5) and (6) of [2], which are not changed by our generalization and are not repeated here. The results are $\mathbf{E}_{q'}^-$, $\mathbf{H}_{q'}^-$, the wavefields at the surface point q' immediately below the surface due to scattering from p in the global frame. Again using the tangent plane approximation as in the forward path calculation, we must first find the components of these fields normal to the propagation plane in order to use TE and TM transmission coefficients in evaluating the fields immediately above the surface at q' .

This is accomplished through the 3×3 rotation matrix $A_{q'}$, the inverse of $B_{q'}$ given in (11-a, b) for point q , except that it applies to a different primed coordinate frame, that applying to the point q' , where the local slopes are different than those at q . The unit normal \hat{n} as given by (4), again points into free-space and is in the $z'_{q'}$ direction in this new coordinate system. The $x'_{q'}$ direction is along that of the projection of the propagation vector \mathbf{k}_s (from q' toward the receiver at point 2) onto the $x'_{q'} - y'_{q'}$ plane (Figure 3). The result in vector-matrix notation is

$$[\mathbf{E}_{q'}^-]' = [A_{q'}] [\mathbf{E}_{q'}^-] \quad (12-a)$$

where

$$(A_{q'})_{jk} = \hat{u}'_{q'j} \cdot \hat{u}_k \quad (12-b)$$

and where $[\mathbf{E}_{q'}^-]'$, $[\mathbf{E}_{q'}^-]$, $\hat{u}'_{q'j}$, and \hat{u}_k have the same meanings as in (11-a, b), except that the specific evaluation of the quantities like $\hat{\mathbf{x}}'_{q'}$, $\hat{\mathbf{y}}'$, $\hat{\mathbf{z}}'_{q'}$, $\hat{\mathbf{x}}$, etc. as indicated in the appendix, are now given in terms of (Θ_s, ϕ_s) , the global direction angles of the wave emerging from q' and propagating toward the receiver rather than (Θ_i, ϕ_i) , the global incidence angles of the wave impinging on q from the transmitter.

After $[\mathbf{E}_{q'}^-]$ and $[\mathbf{H}_{q'}^-]$ have been determined, the next computation is of the y' -components of the fields immediately above the boundary at q' , given by

$$E_{y'}^+(\mathbf{r}_{q'}) = T_{10}^{TE} E_{y'}^-(\mathbf{r}_{q'}) , \quad H_{y'}^+(\mathbf{r}_{q'}) = T_{10}^{TM} H_{y'}^-(\mathbf{r}_{q'}) \quad (13)$$

where T_{10}^{TE} and T_{10}^{TM} are the upward transmission coefficients for TE and TM modes respectively. Next, we calculate the fields immediately above the surface at point q' , given by

$$\mathbf{E}_{q'}^+ = \hat{x}'_{q'} \left[Z_0 H_{q'y'q'}^+ \cos \Theta'_t \right] + \hat{y}'_{q'} \left[E_{q'y'q'}^+ \right] \quad (14-a)$$

$$\begin{aligned} & + \hat{z}'_{q'} \left[-Z_0 H_{q'y'q'}^+ \sin \Theta'_t \right] \\ \mathbf{H}_{q'}^+ & = \hat{x}'_{q'} \left[-Y_0 E_{q'y'q'}^+ \cos \Theta'_t \right] + \hat{y}'_{q'} \left[H_{q'y'q'}^+ \right] \\ & + \hat{z}'_{q'} \left[Y_0 E_{q'y'q'}^+ \sin \Theta'_t \right] \end{aligned} \quad (14-b)$$

where Θ'_t is the spherical polar angle (in the primed coordinated frame) of the propagation vector \mathbf{k}_s for the refracted ray propagating from q' to the receiver at point 2, related to Θ'_i , the incidence angle of q' , the wave propagating upward from p to q' in the primed system, through the expressions $\sin \Theta'_t = \nu_1 \sin \Theta'_i$, $\cos \Theta'_t = \sqrt{1 - \epsilon_{1R} \sin^2 \Theta'_i}$,

The next step is to determine the fields given in Eqs. (14-a, b) in the global frame, given by

$$[\mathbf{E}_{q'}^+] = [B_{q'}] [\mathbf{E}_{q'}^+]', \quad [\mathbf{H}_{q'}^+] = [B_{q'}] [\mathbf{H}_{q'}^+]' \quad (15)$$

where the meanings of all quantities in (15) are analogous to those of their counterparts in (11).

The fields $[\mathbf{E}_{q'}^+]$ and $[\mathbf{H}_{q'}^+]$ are now the source fields for another application of Stratton Chu, this time for upward propagation toward the receiver in free space. The equations that describe this (not shown here) are essentially Eqs. (4) and (4-a, b, c) of [2] except that the surface normal is upward rather than downward, resulting in a sign reversal in all terms, the constitutive parameters are those of free space rather than the soil medium and subscripts q and p are replaced by q' and 2 in all quantities containing those subscripts.

When the wave propagated from the upper surface of the patch centered at q' reaches the receiver at point 2, it undergoes a transformation to the coordinates of the antenna aperture and is weighted by the antenna's receptivity pattern and its peak effective aperture area.

An issue not yet covered in this discussion is the integration over the surface of the patch centered at q on the forward path and that over the patch centered at q' on the return path. For the flat horizontal surface where the patches are rectangular and oriented along the global cartesian coordinate axes, the most accurate method is to assume that the integrand is constant over each patch except for the local phase factor $\exp(jk_0[\alpha_{xa}(x - x_q) + \alpha_{ya}(y - y_q)])$ for the forward path and $\exp(jk_0[\alpha_{xb}(x - x_{q'}) + \alpha_{yb}(y - y_{q'})])$ for the return path, where

$$\alpha_{xa} = \beta_{xa} + \gamma_{xa}, \alpha_{ya} = \beta_{ya} + \gamma_{ya}, \alpha_{za} = \beta_{za} + \gamma_{za},$$

$$\alpha_{xb} = \beta_{xb} + \gamma_{xb}, \alpha_{yb} = \beta_{yb} + \gamma_{yb}, \alpha_{zb} = \beta_{zb} + \gamma_{zb}$$

$$\beta_{xa} = \sin \Theta_{q1} \cos \phi_{q1} + \nu_1 \sin \Theta_{qp} \cos \phi_{qp}, \beta_{ya} = \sin \Theta_{q1} \sin \phi_{q1} + \nu_1 \sin \Theta_{qp} \sin \phi_{qp}$$

$$\beta_{xb} = \sin \Theta_{q'2} \cos \phi_{q'2} + \nu_1 \sin \Theta_{q'p} \cos \phi_{q'p}, \beta_{yb} = \sin \Theta_{q'2} \sin \phi_{q'2} + \nu_1 \sin \Theta_{q'p} \sin \phi_{q'p}$$

$$\beta_{za} = \cos \Theta_{q1} + \nu_1 \cos \Theta_{qp}, \beta_{zb} = \cos \Theta_{q'2} + \nu_1 \cos \Theta_{q'p}$$

$$\gamma_{xa} = \beta_{za}(z_x)_q, \gamma_{ya} = \beta_{za}(z_y)_q, \gamma_{xb} = \beta_{zb}(z_x)_{q'}, \gamma_{yb} = \beta_{zb}(z_y)_{q'}$$

If the x and y dimensions of all patches are all the same and denoted by a_x and a_y , and the factor involving the imaginary parts of the complex refractive index can be assumed constant over the patch, then the integral over the patch on the forward path is approximately

$$I_a = a_x a_y \sin c(\pi a_x \text{Re}(\alpha_{xa})/\lambda_0) \sin c(\pi a_y \text{Re}(\alpha_{ya})/\lambda_0) \quad (16)$$

with an analogous expression for the return path where subscript a is replaced by b .

If this integration method is chosen, then in principle the integral must be evaluated for every patch on the surface in order to find the field at any subsurface point on the forward path or from such a point on the return path. That process is prohibitively CPU-time intensive. Alternatively, we can choose an angular region well within the first lobe of the sinc functions and integrate only over the patches within that region. That method saves considerable time but the decision on the limits of the process is a difficult one. The method we finally decided upon was to use the stationary phase ("sp") approximation and integrate only over sp points. For a flat surface, there is only one sp point for each subsurface cell. For a rough surface, there may be many sp points, but it is still faster to find the sp points and perform the integration only at those points than to use the method discussed above. The result for the forward path is

$$I_a = -\frac{j\pi}{k_0} \left[\frac{r_{1q} r_{qp}}{(r_{qp} + \nu_{1R} r_{1q}) |\cos \Theta'_i|} \right] \quad (17)$$

where ν_{1R} is the real part of ν_1 , with an analogous expression for the return path where subscript a is replaced by b .

The result (17) and its counterpart for the return path show reductions in the $1/R$ spreading factors for the illumination of a given subsurface point p and the return from that point, relative to the case where the integral is carried out for only a few patches centered around the angles at the peaks of the sinc functions in (16), as was done to obtain the results shown in [2]. Those spreading factors would be reduced if we integrated over many more patches, but since as indicated earlier that is prohibitively time-intensive, a better approximation should be attainable with stationary phase. The effects of $1/R^2$ and $1/R^3$ terms and longitudinal wavefields, all due to near field interactions, which were a major theme in [2], are still present in results obtained using (17).

(a) Small-scale roughness only

b) Large and small-scale roughness

3 Results and Conclusions

The simulation of the returns from a subsurface volume containing mines, aggregates of rocks and random variations of complex soil permittivity, was based on the code whose background theory was described in Section 2. As in [1] and [2], the code was run thousands of times in order to simulate the action of the focused array system described in [1] and in more detail in [3]. Referring

back to Section 3 of [1], there are 4 transmitters and 4 receivers, resulting in 16 transmitter-receiver positions. The grid of small volume elements making up the illuminated underground region ($32''$ in crosstrack (“ x ”) direction, $10''$ in alongtrack (“ y ”) direction and $8''$ in depth (“ z ”) consisted of 3072 such elements, each one a cube with x , y and z dimensions of $1''$. Thus the propagation path $1 \rightarrow q \rightarrow p \rightarrow q' \rightarrow 2$ and associated scattering processes described in Section 2, were simulated $16 \times 3072 = 49,152$ times, resulting in 3D image plots as shown in Figures 4 through 9. To obtain these plots we assume a single mine and two rocks in a clutter background due to random soil permittivity inhomogeneties. The burial depth for the mine is $2''$ and those for the rocks are $2.5''$ and $1.75''$. The mine is placed at $x = 0$ and the rocks at $x = 8''$ and $+6''$. The rms deviation of soil permittivity from its mean value is set at 3 percent of the mean. The large-scale surface roughness is modeled through one of the options available in the overall simulation framework [4]. The selected option is based on a two dimensional Fourier series model, where the coefficients can have deterministic and/or random components. To produce these illustrative plots, we have specialized the model to a single sinusoidal function

$$z(x, y) = C \cos \left(2\pi \left[\left(\frac{x}{X_0} \right) + \left(\frac{y}{Y_0} \right) + \Psi \right] \right) \quad (18)$$

and vary the amplitude C from 0 to $0.4''$.

The slopes $(z_x)_q$ and $(z_y)_q$ defined in (4) are:

$$(z_x)_q = \frac{-2\pi}{X_0} C \sin \xi_q, \quad (z_y)_q = -\frac{2\pi}{Y_0} C \sin \xi_q, \quad (19)$$

where

$$\xi_q = 2\pi \left[\frac{x_q}{X_0} + \frac{y_q}{Y_0} + \Psi \right]$$

The slope angles (Θ_{nq}, ϕ_{nq}) can be determined from (5) and (19).

The results presented in this paper are merely illustrative, designed to show that large-scale roughness can have a significant effect on the simulation results under certain conditions. In all of the plots in Figures 4-9, the soil is clay loam (complex permittivity $6.2 - j0.145$ at 1 GHz). The mine is an upright finite circular cylinder of radius $1.5''$ and height $2''$ with permittivity $3 - j0.03$ and the rocks are spheres of radii $.75''$ and $1''$ and permittivity $4.5 - j0.003$ and $4.0 - j0.003$. In Figures 4 and 5, there is no soil permittivity fluctuation clutter. In Figure 4, the air-ground interface is a flat horizontal surface. In Figure 5, the maximum spread of surface height is $0.8''$. There are small differences in the shapes of mine and rock signals on these two plots, but they are not significant. This is because the differences between true and indicated positions are present for a very small number of subsurface scattering points, i.e. those within the volume occupied by the mine and rocks. We conclude that surface height spreads below $0.8''$ have very little effect in the absence of permittivity fluctuation clutter. When we introduce 3% fluctuation clutter, the effect of surface roughness becomes more pronounced, as shown in Figures 6-9. In Figure 6, the interface is horizontal. The mine shows up in the same place as in the zero clutter plots, but the

rock signals are obscured by the clutter. In Figure 7, where the surface height spread is 0.4", the mine is still visible in the clutter and its location is unchanged, but there are many more peaks comparable in intensity with the mine, which could be interpreted as due to discrete objects such as mines or rocks. However, aside from a few peaks that may be due to rocks, nearly all of them would have to be due to permittivity fluctuations that permeate the entire volume. These effects are still more pronounced in Figures 8 and 9, where the clutter level is still 3%, but surface height spreads are 0.6" and 0.8" respectively. In both cases there are so many peaks in various locations that it would be very difficult to infer the presence and location of a mine without further signal processing beyond that inherent in the focused array timing algorithm. An explanation for these effects in the simulation is the possible existence of many stationary phase points for any given subsurface scattering point. Hence some subsurface points would receive (and scatter) much more illumination than predicted by analysis based on a flat horizontal interface and others would receive (and scatter) much less. This should result in more fluctuation in the clutter return than in the absence of surface roughness, as observed in Figures 7, 8 and 9.

4 Continuing Work

Accounting for large-scale surface roughness, the primary focus of this paper, is only one of the generalizations we have implemented in order to improve the accuracy of the modeling. Work is still in progress not only on that issue but also on inclusion of second order scattering effects [5, 6] on the subsurface illuminating fields, but the complete second order theory is prohibitively CPU-time intensive. Even reflections of first-order scattered fields from the underside of the air-ground interface, the simplest of the second order effects to be considered, must be limited to the strongest reflections in order to avoid excessive running time. The decision on which reflections to include is much more difficult with a rough surface, so the current study of this issue is being limited to flat surfaces. The next step is development of a criterion to decide which reflections can be excluded without much of a penalty when the roughness of the interface is accounted for.

Abstract

The project motivating this paper is the deployment of a frequency independent antenna on the transceiver of a monostatic ground-penetrating radar used to detect mines. The design goal is that the radiation pattern and input impedance be nearly uniform over a band from 1 GHz to 5GHz if the antenna is partially immersed in a typical soil medium. The contemplated method of deployment is to have the antenna straddle the air-soil interface i.e. partly in free space and partly underground, radiating into the ground. The particular subclass of frequency-independent antenna under investigation for this application is the conical equiangular-spiral antenna, in which thin wires are wound around a conical frame and the radiation is from the apex and reaches its peak in the axial direction. The conical structure, about 50cm long and with a maximum diameter of 12cm, is thrust into the ground apex-first at an angle of about 70° to the vertical.

The subject of this paper is an analysis of this antenna, first solving the integral equation to find the currents on the wire, then determining the radiation pattern at frequencies between 500MHz and 5GHz. The theory of this antenna in infinite free space was developed by K. K. Mei and others in the 1960s (IEEE Transactions, AP-13, 5/65, pp. 374-378 and Yeh and Mei, AP-15, 5, 9/67, pp 634-639 and AP-16, 1, 1/68, pp. 9-21.) The analysis reported in the present paper is based on these sources. An ultimate objective of the reported work is to determine theoretically the degree of frequency uniformity attainable when the antenna geometry is as indicated above. The ideal "frequency independent" property is theoretically possible if the

cone is infinitely long, so the finite length and width of the frustum imposes limits on the attainable bandwidth. In order to begin to determine the feasibility of this antenna in the contemplated application, this paper will be limited to the analysis of the antenna positioned with its axis in the vertical direction and immersed in an infinite lossy dielectric medium (e.g. clay loam soil). The extension to include the effect of the air-soil interface and the partial immersion of the antenna in the soil at an angle other than vertical will be given in a later paper.

KEYWORDS: mine detection, antennas, ground-penetrating radar, frequency-independent antennas, conical spiral antenna.

1 Introduction

The conical spiral antenna, a subclass of "frequency independent antennas," was studied extensively by a number of researchers in the 1960's [1] - [7] and has been discussed in some more recent antenna texts [8] - [10]. Because of the very large bandwidths attainable with these antennas and appropriate form-factor as a probe, we are investigating their use in anti-personnel land-mine detection by ground-penetrating radar. Ideally, in that application, the antenna's bandwidth should be comparable to that of the transmitted pulses used in the many GPR systems whose durations are of the order of nanoseconds. A conical spiral can achieve that kind of bandwidth in free space and might be able to do so in soil media in which mines are typically buried. It also produces radiation patterns that peak in the axial direction, and although not very directive, focus nearly all of the radiated energy into the hemisphere outside the cone. In the contemplated application, the tip of the cone is manually thrust into the ground at selected intervals at an angle of about 70° from the vertical as illustrated in Figure 1. Each thrust of this probe will illuminate a subsurface volume possibly containing a mine. It is expected that such a hand-held probe would supplement other detectors as a confirmatory sensor.

An obvious issue in the use of a GPR probe configured as described above is that of the operation of the conical spiral in a typical soil, especially a soil with significant lossiness. Another issue is the effect of the air-ground interface on the current distribution, input impedance and radiation pattern, particularly if the interface has significant roughness.

The nominal geometry assumes a circular wire of constant radius wound around a cone 50cm long and with a maximum diameter of 12cm, with cone angle $\theta_0 = 13^\circ$. This antenna has two arms, the first of which is governed by the equation $r = r_0 e^{a\phi}$ and the second by $r = r_0 e^{a(\phi-\tau)}$.

This paper reports on the first part of a particular task in this investigation, which is the generation of a computer simulation to determine the current distribution, near-field pattern and input impedance of this antenna when immersed in a soil medium modeled as a lossy dielectric. In the above-mentioned theoretical and experimental work done in the 1960's, the antenna was assumed to be in infinite free space. Although the early results provide precise information about the behavior of the antenna in free space, and qualitative insights into its expected properties in a dielectric medium, its behavior in a lossy soil cannot easily be quantitatively inferred from them. For this reason the analysis must be repeated for those cases, using the enormous improvements in

computer power during the past thirty years to produce a wider range of results that will aid us in the development of the GPR probe.

The ultimate goal in this simulation phase of the project is to include the effects of a possibly rough air-ground interface and a buried mine on a conical spiral with arbitrary orientation. That level of generality is required to completely evaluate the configuration we have in mind. But the matlab simulation code developed to-date is limited to the case where the antenna is immersed in an infinite lossy dielectric, a theoretically simple extension of the work of K. K. Mei in 1965 [1] and Yeh and Mei in 1967 and 1968 [2, 3].

Figure 1: Deployment of conical spiral as GPR probe

Figure 2: Basic geometry of conical spiral antenna.

2 Theoretical Background

The axis of the cone is along the z -axis of a cartesian coordinate frame whose origin is at the apex, as shown in Figure 2. The spherical coordinates of an infinitesimal current element on the wire wound around the surface of the cone are (r', θ', ϕ') , where

$$r' = r_0 e^{a\phi'}, \theta' = \theta_0 \quad (1)$$

where a is the “spiral constant”, a monotonically increasing function of the pitch angle, θ_0 is the cone angle, assumed constant, and r_0 , is the straight-line distance on the cone surface from the origin to the point p shown in Figure 2. The vector from the origin to the center of the element, is

$$\mathbf{r}' = r_0 e^{a\phi'} [\sin \theta_0 (\hat{\mathbf{x}} \cos \phi' + \hat{\mathbf{y}} \sin \phi') + \hat{\mathbf{z}} \cos \theta_0] \quad (2)$$

The incremental change in \mathbf{r}' as ϕ' varies along the wire is

$$d\mathbf{r}' = [a\mathbf{r}' - r_0 e^{a\phi'} \sin \theta_0 (\hat{\mathbf{x}} \sin \phi' - \hat{\mathbf{y}} \cos \phi')] d\phi' \quad (3)$$

The magnitude of $d\mathbf{r}$ is (with the aid of (1))

$$\begin{aligned}
|d\mathbf{r}'| &= a r_0 e^{a\phi'} d\phi' \sqrt{\sin^2 \theta_0 \left[\left(\cos \phi' - \frac{\sin \phi'}{a} \right)^2 + \left(\sin \phi' + \frac{\cos \phi'}{a} \right)^2 \right] + \cos^2 \theta_0} \\
&= Q dr' , \text{ where } Q = \sqrt{1 + \frac{\sin^2 \theta_0}{a^2}}
\end{aligned} \tag{4}$$

The quantity Q , defined in [2] as the "slowness factor", is a measure of the ratio of the curvilinear distance traversed along the wire to the linear distance r' along the cone surface.

A unit vector $\hat{\mathbf{s}}'$ in the direction of the current element at the point \mathbf{r}' , proportional to $d\mathbf{r}'$ in (3), is

$$\hat{\mathbf{s}}' = \frac{1}{Q} \left\{ \sin \theta_0 \left[\hat{\mathbf{x}} \left(\cos \phi' - \frac{\sin \phi'}{a} \right) + \hat{\mathbf{y}} \left(\sin \phi' + \frac{\cos \phi'}{a} \right) \right] + \hat{\mathbf{z}} \cos \theta_0 \right\} \tag{5}$$

The unprimed version of (5) is corroborated by Eq. (16) of [2]. The distance traversed along the wire, proportional to $|d\mathbf{r}'|$ as given in (4), is

$$s' = Q r' \tag{6}$$

Eqs. (1) - (6) apply to arm 1, which starts at the point p in Figure 2. Arm 2, wound in the same sense as arm 1, starts at point p' , separated from p by 180° . The counterpart of (1) for arm 2 is

$$r'_2 = r_0 e^{a(\phi' - \pi)} \tag{7}$$

If ϕ' is replaced by $\phi' - \pi$ in (2) and the steps from (2) through (6) are repeated, we can obtain the counterparts of (5) and (6) for arm 2, which are given in [2].

To determine the electric field at an arbitrary point designated by a vector \mathbf{r} due to currents along arm 1, we note that the current vector on an element at \mathbf{r}' is denoted by $I(s') \hat{\mathbf{s}}'$. The magnetic vector potential at \mathbf{r} due to this element is

$$\mathbf{A}(\mathbf{r}) = \mu I(s') \hat{\mathbf{s}}' G(\mathbf{r}, \mathbf{r}') ds' \tag{8}$$

where $G(\mathbf{r}, \mathbf{r}')$ is the green's function in the surrounding medium, given by $G(\mathbf{r}, \mathbf{r}') = e^{-jkR}/4\pi R$, and $R = |\mathbf{r} - \mathbf{r}'|$, and where μ and k are the magnetic permeability and propagation constant respectively of that medium. The electric field at \mathbf{r} , as obtained from (8), is

$$\mathbf{E}(\mathbf{r}) = -j\omega \left(\bar{\mathbf{I}} + \frac{1}{k^2} \nabla \nabla \right) \cdot \left[\int_0^L ds' \mu I(s') \hat{\mathbf{s}}' G(\mathbf{r}, \mathbf{r}') \right] \tag{9}$$

where ω is the angular frequency and L is the length of arm 1.

Eq. (9) (or its equivalent in other forms), is the basis of the integral equation from which the currents $I(s')$ are to be evaluated by MOM (Section 2.1) and also the calculation of the field pattern in the surrounding space (Section 2.1). To obtain the field due to both arms, a second term is added

to the right hand side, identical to the expression in (9) but with subscripts 2 on s, \hat{s}', \mathbf{r}' and also on L if arms 1 and 2 have different lengths.

The radius of the wire, denoted by b , is assumed constant in this analysis. That case is discussed on Page 638 of [2]. It is not the theoretically ideal case, in which the antenna is infinitely long and the radius continuously increases along the wire. The prescribed increase in wire radius is feasible in principle but more difficult to implement in practice and obviously a practical antenna must have a finite length. For these reasons, the antenna being investigated here is not truly frequency independent. But it is expected that the constant wire radius version will have a sufficiently large bandwidth for the contemplated application.

2.1 Current Distribution

To obtain the currents $I(s')$, an electric field integral equation (EFIE) is derived from (9) or its equivalent [1]. The point \mathbf{r} is set on arm 1 of the wire. The $r, \mathbf{r}, \hat{\mathbf{s}}$ and s' are given by expressions identical to (1), (2), (5) and (6) respectively except that the primes are removed from all quantities in those expressions. The tangential component of $\mathbf{E}(\mathbf{r})$, equal to $\hat{\mathbf{s}} \cdot \mathbf{E}(\mathbf{r})$, is integrated over the length of arm 1.

The derivation of the EFIE for an arbitrary thin wire antenna is given by Mei in [1] and further specialized to the conical spiral antenna by Yeh and Mei in [2]. It is based on Eq. (11) of [1], which can be derived from (9) in the present paper. The resulting kernel, as given by Eq. (28) of [1] and more specifically by Eq. (12) of [2], is

$$\pi(s, s') = \pi_a(s, s') + \pi_b(s, s') + \pi_c(s, s') \quad (10)$$

where $\pi_a(s, s') = G(s, s') (\hat{\mathbf{s}} \cdot \hat{\mathbf{s}}')$, $G(s, s')$ being the same as $G(\mathbf{r}, \mathbf{r}')$ in (8) but the Green's function is expressed as a function of s and s' ;

$$\pi_b(s, s') = -P \int_0^L dt \left[\frac{\partial G(t, s')}{\partial t} (\hat{\mathbf{t}} \cdot \hat{\mathbf{s}}') + \frac{\partial G(t, s')}{\partial s'} + G(t, s') \left(\frac{d\hat{\mathbf{t}}}{dt} \cdot \hat{\mathbf{s}}' \right) \right] \cos(k(s-t)),$$

P denoting the principal value of the integral on t ;

$$\pi_c(s, s') = -G(s_p, s') \left[(\hat{\mathbf{s}}_p^+ \cdot \hat{\mathbf{s}}') - (\hat{\mathbf{s}}_p^- \cdot \hat{\mathbf{s}}') \right] \cos(k(s-s_p)) u(s-s_p)$$

The last term is due to the step discontinuity at the point p . In this term $\hat{\mathbf{s}}_p^+$ and $\hat{\mathbf{s}}_p^-$ refer to the unit vector $\hat{\mathbf{s}}$ at points just above and just below p respectively and $u(s-s_p)$ is the unit step function, implying that s must exceed s_p .

The counterpart of (10) for arm 2, which is added to (10) to form the complete kernel, is identical to (10) but with s' and $\hat{\mathbf{s}}'$ replaced by $s'_2 = -s'$ and $\hat{\mathbf{s}}'_2$ respectively. The two kernels are additive because $I(s') = I(-s')$, due to the symmetry of the two arms and hence the final form of the EFIE is (Eq. (12) of [2])

$$\int_0^L ds' F(s, s') I(s') = H \cos ks - (jV_0/2Z) \sin ks \quad (11)$$

where $F(s, s') = \pi(s, s') + \pi(s, -s')$, where V_0 and Z are the applied voltage and wave impedance of the medium respectively and where B on the right-hand side is uniquely specified by the requirement that the current must vanish at both ends of the wire, as in the Pocklington and Hallén integral equation ([8], pp. 278-286) for a thin straight wire antenna, of which this antenna is a generalization.

The specific forms of the expressions in (10), i.e. $\hat{s} \cdot \hat{s}'$, $\hat{t} \cdot \hat{s}'$, $\hat{s}_p^\pm \cdot \hat{s}'$, and $\frac{d\hat{t}}{dt} \cdot \hat{s}'$ can be calculated for arm 1 from Eqs. (16) and (17) of [2], where \hat{t} and t replace \hat{s} and s in some of these expressions. Their counterparts for arm 2 can be calculated from (16), (17) and (18) of [2]. These expressions were calculated and incorporated into the matlab code as arrays to form the quantities in (10).

The modeling of the Green's function $G(s, s')$ requires a decision on the inclusion of the integration around the periphery of the circular wire. Referring to literature on the straight circular wire antenna directed along the z-axis [11] in the formulation of the integral equation the current can be assumed to be entirely on the outer surface of the wire and the observation point at the center of the wire. Alternatively, the current can be along the center and the observation point along the surface. These two viewpoints give essentially equivalent results and we have chosen the former. Both viewpoints are based on the assumption that the wire is so thin that the currents flow entirely in the wire direction, i.e. currents transverse to that direction are neglected.

Actually, since the wire is assumed to be a solid perfect conductor, the current flows almost entirely on the outer surface. The true boundary condition is the vanishing of the electric field along the outer wire surface. The choice of both source and observation point on the outer surface in the formulation of the integral equation leads to obvious singularities of the kernel when $s = s'$. Although the effect of these singularities is eliminated in the integrations, as pointed out on Page 637 of [2], they can be entirely circumvented by the approximation indicated above, and for a sufficiently thin wire, should not cause serious errors in the computation.

The modeling of R , the distance between an observation point along the center of the wire and an infinitesimal current element on the outer surface of the wire and parallel to \hat{s}' at the center of the element, can be easily accomplished. The result is

$$R = |\mathbf{r} - (\mathbf{r}' + b\hat{\rho}')| = R(s, s', b, \beta) = \sqrt{A_0 + (u \cos \beta + v \sin \beta)} \quad (12)$$

where β is the local azimuthal angle around the periphery of the wire, and where

$$A_0 = \frac{1}{Q^2} \left\{ s^2 + \left(s'_1 \right)^2 - 2ss'_1 \left(\cos^2 \theta_0 + \sin^2 \theta_0 \cos \Delta \phi \right) + b^2 Q^2 \right\}$$

where b is the wire radius and $\hat{\rho}'$ is a vector normal to \hat{s}' for arm 1 and to \hat{s}'_2 for arm 2. u and v have also been calculated but are not given here.

The Green's function, accounting for integration over the local azimuth angle β , is

$$G(s, s', b) = \frac{b}{4\pi} \int_0^{2\pi} d\beta \frac{e^{-jkR(s, s', b, \beta)}}{R(s, s', b, \beta)} \simeq \frac{be^{-jkR(s, s', b)}}{2R(s, s', b)} \quad (13)$$

where R is approximated as $\sqrt{A_0}$, on the assumption that b is sufficiently small to justify neglect of the terms involving β in (12).

If the terms involving β were comparable in magnitude to A_0 , then the β integration would need to be performed numerically for each current element, which is enormously CPU-time intensive. In the cases to be considered in this study, examination of parameter values indicates that the β terms are sufficiently small compared with A_0 to justify an approximation in the exponential term. It is noted that, as $\theta_0 \rightarrow 0$ and $a \rightarrow \infty$ (i.e. as the spiral approaches a straight wire in the z -direction), $R \rightarrow \sqrt{(z - z')^2 + b^2}$, known as the "thin-wire approximation" for a z -directed linear antenna.

The terms in $\pi_b(s, s')$ involving derivatives of the Green's function can be obtained from (13). In general

$$\frac{\partial G}{\partial s} = \frac{\partial G}{\partial R} \frac{\partial R}{\partial s} = -jkG \left(1 + \frac{1}{jkR} \right) \frac{\partial R}{\partial s} \quad (14)$$

By replacing s with t in (14) and substituting the resulting expressions into $\pi_b(s, s')$ in (10), we can obtain all the quantities needed in the integrand of $\pi_b(s, s')$ for arm 1. With sign changes in these quantities, we can do the same for arm 2.

The next step in obtaining the current on the wire is to expand the current in a set of basis functions $p_n(s')$, i.e.

$$I(s') = \sum_{n=1}^N c_n p_n(s') \quad (15)$$

substitute (15) into the integral equation and apply the method of moments (MOM) to solve for the coefficients c_n . This was actually done by Yeh and Mei in [2], but their technique was not designated by them as MOM because that terminology [12] was not yet in wide use in 1967. They used the most elementary and straightforward form of MOM, that of point matching [13], and a set of basis functions that are nonzero only in the subdomain of s' that contains the matching point, e.g., a set of contiguous rectangular pulse functions. Their pulse functions were multiplied by a set of interpolation functions that were quadratic in s' , which enhanced the rate of convergence relative to flat-top pulse functions. In our work, we have initially used flat-top pulse functions but have studied more sophisticated sets of basis functions [14] with a view toward improving the accuracy of the computations in later work.

2.2 Near-Fields of Antenna

To calculate the near fields within a region around the antenna, we again invoke (9), using $I(s')$ as determined from the MOM solution of the EFIE as discussed in the previous section. To determine the θ , ϕ and r components of the electric field in the same global coordinate system defined earlier, we first find the rectangular components of fields at an arbitrary observation point from a volume distribution of arbitrarily directed infinitesimal current elements from Eqs. (6-108 a, b, c) on pp.

283-284 of [15], which are based on an expression equivalent to (9). This procedure yields a set of electric field components (E_x , E_y , E_z) from a volume integral over current elements J_x , J_y , J_z .

Then the spherical coordinate components are calculated from the relationships

$$\begin{aligned} E_\theta &= \hat{\theta} \cdot \mathbf{E} = \cos \theta (E_x \cos \phi + E_y \sin \phi) - E_z \sin \theta, \\ E_\phi &= \hat{\phi} \cdot \mathbf{E} = -E_x \sin \phi + E_y \cos \phi, \\ E_r &= \hat{r} \cdot \mathbf{E} = \sin \theta (E_x \cos \phi + E_y \sin \phi) + E_z \cos \theta \end{aligned} \quad (16)$$

The volume of integration is then defined as that of the curved wires on arms 1 and 2 of the conical spiral antenna, which (for arm 1) results in

$$E_\theta = \frac{-jZ}{4\pi kQ} \int_0^L ds' I(s') e^{-jkR} \left\{ \begin{array}{ccc} G_1 & [-B] & + \\ " & [A] & " \\ " & [-C] & " \end{array} \begin{array}{ccc} G_2 & [D] & [M_\theta] \\ " & " & [M_r] \\ " & " & [M_\phi] \end{array} \right\} \quad (17)$$

where $D = rA - r_0 e^{a\phi'}$, $M_\theta = r_0 e^{a\phi'} (bb)$, $M_r = r - r_0 e^{a\phi'} (aa)$, $M_\phi = r_0 e^{a\phi'} (cc)$ and where $aa = \cos \theta \cos \theta_0 + \sin \theta \sin \theta_0 \cos \Delta\phi$, $bb = \sin \theta \cos \theta_0 - \cos \theta \sin \theta_0 \cos \Delta\phi$, $cc = \sin \theta_0 \sin \Delta\phi$, $A = aa + \frac{cc}{a} \sin \theta$, $B = bb - \frac{cc}{a} \cos \theta$, $C = cc - \frac{\sin \theta_0 \cos \Delta\phi}{a}$, $G_1 = -[1 + jkR + (jkR)^2]/R^3$, $G_2 = [3 + 3jkR - (jkR)^2]/R^5$, $I(s') = \int_0^{2\pi} d\beta b J(s'\beta)$ and $\Delta\phi = \phi - \phi'$.

Each total field component is the superposition of two terms of the forms in (17), one for each arm. The expression for arm 2 is the same as that for arm 1 except that ϕ' is changed to $\phi' - \pi$ and hence $\Delta\phi$ is changed to $\Delta\phi + \pi$, resulting in sign changes and consequent differences in the values of R , as discussed in subsection 2.1. It is noted that, as required, E_θ and E_ϕ become proportional to $1/r$ and E_r becomes proportional to $1/r^2$ as r approaches infinity.

3 Discussion of Results

Before proceeding to parametric studies of the variation of current and field patterns with frequency and soil properties, we first embarked on an effort to validate the simulation code by comparison with past results. This resulted in the curves shown in Figure 3(a), where our computed currents were compared with those obtained by Yeh and Mei (Figure 7 on Page 638 of [2]). Figure 3(a) shows plots of real and imaginary parts and amplitude of the current in milliamperes against $x = s/\lambda$ as s varies from 1 to 6 wavelengths. For these plots, we have used the same values of input variables as those in Figure 7 of [2], i.e. $a = .035$, $r_0 = .316\lambda$, $b = .0096\lambda$, $\theta_0 = 10^\circ$, and the surrounding medium is infinite free space. The results from [2] are shown in Figure 3(b). Comparing the real and imaginary parts of the current in Figure 3(a) with those in Figure 3(b), we note fairly good agreement in the s -locations of most of the maxima and minima, except for the first peak of the real part, which shows some unstable behavior, and the last maximum and minimum of both real and imaginary parts, whose locations deviate from those of Figure 3(b). Relative amplitudes of some of

the peaks and troughs and the rate of decay of the amplitude are also close to those of Figure 3(b), however, there are enough discrepancies to warrant further analysis of the code, as indicated below. As of this writing, we are not certain of why the two sets of curves are not in exact agreement, but it is probably at least partially due to the fact that our basis functions for the MOM computation were not exactly the same as those used by Yeh and Mei (i.e. we did not use their interpolation functions, as indicated in Section 2.1). Another probable reason is the approximation used in the Green's function (See Eq. (13)) which circumvented the exact integration around the periphery of the wire, which is particularly important in the region in which s is close to s' , where the Green's function reaches very large values. Whatever the reasons for these discrepancies, further work is in progress to improve the accuracy of the kernel of the integral equation, and to try more sophisticated MOM basis functions, both of which are critical to the accuracy of the computed current.

Since all input variables with dimensions of distance are entered in wavelengths in the comparison case discussed above, they are all independent of frequency. They are also independent of constitutive parameters, which are used only to determine wavelength and propagation constant from the inputted frequency and hence are the same for soil media as for free space. Hence they are not useful in the study of the effect of frequency and soil parameters on the current distribution and radiation patterns. To conduct such a study, we enter input variable values in accordance with the model described in Section 1, and those with dimension of distance are entered in meters, not as multiples of a wavelength. Some current distribution computations have been made at various frequencies between 400MHz and 2.4GHz. An example is shown in Figure 4(a) for dry sand as the ambient medium (dielectric constant = 2.55, loss tangent = .008) at a frequency of 1GHz. This result is compared with that in Figure 4(b), where all antenna parameters and the frequency are the same as in Figure 4(a) except that the ambient medium is free space.

In these cases, the total length of the wire is about 200cm. Wavelengths for dry sand and free space are 18.8cm and 30cm respectively, implying wire-lengths of about 10.6 and 6.5 wavelengths respectively at 1GHz. The number of cycles of the real and imaginary parts of the current in Figures 4(a) and 4(b) is obviously the number of wavelengths.

Another example is shown in Figures 5(a) and 5(b), the same as Figures 4(a) and 4(b) except that the frequency is 2GHz. In these cases, the wavelengths are half of those at 1GHz and hence the number of cycles of real and imaginary parts are twice those of Figures 4(a) and 4(b). In all of these cases, the amplitude decays from a high value near the source to a smaller plateau near the termination, but there are significant differences in the shapes of the curves for each medium at the two frequencies and at each frequency for the two media, especially near the source and near the termination. Other sets of results have been obtained for different frequencies within the band of interest and they all show behavior similar to Figures 4(a)-5(b), except those at the low frequencies and, whose amplitudes do not exhibit significant decay with distance.

A general conclusion we can draw from the cases studied to date is that the rates of decay of the current amplitude show an increase with frequency. The frequency above which this occurs is about 950MHz in free space and about 550MHz in dry sand. At frequencies below these values, the amplitude is highly oscillatory and exhibits very little decay with distance along the wire. The wavelength in dry sand is about 63 percent of that in free space for any frequency. This appears

to be the reason for the difference between the two media in the minimum frequency at which significant decay rates begin to occur. For frequencies below that minimum, there is an insufficient number of wavelengths along the wire to realize the typical current distribution of the conical spiral.

As of this writing, we cannot draw conclusions about the effect of these trends on the radiation pattern, which we have not yet studied for the parameter values of our model. Some preliminary radiation pattern computations were made for the validation case, and plots of elevation plane cuts show similar shape but less symmetry than those given in [2]. These results will be shown in the presentation.

4 Conclusions and Plans for Future Work

The results indicate that the modeling we have done to date will be useful in predicting the behavior of the conical spiral antenna in a soil medium, but more work is required to improve its accuracy for the case of an infinite medium and then to include the effects of the air-soil boundary and a mine and possibly other clutter sources in the near-neighborhood of the antenna. Final validation will require favorable comparisons with results to be obtained with the experimental model.

In the immediate future, before considering these refinements, it is planned to take more accurate account of the integration over the outer periphery of the wire and to try other basis functions and weighting functions in the MOM current computation, in hopes that the results will come closer to those obtained in the earlier literature.

Abstract

In previous papers (Proc. SPIE, April, 1998, April, 1999 and August, 1999) the authors reported work on a 3D frequency domain simulation of bistatic GPR scenarios involving signals from buried mines and clutter due to random permittivity fluctuations in the soil, roughness of the air-ground interface, and distributions of rocks. The analysis is based on Born approximations. The emphasis in these papers was on simulation of a focused array radar (Rappaport and Reidy, Proc. SPIE 1997), which is a multistatic system and hence its simulation requires a large number of runs. Simulation of a multistatic GPR system places a high premium on speed, which necessitates some loss of accuracy. Work is currently underway on validation of this code through comparison with experimental results and with results obtained with numerical codes that can achieve great accuracy with very long running times. In the work reported in this paper, results obtained with our code, requiring only minutes of running time, are compared with results of a three dimensional FDTD code, which requires many hours of CPU time for the same case.

Radar, ground penetrating radar, clutter modeling, electromagnetic scattering, mine detection.

1 INTRODUCTION

In three previous SPIE Conference Proceedings papers [1, 2, 3], the authors reported work on a three-dimensional bistatic frequency domain simulation of ground penetrating radar signals from a subsurface region possibly containing mines. The emphasis in these papers was on application of the code to simulation of the action of the focused array radar system [4] in cases where the subsurface clutter consists of random permittivity inhomogeneities in the soil, and distributions of rocks in the vicinity of the mines.

The focused array system is able to resolve signals from different regions within the soil, using an algorithm based on differences in propagation time delay between returns from different regions. A frequency domain simulation, in order to capture that effect, must contain a feature that separates returns on the basis of time delay. In the work reported in our previous papers, such a feature was present, in the form of a simulation of the focused array radar principle. If the air-ground interface is flat, the multistatic returns with a specific relative delay are superposed and their sum is interpreted as arising from a specified subsurface region.

The work reported in the present paper does not contain a time-resolution feature. It is based on a pure CW computation of the wavefields arising from a static transmitting antenna at a height z_1 above an air-ground interface that has an average height designated as zero, but possibly with a small degree of surface roughness (i.e. σ_z , the rms height of the interface, is small compared with the transmitter height h , and with the burial depth of the top of a cylindrical dielectric mine assumed to be placed directly below the antenna). The horizontal coordinates of the centers of both antenna and mine are $x = 0$, $y = 0$. The wavefields arising from the transmitted wave, reflection of that wave from the air-ground interface, its downward transmission through the interface and scattering from the mine are all superposed coherently, resulting in a distribution of field-strength throughout a rectangular volume including both the above-surface region containing the transmitter and the subsurface region containing the mine. The frequency is 960 MHz.

The purpose of the work is to compare the modeling methodology used in [1, 2, 3] as applied to the geometry described above with a FDFD computation of the same geometry performed by R. Young and C. Rappaport [5]. The latter produces extremely accurate results at an expenditure of hours or days of CPU time. The former can obtain results for the same scenario in minutes of CPU time. This is accomplished through the use of approximations discussed in [1, 2, 3]. This produces a less accurate result but possibly one sufficiently accurate to provide a useful forward model for signal processing schemes on data obtained from large scale GPR systems (such as the focused array radar or other multistatic systems, particularly in cases where the simulated scenarios are dynamic or cover large amounts of space with many buried objects to be detected).

2 Description of Problem Geometry

The geometry is illustrated in Figure 1. In the cartesian coordinate system used in this computation, whose $z = 0$ plane is the (average) air-ground interface, the centroid of the transmitting antenna is

at $x = 0$, $y = 0$, $z = h = 10\text{cm}$. The vertical center of the buried mine, which is modeled as a finite upright circular cylindrical object, is at $x = 0$, $y = 0$, $z = -d_m = -7\text{cm}$. The mine's radius r_m is 5cm and its vertical thickness t_m is 4cm . Thus the top surface of the mine is at $z = -d_m + t_m/2 = -5\text{cm}$ and its bottom surface is at $z = -d_m - t_m/2 = -9\text{cm}$. The mine is characterized as a uniform slightly lossy dielectric with relative permittivity $\epsilon_m = 2.9$ and conductivity $\sigma_m = .004\text{ S/m}$. The soil parameters are $\epsilon_s = 6.2$ and $\sigma_s = .035\text{ S/m}$, which characterizes Puerto Rican clay loam.

The three dimensional region over which we must compute the fields, as illustrated in Figure 1, is rectangular with dimensions 50cm , 50cm , and 40cm in the x , y and z directions respectively. The lower vertical limit of this region is 20cm below the air-ground interface. The upper limit is 20cm above the interface. In the horizontal directions, the coverage region extends from $x = -25\text{cm}$ to $x = +25\text{cm}$ and from $y = -25\text{cm}$ to $y = +25\text{cm}$. In the FDFD work, there are two 3D volume grids, one designated as the course grid, whose number of elements in x , y and z directions are 95, 95, and 77 respectively. The other, designated as the fine grid, has 97, 97, and 85 elements in the x , y and z directions respectively. Wavelength is 31.2cm in air and 12.5cm in the soil.

3 Modeling of Electromagnetic Processes

The theoretical modeling behind the simulation was described in some detail in [1], [2], and [3]. The basic process modeled was illustrated in Figure 1 of [2], repeated here as Figure 2b, which illustrates the transmission of a ray from the transmitter at Point 1, intersecting the air-ground interface at q , traversing the interface and propagating downward in the soil toward point p , scattering from point p toward a point q' on the interface, again traversing the interface into free space, then propagating toward point 2.

The total wavefield at point 2, in addition to the superposition of all wavefields due to processes illustrated in Figure 2-b (i.e. for all air-ground-intersection points q and q' and for all subsurface points p whose permittivity differs from that of the ambient soil medium), but also contains two other contributions that were largely de-emphasized in [1, 2, 3], namely the fields of the direct wave from 1 to 2 and the superposition of rays reflected from the boundary at all surface points s . These contributions, which are in general much larger than the scattered wavefields due to subsurface inhomogeneities and buried objects, are illustrated in Figure 2-a. In [1, 2, 3], where the emphasis was on subsurface scattering with a focused array radar, it was assumed that these contributions could be time-gated out through the signal processing inherent in the action of the focused array and through further signal processing that served to isolate the subsurface returns from the direct and ground-reflected signals. However, in the computations performed in this paper, these contributions cannot be eliminated and the fields arising from them at any point above the surface are the dominant contributions to the fields at that point.

There are a few differences between the analysis performed in [1, 2, 3] and that in this paper. First, the focused array is not a subject of this paper. The transmitting antenna, as in the FDFD work, is a Hertzian dipole oriented in the horizontal direction, or more precisely along the x -axis. The basis of the algorithm for the radiated fields is the very simple and well known theory of a

“short” (compared with wavelength) electric dipole at the origin with uniform current, given in many electromagnetic theory texts, e.g. [6, 7, 8]. From Section 15-5, Eqs. (20), (21) and (23) on Page 747 of [6], the electric and magnetic fields in spherical coordinates r, θ, ϕ are:

$$E_r = 2K_0 \exp(-j\beta r) \cos \theta \left(\frac{1}{cr^2} + \frac{1}{j\omega r^3} \right) \quad (1-a)$$

$$E_\theta = K_0 \exp(-j\beta r) \sin \theta \left(\frac{j\omega}{c^2 r} + \frac{1}{cr^2} + \frac{1}{j\omega r^3} \right) \quad (1-b)$$

$$H_\phi = K_0 \epsilon_0 \exp(-j\beta r) \sin \theta \left(\frac{j\omega}{cr} + \frac{1}{r^2} \right) \quad (1-c)$$

where $K_0 = \frac{I_0 \ell}{4\pi \epsilon_0}$, β is the propagation constant of free space and where the dipole is assumed to be in the z -direction.

If we note that

$$\cos \theta = \frac{z}{r}, \sin \theta = \frac{\rho}{r}, \text{ where } \rho = \sqrt{x^2 + y^2}, r = \sqrt{\rho^2 + z^2} \quad (2)$$

then to redirect the dipole into the x -direction rather than the z direction, we redefine the quantities in (2) as follows

$$\cos \theta = \frac{x}{r}, \sin \theta = \frac{\rho}{r}, \text{ where } \rho = \sqrt{y^2 + (z - h)^2}, r = \sqrt{\rho^2 + x^2} \quad (3)$$

In this new geometry, where $z \rightarrow x, x \rightarrow y, y \rightarrow z$, the cosines and sines of the other angular coordinate ϕ are defined by

$$\cos \phi = \frac{y}{\rho}, \sin \phi = \frac{z - h}{\rho} \quad (4)$$

From the standard expressions for the spherical coordinate unit base vectors, in our new coordinate system

$$\begin{aligned} E_\theta &= \mathbf{E} \cdot \hat{\theta} = \cos \theta (E_y \cos \phi + E_z \sin \phi) - E_x \sin \theta \\ E_r &= \mathbf{E} \cdot \hat{r} = \sin \theta (E_y \cos \phi + E_z \sin \phi) + E_x \cos \theta \\ E_\phi &= \mathbf{E} \cdot \hat{\phi} = -E_y \sin \phi + E_z \cos \phi = 0 \end{aligned} \quad (5)$$

Inversion of (5) yields the rectangular coordinates of the electric field vectors at the observation point due to an x -directed Hertzian dipole at $x = y = 0, z = h$. Expressions analogous to (5) yield H_ϕ in terms of ϕ .

$$E_y = E_\theta \cos \theta \cos \phi + E_r \sin \theta \cos \phi \quad (6-a)$$

$$E_z = E_\theta \cos \theta \sin \phi + E_r \sin \theta \sin \phi \quad (6-b)$$

$$E_x = -E_\theta \sin \theta + E_r \cos \theta \quad (6-c)$$

$$H_y = -H_\phi \sin \phi \quad (7-a)$$

$$H_z = +H_\phi \cos \phi \quad (7-b)$$

$$H_x = 0 \quad (7-c)$$

where E_θ , E_r and H_ϕ are given by (1-b), (1-a) and (1-c) respectively and where, from (3) and (4)

$$\cos \theta = \frac{z}{r}, \sin \theta = \frac{\rho}{r}, \rho = \sqrt{(z-h)^2 + y^2}, r = \sqrt{\rho^2 + x^2}, \cos \phi = \frac{y}{\rho}, \sin \phi = \frac{(z-h)}{\rho}$$

The sequence of computations that lead to the results reported in Figures 3-6 are described in what follows:

3.1 Direct wavefield in above-surface region

The first stage of the computation (the $1 \rightarrow 2$ ray illustrated in Figure 2-a) is to specify the location of the transmitter at $x = y = 0$, $z = 10\text{cm}$, and x , y , z at the center of each element in the above-surface portion of the grid, specify the values of I_0 and ℓ (which will affect the end results only as a scale factor), then calculate E_r and E_θ through (1-a) and (1-b) with the aid of (3) and (4) for the center of every grid element above the air-ground interface, i.e. from $x = -25\text{cm}$ to $+25\text{cm}$, from $y = -25\text{cm}$ to 25cm and z from 0 to 20cm . Then for each of the elements the rectangular components of the electric field are computed from these results, using Eqs. (6-a, b, c).

The resulting three-dimensional arrays of electric field components over the above-ground portion of the grid is the first of the outputs obtained and is designated as the "direct wavefield". It represents the field that would be seen at each point in the absence of the lower-half space occupied by the soil.

3.2 Ground-reflected wavefield in above-surface region

The second contribution to the total field in the region above the air-ground interface is the ground-reflected wavefield (illustrated as the $1 \rightarrow s \rightarrow 2$ ray in Figure 2-a). If the interface is perfectly horizontal, i.e. with no surface roughness, then the major contribution is in the specular direction at each point of intersection of the direct wave with the interface. The method of approach is to begin with the direct wavefields immediately above the ground surface, use the tangent plane approximation for the total field just above the surface and evaluate the Stratton-Chu integral [9] over the portion of the air-ground interface included in our simulation domain (tacitly assuming that the region outside that domain has a negligible influence on the results). If the integration is done

by the stationary phase method, then using simple theory reported in many standard references, the stationary phase ("sp") point on the ground given a receiving point at (x_R, y_R, z_R) and a source point at (x_1, y_1, z_1) is easily shown to be

$$x'_{sp} = \frac{x_R z_1 + x_1 z_R}{z_1 + z_R}, \quad y'_{sp} = 0, \quad z_{sp} = 0 \quad (8)$$

where the primed horizontal coordinates are in a system whose $x' - z$ plane is the vertical plane of propagation of the wave from 1 to s to R . The angle ϕ' between that plane and the $(x - z)$ plane of the unprimed system is defined by

$$\cos \phi' = \frac{x_R - x_1}{\rho'}, \quad \sin \phi' = \frac{y_R - y_1}{\rho'}, \quad (9)$$

where $\rho' = \sqrt{(x_R - x_1)^2 + (y_R - y_1)^2}$. The global coordinates of the sp point are

$$x_{sp} = \frac{x_R z_1 + x_1 z_R}{z_1 + z_R}, \quad y_{sp} = \frac{y_R z_1 + y_1 z_R}{z_1 + z_R}, \quad z_{sp} = 0 \quad (10)$$

The computation of the electric field components through Eqs. (6-a, b, c) includes that of the fields just above the boundary. Eqs. (7-a, b, c) are then used to compute the magnetic field components just above the boundary. The electric field component that is normal to the plane of propagation is that of the transverse electric (TE) incident wave at the sp point and the corresponding magnetic field component is that of the transverse magnetic (TM) incident wave at that point. Then the TE and TM reflection coefficients R^{TE} and R^{TM} are computed at the sp point and used to determine the surface fields under the tangent plane approximation. Those fields are then used to evaluate the integral by the sp method, leading to a factor of the form

$$I_s = \frac{-j\pi}{k_0} \left[\frac{r_{1s} r_{sR}}{r_{1s} + r_{sR}} \right] \frac{1}{|\cos \theta_i|} \quad (11)$$

multiplying the Stratton-Chu integrand at the surface points, where r_{1s} and r_{sR} are the distances between transmitter and s and receiver and s respectively, θ_i is the angle of incidence, and where the TE and TM surface fields are given by $(E_i)_\perp (1 + R^{TE})$ and $(H_i)_\perp (1 + R^{TM})$ where $(E_i)_\perp$ and $(H_i)_\perp$ are the components of the incident fields normal to the plane of propagation. If the physical optics method is used to evaluate the integral for each rectangular surface patch, and there is no surface roughness, then the factor I_s in (11) is replaced by an expression of the form

$$I_s = \Delta S \sin c(\pi a_x) \sin c(\pi a_y) \quad (12)$$

where ΔS is the patch area and a_x and a_y are x and y components of the phase factor on the patch, given by

$$a_x = \sin \theta_i \cos \phi_i + \sin \theta_s \cos \phi_s$$

$$a_y = \sin \theta_i \sin \phi_i + \sin \theta_s \sin \phi_s$$

where subscripts i and s indicate incident and scattered respectively. In our code, both the sp method and the po method are available as options.

3.3 Wavefield transmitted into subsurface medium

The first set of outputs in the subsurface grid is the set of rectangular components of the electric fields of the wave transmitted across the boundary into the soil medium. The background theory for this process (the $1 \rightarrow q \rightarrow p$ process illustrated in Figure 2b) was discussed briefly in [1] (Text from Eq. (1) through the paragraph including Eq. (3)) and in greater detail in [2] (section 2 of [2] “Background Analysis”, including Eqs. (2-a) through (4-c) and the remainder of the paragraph below (4-c)) for a perfectly flat horizontal boundary. In [3] the analysis was extended to account for surface roughness. (The discussion of this process in [3] begins above Eq. (1) and extends one paragraph beyond Eq. (11-b)).

Further analysis in [3] (Eqs. (16) and (17) in [3] and the text surrounding these expressions), relates to the selection of the method of evaluation of the Stratton-Chu integral over the lower side of the air-ground interface. The same tradeoff between the greater accuracy of the physical optics method and the greater speed of the stationary phase methods of integration exists for both the reflection process discussed in Section 3.2 and the transmission process under discussion here. On both processes, the code contains both options.

3.4 Scattered wave from subsurface inhomogeneities

The background analysis for the wave scattered from complex permittivity inhomogeneities in the subsurface medium by the Born approximation was covered in [1] (Eq. (6) and associated text) and [2] (Text beginning above Eq. (5) and extending through Eq. (6)). In our previous work the scattered field from a subsurface region needed to be calculated only for observation points on the underside of the air-ground interface as an interim step in obtaining the fields at a specified above-ground receiver location. The Born scattering code was executed for each subsurface source point and for all observation points on the surface grid. In the current study, for each element within the subsurface volume grid whose complex permittivity differs from that of the ambient medium, Born scattering of a wave incident on that element must be computed for observation points at all other subsurface grid elements. The number of computations of Born scattering from each element is increased from $(N_x N_y)$ in [1, 2, 3] to $(N_x N_y N_z)$ in the present study, where N_x , N_y , and N_z are numbers of volume elements in the subsurface grid in the x , y , and z directions respectively and N_x and N_y are also the numbers of x and y surface patches on the air-ground interface.

3.5 Wavefield due to subsurface scattering into above-surface region

The wavefields due to scattering from subsurface inhomogeneities are superposed on the direct and ground-reflected wavefields described in Sections 3.1 and 3.2 respectively as a contribution to the fields in the above-surface grid. This process, illustrated as the path $p \rightarrow q' \rightarrow 2$ in Figure 2b, is

described for the case of the flat boundary in [1] (the “return path,” Eqs. (4) through (6) and associated text) and [2] (Text beginning above Eq. (6) and extending through Eq. (11-b)). It is extended to include surface roughness in [3] (From three paragraphs above Eq. (12-a) through Eq. (17) and the remaining text in Section 2). The same two options for integrating the Stratton-Chu integral over all surface points q' (the *sp* and *po* methods) are available for the return path wave as for the ground-reflected wave (Section 3.2) and the wave transmitted into the subsurface medium (Section 3.3). The factors multiplying the Stratton-Chu integrand for the return path for the *po* and *sp* methods are given respectively by (16) and (17) in [3] for the general case accounting for surface roughness.

3.6 Additional contributions to wavefields

If there is no subsurface clutter due to permittivity inhomogeneities (as we assume for these computations), then in the absence of a buried object such as a mine, the only contributions to the above surface wavefields are those due to the direct wave (Section 3.1) and the ground reflected wave (Section 3.2) and the only contributions to the subsurface wavefields are those due to the transmitted wave (Section 3.3). That is the first set of cases we are running.

If a plastic mine is present, then the Born scattering processes described in Sections 3.4 and 3.5 are also present and contribute to the total wavefield in the subsurface and above-surface regions respectively. This suffices for the first order Born approximation. It is evident that the contrast between mine and soil permittivity is too large to ensure accuracy with first order Born scattering. Accuracy would probably be significantly enhanced with second or higher order Born, i.e. the incident wavefield at the mine location includes the effect of downward reflection of the first order scattered fields from the underside of the air-ground interface and possibly further back-and-forth interactions between lower order scatterings from the mine and reflections of these scattered fields from the underside of the boundary. Although the code to implement these higher order effects can easily be made available, we have not attempted to include it in this study. The reason is the enormous proliferation of required running time for each higher order process. Since the major advantage of our approach over highly accurate numerical codes such as MOM or FDFD is computation speed, it might be counter productive to go too far in this direction.

4 Results and Conclusions

The results of the computations discussed above are presented in Figures 3 through 6, each of which is a 3 dimensional plot of the amplitude of the electric field vs. a horizontal coordinate (x or y) on one axis and the vertical coordinate (z) on the other axis. The xz plots (Figures 3 and 4) are from $x = -25cm$ to $+25cm$, $z = -20cm$ to $+20cm$ and $y = 0$. The yz plots (Figures 5 and 6) have the same range of y and z with $x = 0$. In each case, the computations were of the three rectangular components of the electric field amplitude, $|E_x|$, $|E_y|$ and $|E_z|$ and the total field amplitude $\sqrt{E \cdot E^*}$. Only the total amplitude is shown on the plots. Figures 3 and 5 are for the case of a flat air-ground

interface without the mine and with the mine respectively. Figures 4 and 6 are also for the cases of no mine and mine respectively. It is evident that there is no perceptible difference between these four plots. First, the mine and no-mine cases cannot be distinguished on the xz plots or on the yz plots. Secondly, the xz plots and the yz plots show nearly perfect symmetry about the yz and xz planes respectively, which is expected since the transmitter is located at the horizontal center of the simulation domain.

Also, the xz and yz plots show only miniscule differences in shape in both sets of plots and the amplitudes appear to be zero in the subsurface region. In the output files, the subsurface fields are not zero but are so small compared to the peak values in the vicinity of the peak that they plot as zero. This is because the amplitude resolution was chosen to include the peaks on the plots. Plots that are made with finer resolution showed small nonzero values in the subsurface grid but truncated the peaks. Small differences between xz and yz plots do appear when amplitudes of field components rather than total field are plotted (Figures 7 and 8). This is expected because the dipole is parallel to the xz plane and therefore the xz and yz planar cuts are different.

The comparisons between these results and FDFD results are not yet completed as of this writing. It is planned that comparison results will be shown at the conference presentation. Current indications are that the general shapes of the two curves are similar for the resolution scales used. However, much better distance resolution is available for the FDFD computations, which are run on a computer with ten times the RAM currently available for the ray-based computations. For this reason, some of the fine detail that shows up on the FDFD plots is suppressed on the ray-based plots. Running times for the FDFD code are between 30 and 40 hours while those currently being done with the ray-based code require about one minute for the no-mine case and about seven minutes for the case with a mine present. For the latter computations, enhancing the distance resolution, using physical optics rather than stationary phase for the integration over the boundary, and using higher order Born approximations for scattering from the mine will certainly increase CPU time, but we have not yet determined the amount of the increase.

Abstract--This study attempts to quantify the ground penetrating radar rough ground surface clutter by numerical modeling of wave scattering, and establish a strategy to suppress the clutter for given test signals. The goal is to improve the GPR detection statistics for small, buried, low-contrast nonmetallic antipersonnel mines. Using a model of an experimentally measured impulse GPR signal, we simulate the ground surface and buried low-contrast mine target scattered responses. We employ a 2D finite difference time domain (FDTD) method to analyze the pulse shape, delay, and amplitude characteristics of the scattered waves -- with and without buried nonmetallic mine targets -- as a function of roughness parameters. Five hundred Monte Carlo simulations of various test cases of specified ground root mean square height and correlation length were run to generate statistics for the clutter and target signal variations. In addition, the effectiveness of identifying and removing the ground surface clutter signal for detecting subsurface targets is presented. Results indicate that even with moderate roughness, statistics can be generated to enhance the detection of small, shallow, low contrast targets.

1. INTRODUCTION

The problem of detecting buried dielectric targets -- such as nonmetallic antipersonnel mines -- with ground penetrating radar (GPR) is important and challenging. Because the dielectric constant and electrical conductivity of the mine target (2.9 and 0.0001 at 1 GHz) is similar to that of the surrounding soil and its size is comparable to the thickness of soil above it, detection and discrimination are difficult. In addition, the soil dielectric constant may not be well characterized, and the ground surface will usually be rough, often with surface height variations of the order of the target burial depth. While there are many sources of clutter obscuring the mine target signal — including volumetric inhomogeneities (rocks, roots, metal fragments) and surface vegetation — the largest single source of undesirable signal is the ground surface itself. Since the ground has an infinite surface and presents a larger impedance mismatch with the air above it than with the low-contrast, nonmetallic target within it, its contribution to clutter is quite significant. Further, since buried clutter objects can only be inferred by imaging and reconstruction, the ground surface is unobscured, and its effects can be measured directly.

Impulse ground penetrating radar has been used as a robust and relatively inexpensive means of detecting underground objects [1]. By observing the arrival time of a subsurface scattered pulse and eliminating the reflection from the ground surface by time gating, it is possible to detect deeply buried anomalies. However, when the target is small, shallow, and of low contrast, special modeling and processing are required to characterize and separate the ground surface clutter from the target signal. A commonly used procedure of

background averaging to remove the ground clutter signal can be effective for very smooth ground surfaces, but tends to rapidly degrade for moderate roughness. In this study, we simulate the effects of rough ground on the GPR signal using Monte Carlo FDTD modeling of random surface variation. Because of the need for multiple case studies of hundreds of Monte Carlo runs, we used a very fast 2-D TM FDTD code, specifically adapted to frequency dependent, lossy media, with a lossy Perfectly Matched Layer (PML) ABC [2-4]. Clearly, more accurate modeling is afforded with a three-dimensional FDTD model, but each set of 500 runs would require 2000 hours of supercomputer CPU time. Instead, this study presents a range of possible signal delay, attenuation, and distortion characteristics, with associated statistical variation as a function of ground surface roughness.

As a baseline, we model the wave scattering for a bistatic impulse GPR geometry, based on the Geo-Centers EFGPR mine detection system, as shown in Fig. 1, using the measured Geo-Centers TEMR antenna element radiated signal as the excitation, presented as a function of time in Fig. 2 [5]. This pulse is wideband, with frequency response (6 dB roll-off) from 700 MHz to 1.3 GHz. This frequency range is ideal for detecting antitank mines, which are thicker and more deeply buried than antipersonnel mines, but is a little too low for optimal discrimination of objects with scale lengths of the order of 5 cm. The TEMR element radiates a fairly broad beamwidth nearfield antenna pattern, with wideband half-power points at roughly $\pm 60^\circ$ relative to boresight. The FDTD time and space steps used are $\Delta t = 20\text{ps}$ and $\Delta = 1.22\text{cm}$, maintaining a Courant condition $r = 0.5$. Simulations are run for 500 surface realizations -- with and without a

mine target at a typical burial depth of 8.5 cm below the nominal surface level -- for a variety of roughness statistics.

2. ROUGH SURFACE MODEL FORMULATION

Assuming that the random height of the ground surface has a Gaussian distribution with zero mean and standard deviation equal to σ_h , the probability density function of the height z is [6]:

$$p(z) = \frac{1}{\sigma_h \sqrt{2\pi}} \exp\left(-z^2 / 2\sigma_h^2\right) \quad (1)$$

This statistical distribution of the height provides no information about the distances between the hills and the valleys of the surface [6]. An additional function is needed to describe the density of the surface irregularities of the rough surface. This function is the autocorrelation function or its Fourier Transform, the surface profile power spectral density function. The autocorrelation function $R(x_d)$ gives the correlation between the random heights at two different points on the surface, x_1 and x_2 . It is defined by [6, 7]:

$$R(x_d) = \frac{\langle f(x_1)f(x_1 + x_d) \rangle}{\sigma_h^2} \quad (2)$$

where $x_d = x_2 - x_1$. For full correlation, $\lim_{x_d \rightarrow 0} R(x_d) = 1$, and for independence,

$\lim_{x_d \rightarrow \infty} R(x_d) = 0$. Moreover, if the surface profile spectral density function $W(K_x)$ is given,

then the auto-correlation function $R(x_d)$ can be obtained by the inverse Fourier Transform as:

$$R(x_d) = \frac{1}{s_h^2} \int_{-\infty}^{\infty} W(K_x) \exp(iK_x x_d) dK_x \quad (3)$$

Thus, the Gaussian joint probability density function for two heights on the surface, z_1 and z_2 , with zero mean and standard deviation σ_h is given by [6, 8]

$$p(z_1, z_2) = \frac{1}{2\pi s_h^2 \sqrt{1 - R^2(x_d)}} \exp\left(-\frac{z_1^2 - 2R(x_d)z_1z_2 + z_2^2}{2s_h^2(1 - R^2(x_d))}\right) \quad (4)$$

If the surface spectral density $W(K_x)$ is assumed to be Gaussian as [7]

$$W(K_x) = \frac{l_c s_h^2}{2\sqrt{p}} \exp\left(-\frac{K_x^2 l_c^2}{4}\right) \quad (5a)$$

in which K_x is the surface profile wave number. Thus from (3), the auto-correlation function will also be Gaussian given by

$$R(x_d) = \exp\left(-\frac{x_d^2}{l_c^2}\right) \quad (5b)$$

where l_c is the correlation distance for which $R(x_d)$ will drop to the value e^{-1} .

While other statistical variations for randomly rough ground surfaces may be more applicable for some rough ground surfaces, the Gaussian provides a sufficiently rich family of surface realizations to establish a population for analyzing clutter effects.

Although statistical analysis can be done on the received signals themselves, it is more useful to consider the particular effects on these signals caused by scattering by the rough ground. For example, Fig. 3 shows the computed received signals from 100 rough surface realizations of a ground surface with height and correlation length $\sigma_h = 3\text{cm}$ and $l_c = 10\text{cm}$, without (Fig. 3a) and with (Fig. 3b) a buried target. The mean signal and levels

one standard deviation above and below the mean signal is overlaid on each plot. It is clear that there is no discernable difference between the signals for the buried target plot and the target-free plot.

If the correlation length l_c is large, the received signal will retain its pulse shape in time, experiencing primarily a shifting in time and a change in amplitude corresponding to greater or lesser propagation distances from source to ground to receiver. By identifying these parameters and measuring their statistics separately, much added information about the clutter becomes available. In addition, compensating for the time shift and amplitude scaling allows the shape of each individual received signal to be examined, and used in the determination of whether a buried target is present.

To identify the amplitude scaling A_i of the received pulse S_i for a given trial, we compute the square root of the total energy in the signal divided by the energy in a suitable reference signal. We use the computed received scattered signal from an ideal soil half-space with a flat boundary as the reference S_f :

$$A_i = \sqrt{\sum_{n=1}^N |S_i(n)|^2} / \sqrt{\sum_{n=1}^N |S_f(n)|^2} \quad (6)$$

Alternatively, the value of the signal peak could be used for this scaling, but it was determined that energy normalization is superior for rougher surfaces that generate greater pulse distortion.

The time shifting is found by cross-correlating each signal under test with the same reference signal, each normalized to the square root of its energy. The cross-correlation

function indicates the inter-dependence of the values of two different processes at two different times:

$$C_{fi}(m) = \frac{\sum_{n=1}^{N-|m|} S_f(n) S_i(n+m)}{\sqrt{\sum_{n=1}^N |S_f(n)|^2} \sqrt{\sum_{n=1}^N |S_i(n)|^2}}, \quad \text{for } m \geq 0 \quad (7a)$$

$$C_{fi}(m) = C_{if}(-m), \quad \text{for } m < 0 \quad (7b)$$

where $i = 1, 2, 3, \dots, M$ is the rough surface realization index, M is the size of Monte Carlo sample, and N is the total number of time steps. Note that the normalized cross-correlation of the reference signal with itself has a maximum of unity at $m = 0$; that cross-correlation with a shifted copy has a unity maximum at the index corresponding to the shift; and that cross-correlation of dissimilar signals will have a maximum less than unity. The maximum value of this cross-correlation function is a measure of the pulse shape distortion from that of the ideal flat ground response.

3. NUMERICAL RESULTS

Numerical experiments were performed on the well-measured Puerto Rican clay loam with 10% moisture and 1.4 g/cc density [9]. This soil has dielectric constant varying as $6.4 < \epsilon' < 6.1$ and electrical conductivity $0.033 < \sigma < 0.067$ and the wavelength in this soil varies from $17.0 < \lambda < 9.5$ cm over the 700 MHz to 1.3 GHz bandwidth. The dispersive FDTD model employed uses the Z-transform supplemental equation model for frequency dependent conductivity [2]. With this model, the real dielectric constant is

assumed to be constant and the ratio of electric current density and electric field is given by:

$$\mathbf{S}(\mathbf{w}) = \frac{b_0 + b_1 Z^{-1} + b_2 Z^{-2}}{1 + a_1 Z^{-1}},$$

where $Z = e^{-i\mathbf{w}D}$ for the frequency \mathbf{w} . For the particular type of Puerto Rican clay loam, the parameters have been found to be [3]: $b_0 = 0.916249$, $b_1 = -1.67662$, $b_2 = 0.761072$, $a_1 = -0.88$, and $\epsilon'_{Av} = 4.167$. Note that since the imaginary part of $\sigma(\mathbf{w})$ is non-zero, it will contribute to the real part of the dielectric constant, raising it above the ϵ'_{Av} value to the measured values 6.1 to 6.4 .

For each pair of Gaussian height and correlation parameters, 500 FDTD runs were performed on different surface realizations. In each case, the scaling and shift were determined using (6) and (7). An example of the distribution of these characteristics for the pair $\sigma_h = 3\text{cm}$ and $l_c = 30\text{cm}$, is shown in Fig. 4. The average scaling is 0.995 and the average shift is -55 ps. From these histograms, it is apparent that although the ground heights are normally distributed, the amplitudes and time shifts are not.

With the ultimate goal of target detection, it is important to observe the differences in the received signal when a mine is buried under the rough ground surface. For each surface realization, this difference can be clearly seen by simply subtracting the nominal ground-only signal from the signal with the mine present. In this simulated situation, the clutter would be known *a priori* and numerically removed. In practice, this is not possible, since the clutter signal is not separately available. It is the goal of these Monte Carlo

experiments to reasonably estimate the rough surface clutter effects so that they can be suppressed relative to the mine signal, without the *a priori* knowledge of the ground clutter effect for a given trial.

Using the individual FDTD differences, the responses due to the presence of mines can be compared to the signals from the ground surface alone. The mine position is usually determined by measuring the time delay corresponding to the path to and from the buried target. However, with rough ground, the path from the transmitter to ground to mine and back out to the receiver, changes with the local ground surface height, or the height of the antenna. Since the wave propagation velocity is quite different in air as opposed to soil, the target time delay for a given mine depth varies considerably.

Scatter plots showing the distribution of the shifts of the ground scattered signals $\tau_{\text{gnd}(i)}$ compared to the time delay of the mine scattered signals $\tau_{\text{mine}(i)}$ relative to a nominal perfectly flat ground for different rough surface parameters are shown in Fig. 5. For low contrast targets the dominant aspect of each scattered signal is the ground scattering, so the cross-correlation function gives $\tau_{\text{gnd}(i)}$. To find $\tau_{\text{mine}(i)}$, (7a) is applied to the difference between the signal scattered by the ground and mine and the ground alone (the target signal with *a priori* ground clutter signal removed). The surface root mean square height is $\sigma_h = 3\text{cm}$ in Fig. 5a and Fig. 5b while it is 2cm in Fig. 5c and Fig. 5d, and 1cm in Fig. 5e and Fig. 5f. The correlation length is $l_c = 10\text{cm}$ for the figures on the left and 3cm for those on the right. There is a strong correlation between $\tau_{\text{gnd}(i)}$ and $\tau_{\text{mine}(i)}$. A regression analysis is conducted to fit these simulated data with a straight line. The slope of this line

corresponds to the relative delay between the ground and target scattered signals. The slope is negative, and for very long correlation lengths—corresponding to large, flat raised or lowered portions of ground—would be equal to the $(1-\sqrt{\epsilon'})$. Since a positive shift in τ_{gnd} indicates the presence of a depression, which in turn implies less soil covering the mine, the time delay for the mine signal, τ_{mine} , is reduced by the difference of the wave velocities in air and soil times the depth of the depression. As shown in Fig. 5, the fitting error increases with the root mean square slope $\sigma_s = 1.414 (\sigma_h / l_c)$ [10]. Also, it can be seen that the distribution of points is closer to the mean for small height variation σ_h .

The clutter signal can be suppressed and consequently the target signal can be enhanced using physics-based signal processing. Subtracting the measured or modelled ground surface clutter signal has been a successful strategy to enhance the signal under test [11]. It is possible to improve on this basic algorithm for rougher surfaces using a multiple pass process. First, the average clutter signal is found by shifting each ground-only signal by $-\tau_{\text{gnd}(i)}$, then taking the ensemble average [12]. Note that this is an average over signals, not time, so the resulting signal will be the average pulse shape for the rough ground with delay compensation for the local height variation. Second, this average signal is shifted back by $\tau_{\text{gnd}(i)}$, and scaled by factor A_i in (6) for each mine-in-ground signal and subtracted from these signals. By using the previously modeled (or measured) surface signals to find the ensemble average pulse shape gives the best estimate for the local clutter that corrupts the target signal. Fig. 6 shows the result of this subtraction on each of the 100 signals of Fig. 3. The differences between the ground-only (Fig. 6a) and

mine-present (Fig. 6b) signals are now quite clear. The maximum amplitude of each processed signal is considerably smaller than for each of the original signals in Fig. 3, since much of the clutter has been removed. Since the appropriately delayed average ground clutter signal has been subtracted rather than the *a priori* known clutter signal for each trial, the clutter removal is not perfect. The ensemble averages for the ground-only and mine-in-ground cases in Fig. 6 indicate that for the particular soil type, mine depth, and radar excitation, the presence of signal at a certain time interval and above a given threshold corresponds to a buried target. This provides the basis for a statistical target detection procedure. The results for this example case do not apply for all cases, but the strategy for suppressing ground surface clutter is generally applicable, as long as the mine is not too close to the surface, or the excitation pulse too long. This approach could be used in realistic field measurements, without separately measuring the ground roughness or knowing if a target was present.

If the surface scattered wave were primarily due to a single specular reflection – as would be the case if l_c were large – then this procedure would suppress most of the surface clutter. However, it is possible that the surface scattering occurs at multiple points. In this case, the cross-correlation/shifted ensemble averaging and subtracting procedure is repeated. This process is shown schematically in the flowchart of Fig. 7. The initial box labeled “Raw Signals” refers to either the 500 Monte Carlo FDTD simulated signals or actual measured data, obtained progressively with updated averaging.

The signals produced from these multiple subtractions represent the signals scattered just from the target. The obtained shifts τ_i are amplified by the slope values of the straight lines shown in Fig. 5 and then used align these target-only signals. Fig. 8 shows the result of multiple subtraction and shifting to realign the mine signals. Note that this realignment would have to be performed for every presumed mine depth. This procedure can be performed during actual GPR operation in the field, using several ground-only calibration measurements as the average signal. For hardware focused systems, the ground surface clutter suppression must occur at each receiver, before the signals from multiple receivers are combined.

The average clutter suppressed signals for ground with mine present have been obtained for the same Gaussian roughness parameters of Fig. 5, and shown in Fig. 9. Also shown are curves indicating one standard deviation above and below the mean. As expected, the standard deviation is much smaller for the target signal than for the clutter signals. Also visible in Fig. 9 is the increase of clutter with the surface mean square slope σ_s . Correlating any trial signal for a given statistical ground roughness and the average signal for that roughness with inverse weighting by the standard deviation provides a strong parameter for estimating the presence of a mine at a given position.

Note that the ground signal is detected for each trial signal, so that any given ground roughness variations, or even radar antenna height variations are accounted for. That is if the GPR bounced or sagged at a given sample, the ground signal would still be correlated with the shape of the average ground signal, and the appropriate shift is determined.

4. CONCLUSIONS

Identifying the time shift and amplitude scaling of the ground surface clutter by correlation with the ideal flat ground provides a means for ground surface clutter removal for a given signal. Shifting this clutter-suppressed signal by a time delay roughly proportional to the differential propagation velocity in the effective soil layer (or absence of soil) relative to the nominal soil level realigns the target signal to its expected temporal position. Using this procedure, even fairly shallow buried nonmetallic mines signals can be distinguished from rough ground surface clutter using available (nonideal) impulse GPR sources.

Although this study is based on two-dimensional synthetic modeling, it presents a representative set of randomly cluttered signals, and shows that the physics-based processing suppresses clutter and leads to enhanced target detection. The problem of mine detection is certainly more complicated than detecting anomalous signals generated by subsurface objects. The issue of distinguishing the particular mine target, as opposed to other buried objects: rocks, roots, pockets of water, is not addressed in this study. However, combining the information from multiple views from different radar positions will help characterize the shape of the anomaly. In addition, fusing information from other modalities—such as electromagnetic induction, acoustic, and infrared detection—with GPR will help reduce false alarms, giving some hope in the effort to characterizing buried mines.

Imaging infrared polarimetry: initial results and potential in detection of scatterable mines and surface disturbances

Herman E. Scott, Stephen H. Jones and Frank Iannarilli
Aerodyne Research, Inc., 45 Manning Road, Billerica, MA 01821-3976¹

ABSTRACT

Over the past year with the support of the Army Humanitarian Demining MURI, Aerodyne has substantially moved forward in developing and demonstrating the value of an affordable and fieldworthy IR polarimetric hyperspectral imager for inclusion in multisensor demining. Such technology promises powerful clutter suppression and enhancement of man made objects, particularly applicable to the reliable detection of scatterable mines, especially plastics, and any UXO that are partially exposed.. We have achieved the first 3 steps of a 4 step, controlled-risk program defined as follows: (1) LWIR (non-imaging) Spectral Polarimeter to demonstrate the effectiveness of combined polarimetric and hyperspectral discrimination capabilities in observations on static scenes; (2) LWIR Uncooled FPA Imaging (broadband) Polarimeter to verify the sensitivity of an affordable Uncooled FPA in a broadband configuration against static scenes; (3) Multispectral Imaging Polarimeter to quantify clutter rejection performance improvements to be realized from multispectral imaging polarimetry; and (4) IR Polarimetric Hyperspectral Imager designed with optimal spatial and spectral resolution and sufficient throughput to achieve the reliable performance required in surface mine and UXO detection applications. We present results for Steps 1 and 2, and initial results for Step 3 from the ongoing demonstrations in simulated surface mine detection.

Keywords: Infrared polarimetry hyperspectral multispectral imaging demining,unexploded ordnance UXO microbolometer

1. INTRODUCTION

1.1. Background

For more than 15 years Aerodyne Research has worked systematically toward the development of passive IR spectral and polarimetric discrimination techniques. In the first 10 years of these activities Aerodyne focussed on the development and validation of a first principles computer model called POLAR^{1,2,3} that computes the spectrally dependent Stokes vector and user-selected in-band IR polarimetric images of targets given the geometry, optical properties⁴, and thermal description of the target. Support for the POLAR model came from Northrop⁵, the NADC/Warminster^{6,7,8,9}, and internal R&D. Then in recent years, emphasis has turned to the systems applications of polarimetric attributes such as non-cooperative target identification^{9,10} and the discrimination of targets in highly cluttered natural backgrounds.

In 1993 - 95 several important steps were accomplished: Aerodyne and the Boeing Defense and Space Group with the support of NAWC/Warminster used the modified IRAMMP sensor, POLIRAMMP, to collect quasi-polarimetric IR imagery of aircraft on the ground to validate the POLAR model.¹¹ Results showed a strong correlation between the analytic model predictions and measured data. Subsequently in 1994 Aerodyne produced a seminal paper¹⁰ on a polarimeter sensor concept (3-Channel Simultaneous Acquisition Polarimeter) specifically designed for the long range Counter-Air Target Identification application. Shortly thereafter, Boeing and Aerodyne applied the Improved POLIRAMMP sensor in the 1994 Navy Long Jump Tests at China Lake to collect surface-to-air polarization imagery of aircraft and thereby further validate the POLAR model.¹² It was at this test site that we conducted our first primitive simulation of surface mine detection using the two-channel POLIRAMMP sensor. Even though this test simulated only surface mine detection¹³, it provided quite convincing evidence of the clutter suppression capability of IR polarimetry.

In 1997 under a Phase I SBIR for the Air Force Research Laboratory (AFRL), Aerodyne invented a IR Polarimetric Hyperspectral Imager concept¹⁴ capable of providing the perfectly co-registered, polarimetric hyperspectral imagery desired for locating polarized objects in a cluttered background from a dynamic moving platform. We are in the process of building the prototype hyperspectral IR polarimeter under Phase II SBIR support from the AFRL. In a parallel project sponsored by

the Army Research Office (ARO) Humanitarian Demining MURI / Northeastern University (NEU) Team, we are taking incremental steps to demonstrate the value and reliability of LWIR spectral polarimetry in the detection of antipersonnel (AP) mines, especially plastic flush-buried and scatterable types.¹⁵ Our stepwise progress and the LWIR polarimetric spectral imaging proof-of-concept demonstrations in the demining application are the topics of this paper.

1.2. Scope

Many researchers have investigated LWIR and multiband passive infrared sensing techniques for applications in demining;¹⁶ a few investigations have considered passive IR polarimetry and costly hyperspectral imaging methods separately for locating land mines;¹⁷ yet insofar as we have found, no previous investigators have pursued the combination of hyperspectral IR polarimetry and affordable LWIR uncooled focal plane arrays. Effort in this Demining MURI is devoted to deliberate, controlled-risk, proof-of-concept demonstrations that verify our particular innovative combination of LWIR hyperspectral polarimetry and affordable uncooled FPA technology can be reliable and effective in surveying and locating exposed surface mines of any material type. The exploitation of polarimetric attributes that are demonstrated in this project effort were in most cases suggested and supported by our earlier analytic investigations into systems applications of IR polarimetry^{9,10,18} In addition to the proof-of-concept tasks, we are investigating surface optical properties of the relevant classes of materials and coatings for mine fabrication; this is a concurrent laboratory effort to fill the important gaps remaining from prior optical properties measurements.

The present effort is focused on antipersonnel mines, many of which are partially exposed on the surface or are buried in a very shallow manner. Therefore, we are placing much greater emphasis on the optical properties of materials, emissivity and reflectance, and less emphasis than usual on the material thermal properties. We make no claims to be dealing with the full complexity of thermal conduction issues associated with buried mines, consisting of a wide range of materials in all manner of soils and terrain. Many investigators^{16,19} have examined the conductance and differential heating/cooling effects for opportunities to exploit in locating buried mines using passive IR techniques. Our premise is simple; IR spectral polarimetry is only one of a large arsenal of affordable and reliable technologies required to deal with the extensive, worldwide demining and unexploded ordnance problems. Our objective is to make IR spectral polarimetry an affordable and reliable technique to locate mines having any significant exposure on the surface, regardless of the material composition and including common types of paints and coatings. If we are successful, our method simultaneously positions us to include and exploit significant thermal effects as well since these effects exhibit themselves in the same LWIR wavelength regime. We must give close attention to the magnitude and impact of the heat transfer effects even as we examine the optical properties of materials and coatings.

Since we are implementing a controlled-risk, step-by-step effort to demonstrate a new combination of technologies including the uncooled focal plane array (UFPA) microbolometer, it is important that we establish the terminology for these steps and the technologies to be demonstrated:

- Step (1) - LWIR Spectral Polarimeter
(8 - 12 μm Spectral Region, Non-Imaging, Static Scenes).
- Step (2) - LWIR Uncooled FPA Imaging Polarimeter
(8 - 12 μm Broadband, No Spectral Resolution, Static Scenes).
- Step (3) - LWIR Uncooled FPA Multispectral Imaging Polarimeter
(Multiple Bands in 8 - 12 μm Spectral Region, Static Scenes).
- Step (4) - Uncooled IR Polarimetric Hyperspectral Imager
(8 - 12 μm Spectral Region, Spectral Resolution $\sim 0.02 \mu\text{m}$, Imaging,
Registration and Simultaneity in Polarimetric Channels for Dynamic Scenes).

2. LWIR SPECTRAL POLARIMETER DEMONSTRATION TEST

The data reported in this first proof-of-concept demonstration were collected for a variety of mine-like materials and coatings, including Army CARC (Chemical Agent Resistant Coating, both tan and green), a plastic frisbee, asphalt, and quartz sand. The backgrounds consisted of sand or sandy asphalt in all cases. The asphalt is a particularly challenging background, having a degree of polarization in the infrared that is comparable to or higher than many paints and plastics. Table 1 summarizes the data collection geometries and simulated mine target areas for each location. It is particularly

important to note the ranges and the grazing angles between the sensor (polarimeter) line-of-sight and the target normal. These geometries closely approximate a reasonable deployment geometry for an LWIR spectral polarimeter mounted on either a land vehicle with boom or a low flying UAV platform; however, the modified FTIR spectrometer used in this proof-of-concept demonstration was in no way related to our concept for a field deployable multi-channel polarimeter.

The LWIR spectral polarimeter consisted of an FTIR spectrometer with a wire grid analyzer adapted to it. For this demonstration we used 4 cm^{-1} resolution at 10 scans/sec and collected 200 scans per data point per analyzer angle. The detector was MCT with $D^*_{\text{peak}} = 4 \times 10^{10}\text{ cm Hz}^{1/2}\text{ W}^{-1}$. The wire grid analyzer was 1200 lines/mm on a ZnSe substrate with antireflection coatings on both sides.

As illustrated in Figure 1, reflections from a flat surface induce polarization perpendicular to the plane of incidence (the plane of the page). Emission is polarized parallel to this plane.²⁰ Wire grid polarizers transmit radiation when the E-vector is perpendicular to the wire and reflect radiation when the E-vector is parallel to the wire. We use the convention of 0-degree polarizer angle to mean the wire grid is oriented vertically. Also, we use the spectroscopic notation $\sigma(\sigma)$ for wavenumber (cm^{-1}), and our plots will appear reversed to many readers. The materials used in this demonstration do not transmit in the spectral region of interest, so the simple relationship between the reflectance and emissivity of the materials applies, $\epsilon(\sigma) = 1 - \rho(\sigma)$.

This proof-of-concept demonstration was set up locally in a parking area (see Figure 2) surrounded by several large white pine trees and on the northwest side by a steep embankment of rock outcroppings, rocky soil and scrubs. The parking surface was asphalt, and in the winter months when these data were collected, the asphalt was lightly covered with a residue of sand. The data of interest were collected at locations 4 and 5 as shown in Figure 2 and consisted of fifty polarimeter spectra for the various combinations of target, background, target angle, wire grid analyzer angle, ambient temperature and cloud cover. Again, the setup geometry details are listed in Table 1. Most of the data for these locations were collected in the late afternoon, both before and after sunset, on two successive days with the ambient temperatures between 0- and 15-C. Each spectrum required 20 sec to collect. Since the data collection time was not a primary driver in this demonstration, we made no effort to minimize the time, but it is quite clear that the SNR achieved would allow the collection time to be less than 2 sec per data point per analyzer angle with no important degradation of the results.

2.1. Interpretation of the LWIR spectral polarimeter data

For a view of the spectral data and an understanding of the analysis procedures, we show several overlays of the spectral data in Figures 3 and 4, each at two angles of the wire grid analyzer. As called for in our analysis procedure discussed below, data were normally collected for wire grid analyzer angles of 0-deg (vertical wire grid) and 60-deg; for verification and redundancy we also collected data intermittently at wire grid orientations of 90-deg and 120-deg. Our convention in this analysis is to use the 0-deg and 60-deg wire grid angles as the orthogonal components to differentiate the reflected and thermal emitted radiation components coming from the target and background sources within the field-of-view. The spectra are plotted with the envelope of the shaded area being the spectrum for 0-deg analyzer angle; this spectrum represents the polarized reflection component in the 'horizontal earth' geometry selected for the demonstration. Relative to this the predominantly emission component, passed by the wire grid analyzer in the 60- or 90-deg position, is plotted as a thin solid line lying close to and just above the envelope of the shaded area. The white empty band area, or the difference, between these two envelopes is a measure of the degree of linear polarization (DoLP) of the spatially unresolved scene in the field-of-view of the spectral polarimeter. Note that the DoLP and hence the polarimetric SNR of a spatially resolved mine target will typically be higher than this average of the entire scene, proportionate to the target/scene fill factor. When the scene radiation is totally unpolarized, the orthogonal polarimetric component spectra are coincident over the full spectral range of sensitivity for the polarimeter. Here the spectral region of interest is $800 - 1250\text{ cm}^{-1}$ (or $8 - 12.5\text{ }\mu\text{m}$). The general procedure for extracting scene DoLP from the spectra is given below, and the results are plotted in Figure 5.

Alternatively, the white empty band in between the shaded area envelope and the line plot above represents the spectrally dependent, available polarimetric signal to be exploited. For any given broadband polarimeter the average area under the 2 orthogonal polarizer orientation spectra such as in Figure 3(a) is a measure of the total signal while the difference between these integrated orthogonal polarizer spectra is a measure of the scene polarization signal, the fraction of scene radiation that is linearly polarized. From the integrated areas measured for the materials in Figures 3(c), 3(d) and 4(a), we find the adjusted fraction of target radiation that is linearly polarized when extrapolated to fill the entire FOV of the sensor to be of the order of 10%.

Fractional Area of Total Weighted FOV Occupied by Projected Area of Target	Do Not Know Frac of Asphalt Covered by Sand	0.24	0.07	0.15
DoLP of <u>Scene</u> , adjusted to remove any DoLP of Sandy Asphalt, for the Spectral Region 800-1250 cm^{-1}	0.02	0.02	0.01	0.02
Percent of <u>Target</u> Radiation that is Linearly Polarized When Extrapolated to Fill the FOV of Sensor	----	8%	14%	13%

Upon closely examining the polarimetric component spectra in Figures 3(a) and 3(b), we find that these 0-deg and 60-deg spectra are coincident over the 800 - 1250 cm^{-1} region for soil and sand near normal incidence, so we may expect the degree of linear polarization (DoLP) for these background materials to be very small or zero. Below, we compute the DoLP spectra and indeed show these background materials are substantially unpolarized.

This is not the case, however, when we examine the polarimetric component spectra for the plastic frisbee on sand, CARC on sand, and sandy asphalt by itself in Figures 3(c), 3(d) and 4(a), respectively. In Figures 3(d) and 4(a) we find large separations in the polarimetric component spectra indicating that CARC and asphalt exhibit strong LWIR polarization effects. Furthermore, the separations in CARC and asphalt show an interesting spectral dependence, being very strong near the greybody curve peak at 925 cm^{-1} and gradually narrowing until the gap closes at about 1250 cm^{-1} . While the general shape of the spectra are determined by the greybody temperature and the spectral polarimeter response function (including the optics, analyzer, antireflection coatings and detector), the sharp spectral features in the 1100 - 1200 cm^{-1} region are attributed to quartz sand. Notice these features are not present in the soil spectrum, Figure 3(a). These spectra, rich in features, demonstrate very clearly our interest in the LWIR and our rationale for pursuing hyperspectral polarimetry as a powerful technique to discriminate man made target materials against natural background clutter.

Figure 4. Spectral polarimeter measurements at the noted analyzer angles for sandy asphalt with and without CARC panel present. The relative intensity for the same analyzer angle is always greater with the CARC panel present in the FOV.

2.2. Analysis of polarimetric measurements

The degree and angle of linear polarization (DoLP and AoLP) of a *partially linearly polarized* wave can be obtained from measurements made at three different analyzer angles. The intensity measured at the output of the analyzer oriented at angle α is given by^{10, 20}:

$$I(\alpha) = 1/2 I_u + I_p \cos^2(\theta_p - \alpha) \quad (1)$$

where

$$\begin{aligned} I_p &= \text{Polarized light from target} \\ I_{u-tgt} &= \text{Unpolarized light from target} \\ I_{u-bkg} &= \text{Unpolarized light from background (here assumed unpolarized)} \\ I_u &= I_{u-tgt} + I_{u-bkg} \\ \text{DoLP} &= I_p / (I_{u-tgt} + I_p) = \text{Degree of linear polarization of target} \\ \theta_p &= \text{Angle of linear polarization.} \end{aligned}$$

As is frequently the case with simultaneous trigonometric equations, general solutions in terms of well known functions are difficult to find; a numerical solution can be obtained by searching for it using Newton's method based on minimizing an objective function such as the sum of the squared differences between the measurements and the theoretical value (i.e. left hand side minus right hand side of Eq (1)). The field measurements obtained at Aerodyne were performed such that the surface normal vector of the targets was in the plane of incidence, thereby constraining the emitted light to a 90-degree analyzer angle and the reflected light to a 0-degree analyzer angle. Careful attention was paid to orienting the spectral polarimeter such that cold sky was reflected. Under these circumstances, it is reasonable to make the simplifying assumption that $\theta_p = 90$ degrees (i.e. the reflected component of I_p is negligible). Equation (1) then becomes

$$I(\alpha) = 1/2 I_u + I_p \sin^2(\alpha) \quad (2)$$

By choosing an analysis angle of 0-degrees, the unpolarized intensity is immediately obtained. The polarized intensity can then be obtained by using any other angle (albeit within the limitations of SNR). In the present case of 90-degree angle of polarization, the greatest signal to noise ratio is obtained by using 90-degrees for the second analysis angle. A 1.25 dB loss in SNR results from the use of 60-degrees instead of 90 in this case.

2.3. Results

Using the simplified analysis approach represented in Equation (2), we extracted a quick-look approximate "residual scene DoLP spectrum" for each of the materials observed in this demonstration, presented in Figure 5. Since the quartz sand background was present in varying yet nearly equal abundances within the field of view for 4 of these data, a constant intensity spectrum of sand (corresponding to 100% fill of the field of view) was subtracted in each case. Each residual scene DoLP spectrum thus is an approximate unnormalized (for target fill factor) target material DoLP spectrum. Other features in these DoLP spectra deserving comment are:

1. Soil is effectively unpolarized and provides a point of reference for the other materials plotted in Figure 5.
2. CARC and sandy asphalt exhibit essentially the same DoLP, indicating they will not be easily distinguished using a broadband polarimeter. Refer ahead to view the CARC panel on sandy asphalt in Figure 9.
3. In the 1000 – 1100 cm⁻¹ region the trace effect of ozone remains observable in the spectrum.
4. Fringes apparent in the spectra are attributed to a polarization sensitive beam splitter effect in the FTIR spectrometer.

2.4. The special case of CARC target on sandy asphalt background

The combination of the CARC target imbedded in a sandy asphalt background is a key piece of data from our proof-of-concept demonstration. The reason for this can be seen in Figure 5. Over the spectral interval 800 - 1250 cm⁻¹ the measured DoLPs are the same for CARC on sandy asphalt and sandy asphalt alone; CARC and sandy asphalt cannot be differentiated solely by the broadband linear polarization attribute, i.e. by a single broadband imaging polarimeter. In Section 4 we show image data to confirm this. However, this case provides an excellent example of the powerful tool obtained when the

Figure 5. A plot of the residual scene degree of linear polarization (DoLP) for 4 scenes, and soil-only. A constant sand background intensity, with varying abundances in the FOV for the four scene measurements, has been subtracted as a quick-look means of isolating the approximate target material spectrum. The angle noted is between the sensor LOS and the material surface normal.

Figure 6. Inert antipersonnel mines used in grazing angle reflectance measurements and in imaging polarimeter field demonstration

polarimetric and spectral capabilities are combined in an LWIR spectral polarimeter. One set of the data for tan CARC on sandy asphalt collected with our basic combination of FTIR spectrometer and wire grid polarizer are shown on a magnified scale in Figures 4(a), 4(b) and 4(c). Figure 4(c) is an overlay of four plots - two for the 'CARC present' and two for 'only sandy asphalt'. By inspection of their spectral dependence we can easily distinguish the presence of CARC in the sandy asphalt background. At 900 cm^{-1} the 0-deg and the 60-deg analyzer plots are identical with and without the CARC present; no differentiation here. However, as we move along the wave number axis toward 1200 cm^{-1} , two effects are evident. First, the separation by analyzer angle for each pair of curves (with and without the CARC present) is becoming less and washes out completely by 1250 cm^{-1} (see Figure 4(c) for this to be apparent in the 'CARC present' case). Secondly, the 'CARC present' traces are decidedly higher than 'without CARC' plots over the spectral region $1050 - 1250\text{ cm}^{-1}$. This effect is shown clearly in Figure 4(c). Therefore, in the spectral dimension (at $1050 - 1250\text{ cm}^{-1}$, not 900 cm^{-1}) we have a very strong differentiation of the CARC present in the sandy asphalt background even though the DoLP for the combined CARC and sandy asphalt background afforded no differentiation. This is true even though separately both the CARC and the sandy asphalt exhibit strong polarization effects. These data make a clear case for the importance of adding the spectral dimension to the LWIR polarimeter. Our goal in the demining application is to demonstrate an affordable and effective polarimeter having both spectral and imaging capabilities.

3. LABORATORY MEASUREMENT OF GRAZING ANGLE IR SPECULAR REFLECTANCE OF ANTIPERSONNEL MINE CASINGS

In order to exploit unique spectral features (particularly low emissivity regions) of land mine casings and similar man made objects (typical plastics such as ABS and blended polymers) we must know the spectral features of both the man made materials and the natural backgrounds in these spectral regions. Our laboratory measurement of grazing angle specular (80-deg) reflectance of four AP mine casings and several related, simulant materials of interest confirm the availability of many LWIR spectral features to be exploited in multi- or hyper-spectral polarimetry. These reflectance spectra exhibit the characteristic dispersion curve shape near the centers of absorption features in the materials.

Our laboratory grazing angle reflectance spectra were collected with an FTIR spectrometer at a resolution of 4 cm^{-1} and generally covering the range of 3 - 15 microns ($666 - 3333\text{ cm}^{-1}$). In each case the sample spectrum has been ratioed to the spectrum of a front surface gold mirror that has a reflectance greater than 0.99 over the entire spectral range covered here. The inerted AP mine casings that were available for study are listed in Table 2 and pictured in Figure 6. In addition, Table 2 includes several related or simulant materials of interest for which we collected reflectance spectra, but not all of these will be discussed here.

Sample grazing angle reflectance spectra are plotted in Figures 7(a), (b) and (c). To make the examination of these spectra easy it is important first to eliminate from further consideration all spectral features attributed to the incomplete removal of water vapor and carbon dioxide from the optical path in the laboratory spectrometer; even though the path was constantly under purge with dry nitrogen, this did not completely remove all atmospheric gases from the sample compartment of the instrument. The spectral features to be ignored are water vapor bands at 2.7 and 6.3 microns and carbon dioxide bands at 4.3 and 15 microns. Then it is important to remember that the dispersion features in the reflectance spectra mark the locations of absorption features for the material. Since the material does not transmit radiation at these characteristic absorption wavelengths, the grazing angle reflectance, like the index of refraction, shows a strong change across the width of an absorption feature.

Our hyperspectral polarimetry approach to developing a reliable detection method for partially exposed scatterable land mines exploits differences in the emissivity and

Figure 7. Laboratory measurements of grazing angle specular reflectance for several antipersonnel mine casings and related materials of interest.

polarimetric attributes of mine materials and coatings relative to these same properties for natural backgrounds. Typically, we will examine the spectral reflectance, and thereby the spectral emittance, of the mine materials for unique spectral features and high grazing angle reflectance compared to the backgrounds. With this in mind the measured reflectance spectra presented in Figure 7 have a number of features of interest. First, examining the spectra in Figure 7(c) for similarities, we find the M-14 and Butterfly (PFM-1) mine casings very similar in having very little spectral structure and a difference in overall reflectance level that is accounted for simply by the difference in surface roughness. Although not shown here, reflectance at 14.3 microns is similar between the M-14 mine and the floppy diskette shell, making the latter a very sensible simulant for M-14 surface properties. Also in Figure 7(c) the plastic shells of the TS-50 and VS-50 (not over plotted to avoid confusion) have identical spectral features at 8.1, 8.9 and 10.7 microns and are apparently the same polymer blend. We believe this to be an ABS (acrylonitrile butadiene styrene) plastic, but we have more work to do in matching spectra to polymer blends before claiming to have identified the materials.

Second, examining the spectra of the rubber materials in Figures 7(a) and (c), we find that the TS-50 rubber center and RTV 3110 have the same spectral features at 7.87, 8.96, and 12.2 microns. We conclude the TS-50 center element is actually an RTV silicone rubber. Comparing these same features to the reflectance spectrum for the VS-50 center element in Figure 7(c), we find them to be wholly different and learn by comparison to another spectral database that the VS-50 center element is natural rubber.

In Figure 7(b), we examine the spectrum of an Army camouflage paint of interest, green and tan CARC, because it is a low reflectance coating purposefully formulated to have the optical properties of the natural background. The grazing angle spectral reflectance features measured for tan CARC are located at 9 and 12.5 microns, with the 9 micron feature being very robust. The infrared spectral features of CARC have been studied extensively in the Joint Multispectral Program (JMSP)²¹ for the purpose of identifying spectral bands that provide a dependable two-color discriminant for CARC in a variety of backgrounds. Using apparent spectral contrast data collected over a wide range of backgrounds and local meteorological conditions, this study concluded that the 9 micron feature provides a persistent two band spectral contrast discriminant for CARC (8.73 / 9.23 microns). This is a successful illustration of our effort to use narrow band spectral features for discrimination of mines within clutter when broadband polarimetry alone cannot eliminate all of the clutter.

In general, our laboratory measurements of grazing angle specular reflectance for the materials listed in Table 2 compare well to the more comprehensive and dedicated measurement efforts of Salisbury and D'Aria²² on the spectral reflectance of terrain background materials, of Johnson and coworkers²³ on the spectral emissivity variations in disturbed soils, and of Cederquist and coworkers^{24,25} on the spectral reflectance of target materials and coatings. For insight into the spectral features of blended polymers we found the book by Garton²⁶ to be very useful. Our purpose in making comparisons to these dedicated studies is to confirm our approach and to put a quantitative foundation under our efforts to apply spectral polarimetry to mine detection.

Given that reliable mine detection has proven to be a difficult and frustrating challenge for many qualified investigators, we stand firmly by our stepwise, controlled risk approach as outlined above, and note here again that our laboratory measurement of mine materials spectral reflectance features is a key element in our approach. These data tell us if and where we can expect to apply spectral polarimetry to antipersonnel mine detection successfully. Overall we are encouraged by the availability and robustness of spectral features for plastic mine casing materials found in the LWIR region of interest.

4. LWIR IMAGING POLARIMETER DEMONSTRATION MEASUREMENTS

A series of demonstration measurements were performed on a sampling of inerted non-metallic antipersonnel (AP) mines in various natural backgrounds. The images were collected using an uncooled microbolometer imager operating in the 8–12 μm band. A manually rotated wire grid polarizer (1200 lines/mm) was mounted to the camera in front of a 25 mm focal length f/1.0 germanium lens. Although complete characterization of the polarization state requires four independent measurements (three if partial linear polarization is assumed), only two measurements were made in this proof-of-concept demonstration. The justifications for this are twofold. First, it can be assumed that the elliptical polarization is small. Second, the geometry of the scene was chosen such that the angle of polarization for the objects of interest was either vertical or horizontal, in which case the maximum image contrast will be seen in the difference between images made with the polarizer in these two orientations. A sequence of 10 frames was co-added for each polarization angle before subtraction.

Figure 8. Polarization difference image (0 - 90 degrees) of landmines in sand. (a) Note the raked area at top and disturbed area around lower three mines; (b) Note the sand has been raked and graded to a uniform depth.

Figure 9. Polarization difference image (0 - 90 degrees) of landmines in sand. Note the polarized emission from the vertical faces of the guardrail and asphalt curbing and the polarized reflection from the horizontal strip of bark mulch beneath the railing.

The Fresnel reflectance relations indicate that the angle of polarization of reflected radiation is perpendicular to the plane defined by the incident and reflected beams while that of emitted radiation is parallel to this plane. Wire grid polarizers transmit radiation when the E-vector is perpendicular to the wire and reflect radiation when the E-vector is parallel to the wire. In this paper we use the convention of 0-degree polarizer angle to mean the wire grid is oriented vertically. Consequently, in the intensity difference images (0 - 90 degrees) discussed below, net reflected (emitted) polarized regions appear brighter (darker) than unpolarized regions for horizontal surfaces, with the converse for vertical surfaces.

4.1. Discussion of the LWIR imaging polarimeter data

Figure 8(a) shows the polarization difference image for four mines, a disk of RTV 3110, and a rubber hockey puck buried flush to the surface in sand. The mines, from front to back, are as follows: TS50, VS50, M14, and PFM-1 (Butterfly), followed by the RTV disk and the puck. It is clear from the image that these materials are easily distinguished from this relatively unpolarized and clutter free background. The polarization appears due to emission. It is noteworthy that the top surfaces of the sandbox frame appear significantly polarized, wood being a material used in the construction of certain land mines. A more subtle, yet equally important feature of this image is the contrast evident between the disturbed and undisturbed regions of the sand. A horizontal (i.e., left to right) strip at the rear of the sandbox, extending to the butterfly mine was purposefully raked with a spring steel rake, and the areas surrounding the mines were disturbed to bury them. These areas are clearly distinguishable in the original images. This effect is attributed to a combination of contrast reduction caused by fine-grained particle coatings on the disturbed soil and the increased moisture content of the surface sand in the disturbed regions.^{22,23} In these measurements the undisturbed sand had received two days of sun since the last rainfall, so the surface was very dry. The disturbed areas brought noticeably moist, but not wet, sand to the surface.

Figure 8(b) shows the sandbox rotated 180° so the objects are in reversed order. In this case, the entire surface was well raked and graded to a uniform depth. The uniformity in the image is evident.

Figure 10 shows the same objects in a more natural background consisting largely of undisturbed aged bark mulch. Other elements in the scene include a rock (about 15 cm diameter), a bush, and some small weeds. The two objects labeled “CARC panel” are metal panels painted with CARC. In this image, the absolute value of the polarization difference is taken so net emission and reflection polarization energy both appear as bright. The bush, a small central portion of the rock, and the rear CARC panel were deliberately underexposed while the front CARC panel and the left edge of the mulch were overexposed. This was done to achieve maximum sensitivity in the region containing the mines and is a limitation of the 8-bit digitizer in the frame grabber rather than the imaging polarimeter itself. Clearly, the mines are evident in Figure 10, yet there is much less contrast against the bark mulch, which itself yields partially polarized radiation, compared to the sand in Figures 8(a) and 8(b). Although the contrast is low, most of the clutter in the thermal image has been suppressed. By contrast, Figure 11, showing only the 0-degree image component of Figure 10, exhibits the wide range of thermal variations present in the scene. Notice that in polarization the two CARC panels appear very similar on the gray scale in Figure 10 while in the intensity image (Figure 11) the sunlit CARC panel appears quite hot in comparison to the shaded panel near the bush.

Figure 9 shows the sandbox using the same camera and lens but now at a greater range (about 4 m). The mines and soil disturbances are still evident, but the scene also includes a large wood guardrail, a strip of aged bark mulch below it, and a vertical asphalt curbing. For two materials in the scene, wood and asphalt, we have both horizontal and vertical surfaces of the same materials in view at the same time. It is useful to observe how the contrast flips for the same material as the orientation and therefore the plane of incidence changes between horizontal and vertical. The vertical surfaces of the guardrail, sandbox wall, and curbing are bright in this difference image (0 - 90 degrees) because the plane of incidence is now horizontal.

There are several other basic polarization phenomena to be observed in this scene (Figure 9). The railing is painted dark brown and consequently heats up considerably during the day. The left end of the railing is seen to yield net polarized emission as the view angle increases off-normal. The mulch exhibits polarized reflection when viewed at this grazing angle. The odd-shaped reflective lines near the sandbox are tar-filled cracks in the asphalt. One of the CARC panels is located on the asphalt just beyond the top left corner of the sandbox. Even though the CARC can be distinguished from the asphalt when we know where to look for it, the two exhibit nearly the same degree of linear polarization as seen here in the gray scale image. This confirms the quantitative DoLP results (Figure 5) obtained earlier in the LWIR spectral polarimeter data for CARC on an asphalt background. The top horizontal edges of the wood sandbox are dark, indicating polarized emission from the wood. Since the

Figure 11. Intensity image (at 0-degree analyzer angle) of landmines in bark mulch background with various natural debris and small plants.

Figure 12. Polarization difference image (0-90 degrees) of bark mulch (a) at a range of 12 ft. Note the polarized reflection from individual bark mulch chips at this range where detector IFOV footprint is about 0.5 inches; (b) at range of 45 ft. Note the bark mulch, directly below the black body illuminator, is not discernible from the background at this range where detector IFOV footprint is about 2 inches.

Figure 13. Bark Mulch Spatial Scale

wood is in contact with the hot sand and asphalt, it can be expected to be warm; however, when wood is in contact with cool moist soil, this may not be the case. Finally, notice the rings of disturbed soil around the mines in the sandbox. Our consistency of detecting disturbed soil encourages us to refine our approach by using narrow band filters (multispectral) that are optimized for the characteristic spectral features of various soil types.^{22, 23}

4.2. LWIR imaging polarimeter - importance of spatial scale

These imaging polarimeter data yield an empirical understanding of the spatial scale requirements for a polarization sensor. The polarimetric signal manifested at the detector will be a superposition of the vectorial (Stokes) polarization contributions from the various elemental surfaces of the target, as "ensquared" within a sensor's instantaneous field-of-view IFOV. If the IFOV is too large for the spatial scale of the target features in the scene, the distinctive polarization attributes of the target can be obliterated. Even though it does not provide a direct example of a wrong choice of spatial resolution, the degree of polarization exhibited by the bark mulch, that is the clutter, in Figure 10 illustrates the importance of spatial scale. Here the bark mulch and the flush-buried mines are similar in dimensions. As a result the bark mulch is an effective polarimetric background clutter for mines in this instance where the only attribute being measured is the degree of polarization with a broadband polarimeter. It is correct to infer from this that an investigator who chooses to apply broadband polarimetry alone to scenes of arbitrary spatial scale will fail.

For a more direct illustration of the importance of spatial scale, Figures 12(a) and (b) are polarization difference images, recorded under controlled conditions, of the box of bark mulch shown in the photograph, Figure 13. For Figures 12(a) and (b) the angles between the illuminator, the normal to the bark mulch box and the polarimeter were held constant while the range between the bark mulch and the polarimeter increased from 12 ft in Figure 12(a) to 45 ft in Figure 12(b). The IFOV footprint at the bark mulch is about 1/2 inch in Figure 12(a) and 2 inches in Figure 12(b), compared to a mean dimension of 3/4 inches for the bark mulch chips. As expected the polarized reflectance from individually resolved bark mulch chips are visible in Figure 12(a) but obliterated by the coarser spatial resolution in Figure 12(b).

Clearly, in the design of an hyperspectral polarimeter, the spatial resolution is an enabling design parameter²⁷, making the spectral and polarization attributes of the target accessible to be used as additional discriminants. At the same time, no amount of effort in tailoring the spatial resolution will help in the event the spatial dimension and polarimetric attributes of the clutter are nearly the same as that of the target. In this situation the broad spectral band imaging polarimeter will not be successful, and the need to invoke hyperspectral polarimetry, thereby adding the spectral attributes for discrimination purposes, is clear.

4.3. LWIR imaging polarimeter - performance

The microbolometer FPA demonstrated strong performance when applied in the broad spectral band imaging polarimeter mode with the 1200 line/mm polarizer mounted in the optical train. In addition to the imaging polarimeter that we have assembled around an uncooled FPA being affordable, we can report the following performance on static scenes:

1. With f/1 optics and modest additional effort to hold the temperature of the optics constant when operating in the field, the polarimeter delivered a NEDT $< 0.1^{\circ}\text{C}$.
2. The polarimeter consistently detected disturbances in sand, soil and bark mulch created by burying objects and bringing fresh sample to the surface.
3. The system detected flush-buried antipersonnel mine casings and simulants both night and day, with and without cloud cover.

5. LWIR UNCOOLED FPA MULTISPECTRAL IMAGING POLARIMETER

Even though we are quite pleased with the performance of the uncooled FPA microbolometer in the mode of a broadband imaging polarimeter, it is necessary to next demonstrate its performance as a multispectral imaging polarimeter. There are two goals here. The first is to combine spectral, polarimetric, and imaging feature spaces together in order to demonstrate the increased discrimination gain, relative to earlier abbreviated combinations (i.e. spectral/polarimetric, spatial/polarimetric). The second is to experimentally ascertain the radiometric sensitivity performance when using an uncooled FPA with spectral filters. We recognize that the NEDT of the current uncooled FPA technology is an order of magnitude higher than for cooled FPAs, and thus we anticipate the division of the available polarization signature into say 10 (multispectral) or 100 (hyperspectral) bins implies the uncooled FPA performance as a multi- or hyper-spectral polarimeter may be marginal. We

nevertheless are of course motivated to see how far the uncooled FPA technology can be pushed, given its nearly two orders of magnitude affordability over cooled FPA technology. Our experience to date with the uncooled FPA indicates that its actual NEDT performance can be as much as a factor of two better than the nominal specification.

The LWIR (broadband) imaging polarimeter, implemented using a microbolometer uncooled FPA as described in Section 4, was recently modified to add a 6-slot filter wheel. Two of these bandpass filters were chosen to spectrally discriminate CARC (when using 2-band processing). The desired bandpasses were 8.1–9.2 and 9.2–10.2 μm , but compromising in order to employ inexpensive off-the-shelf filters yielded 8.1–9.3 and 9.3–10.2 μm . Another filter was chosen as an LWIR bandpass of 6.5–14 μm , since the unfiltered microbolometer detector response due to the much broader Germanium optics passband is roughly 3–14 μm , which includes (at times undesired) solar scatter. Two additional filters divide the LWIR into 7.5–10.2 and 10.0–13.6 μm passbands. Finally, the 6th slot was open, allowing the aforementioned full 3–14 μm response. The following sequence of measured imagery constitute early-look results that indicate the discriminative power of polarimetric multispectral imaging.

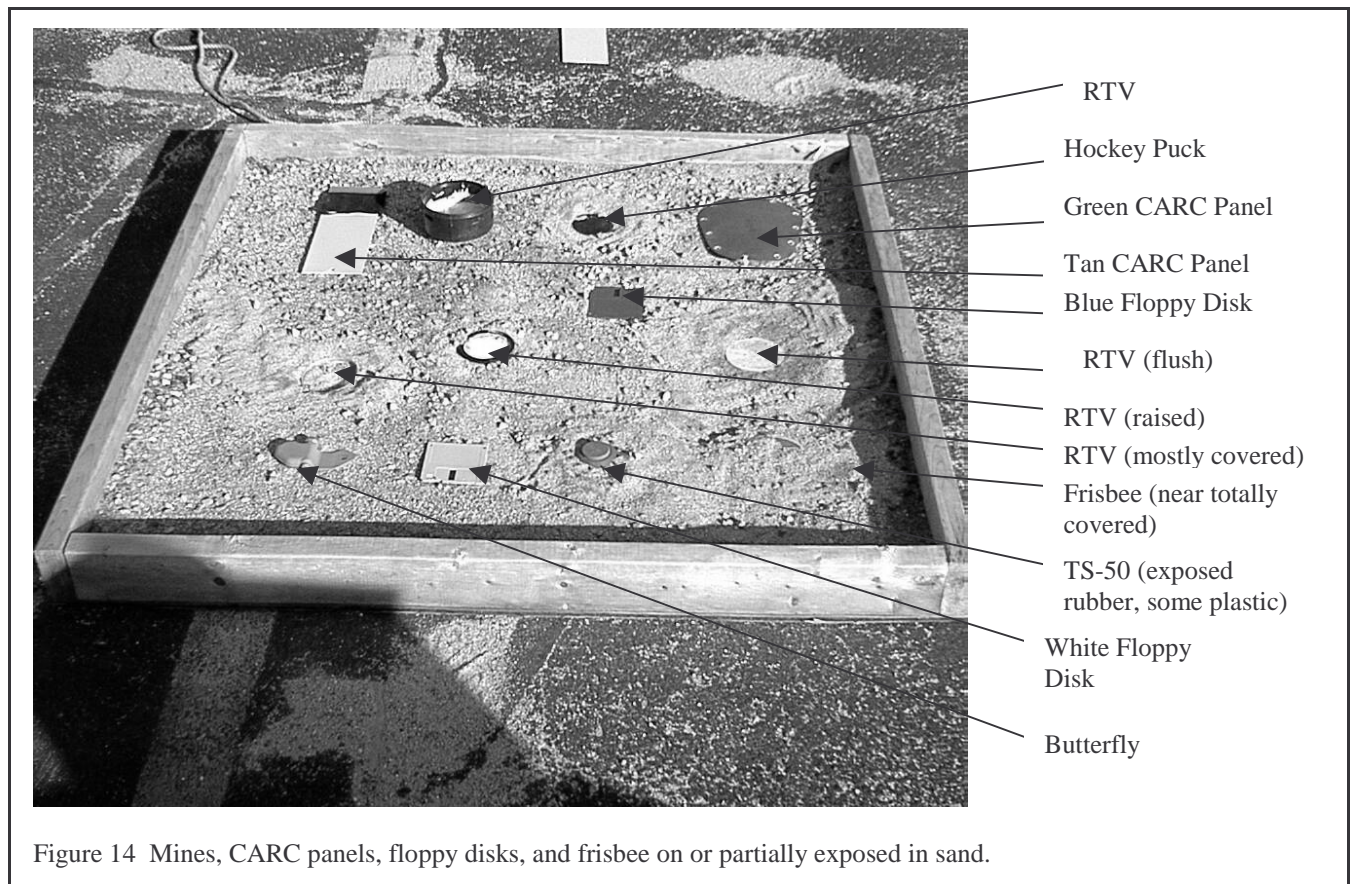

Figure 14 shows the measurement setup of the various target materials on or partially exposed in sand. The RTV silicone rubber is spectrally identical to the rubber center of the TS-50 AP mine (per discussion in Section 3). In order of increasing aggregation of feature spaces (and discrimination processing sophistication) are Figures 15–18. Figure 15 is a broadband LWIR (6.5–14 μm) conventional intensity image. Figure 16 is the polarization difference image (0–90) through the same broadband LWIR filter (6.5–14 μm). Figure 17 is a multispectral PCA (principal components analysis) image showing intensity based on projection of the data comprised of the 5 previously stated LWIR passband filters onto the 2nd most energetic eigenvector. Figure 18 is a polarimetric multispectral PCA image, this time projecting 12-vector imagery consisting of all 6 bands, with 0-deg and 90-deg polarizer orientations for each, onto its 2nd most energetic eigenvector. Initial eigenanalysis on subset polarimetric multispectral data supports the visual conclusions: for the 2nd eigenvector is predominantly synthesizing the polarization difference yet includes some multispectral projection, while the 3rd eigenvector is predominantly synthesizing a spectral filter. The 2nd eigenvalue is about 3x the energy of the 3rd eigenvalue.

6. CONCLUSIONS

6.1. Rationale for combining hyperspectral and polarimetric IR imaging

We have presented several pieces of evidence to motivate the marriage of hyperspectral and polarimetric IR imaging. Basically we recognize that polarimetric and hyperspectral attributes supplement one another, and that all available independent supplemental pieces of information can be used to advantage for discriminating target objects from background clutter. Polarimetry appears particularly suited to segregating partially exposed man made objects from natural background based on the typical smoothness of the former, and typical roughness of the latter. While we expect to exploit the broadband attributes of man made objects, knowledge of the characteristic spectral features for a large number of both man made and natural background materials (for example, quartz sand and the mine casing spectra presented above) enables an additional hyperspectral polarization discrimination capability that comes in the form of the narrow spectral features.

6.2. Polarimeter design process and some useful insights

Our current understanding of the best design process for an imaging multi- or hyper-spectral polarimeter application^{10,13,17,18,28,29,30} includes the following points:

1. The spatial resolution will be determined and even constrained by the spatial scale of the target and primary clutter sources in the scenes and scenarios of interest. A polarimeter geared toward mine detection requires a spatial scale consistent with the mine dimensions and respective of the spatial scale of primary clutter sources. Recall the bark mulch images in Figures 12(a) and (b).
2. Given this spatial scale constraint the spectral range, resolution, and choice of detector are a compromise between the need for signal (broadband operation) and the availability of distinguishing "narrow" spectral features to exploit (multi- or hyper-spectral operation).
3. Prerequisite to this process is a very clear realization¹⁰ that at least two, and preferably three, independent polarization measurements must be acquired at near perfect registration, which for moving platforms means simultaneously. Otherwise the misregistration of polarimetric detection channels will masquerade as serious to overwhelming polarimetric clutter, induced particularly by time-dependent effects such as sensor platform motion, substantial changes in the downwelling radiation incident upon the target, and even small temperature and sensitivity drifts in the detector.
4. Multispectral or hyperspectral polarimetry offers essential advantages over broadband polarimetry in applications such as demining where spectral techniques allow discrimination against similarly polarized backgrounds such as asphalt, and potentially when tuned to discriminate surface spectro-polarimetric texture disturbances indicative of sub-surface mines.

6.3. Overall status of IR polarimetric hyperspectral imaging effort

More important than any one of the above proof-of-concept demonstrations, each of which represents a successful step in the risk-reduction sense, is to put all these elements together into the same sensor, an IR Polarimetric Hyperspectral Imager; this is our goal and represents our most significant effort to go beyond state-of-the-art. If we are successful, we will have captured the spectral, spatial and polarimetric attributes in one sensor, all simultaneous in time and perfectly registered spatially.

Going beyond the current proof-of-concept sensor configuration intended for static scenes, we now have an innovative sensor design in hand and are building the prototype IR Polarimetric Hyperspectral Imager. We have verified in a laboratory visible-band implementation that our design allows us to extract any angle or degree of polarization in the scene at a frame rate determined by the multiplexer and signal processor. For initial application purposes we are using a cooled FPA in the IR prototype, yet we anticipate the opportunity to test uncooled FPAs for the demining/UXO applications. Having all of the spectral, spatial and polarimetric attributes available to us at the same time provides a powerful discrimination and clutter suppression capability that is quite unique. All indications from analyzing our sequentially collected data are that these attributes taken together will comprise a reliable sensor for the detection of surface and flush-buried land mines, as well as for disturbed soil and shallow-buried mines over diurnal cycles or with microwave enhance heating.

Laboratory measurements or other knowledge of the spectral reflectance and polarimetric properties of the targets in each application are necessary to support hyperspectral polarimetry. Our laboratory data help directly to (a) determine the locations and widths of spectral features needed to infer the value added of hyperspectral over multispectral polarimetry and thereby to (b) determine in potential applications whether broadband, multispectral or hyperspectral polarimetry applies.

In summary, using somewhat sparse, but very reproducible, data from field and laboratory measurements to date, we have presented a case for LWIR polarimetric hyperspectral imaging in applications requiring the detection of plastic, as well as metal, flush-buried and scattered surface mines. This approach applies equally well to partially exposed unexploded ordnance (UXO) and to shallow-buried mines subjected to microwave enhanced heating and diurnal cycles. Our rationale for combining hyperspectral and polarimetric imaging was presented.

Polarimetric-Spectral Intensity Modulation (P-SIM): Enabling simultaneous hyperspectral and polarimetric imaging

Frank J. Iannarilli, Jr., Stephen H. Jones, Herman E. Scott, and Paul Kebabian

Aerodyne Research, Inc., 45 Manning Rd., Billerica, MA USA 01821

ABSTRACT

We introduce the method of Polarimetric-Spectral Intensity Modulation (P-SIM) and discuss how it enables a new robust class of hyperspectral polarimetric imaging sensors. P-SIM was invented by one of us (P. Kebabian) and has been submitted for patent. We are presently building a sensor, dubbed the IR Polarimetric HyperSpectral Imager (IRPHSI) which implements the P-SIM concept. P-SIM employs a novel and robust optical multiplexing scheme that enables simultaneous measurement of spectral and full elliptical polarimetric image content, employing a single focal plane detector and conventional optics, and eliminating moving parts and difficult alignment issues. The technique is equally viable across the visible through long-wave infrared bands. The P-SIM concept constitutes a breakthrough for the inclusion of polarimetry in optical hyperspectral imaging. To date, even single-band polarimeter designs for remote sensing are compromised due to their lack of spatiotemporal measurement registration, inapplicability to marginally resolved scene elements, costly optical configurations, or polarimetric ambiguity from too few “channels”. Polarimetric imaging from a moving platform (i.e., moving field of regard) or against moving targets rules out the standard methods of time-sequential polarimetry via rotation of a polarizer or waveplate. P-SIM eliminates these limitations while additionally extending polarimetry into the spectral imaging domain.

Keywords: Optical infrared polarimetry hyperspectral discrimination imaging sensing

1. MOTIVATION FOR POLARIMETRIC AND SPECTRO-POLARIMETRIC SENSING

Sensor technology has progressed to the point where it is practical to detect and measure the spatial, spectral, and polarimetric distribution of optical radiation of sample objects or remote scenes. Such in-situ and particularly remotely sensed radiation characteristics reveal a substantial amount of information about the objects or phenomena under study. For instance, numerous air- and spaceborne optical sensors produce spectrally resolved imagery used for military surveillance as well as geophysical and earth resource mapping. The polarimetric state of received radiation also contains valuable information about source object surface roughness and orientation. Optical polarimetric sensing has been advocated for a number of years for various military and remote sensing applications. Because natural backgrounds are typically unpolarized[†], relative to other modalities, polarimetric sensing can offer superior clutter suppression in the discrimination of typically polarized manmade objects. For image recognition applications, the predictable Fresnel behavior of polarimetric observables may enable passive inference of surface orientation and object shape¹. Imaging polarimetric and spectro-polarimetric sensors provide a significant increment in our capability to respond to existing requirements, as well as to our insatiable need for more information in remote sensing applications.

2. FUNDAMENTAL POLARIMETRIC SENSOR REQUIREMENTS FOR DYNAMIC PLATFORMS

2.1. The requirement for spatio-temporally registered full-channel polarimetry

The prior art contains numerous responses to this demand for polarimetric and spectropolarimetric sensors. Polarimeter designs can be classed into 2 general categories: (1) time-simultaneous or (2) time-sequential techniques. Time-simultaneity invariably involves a division of power among sensing “channels”. One approach for time-sequential polarimetry involves the rotation of retarders as in the case of the infrared spectropolarimeter by Goldstein et al, US patent 5,045,701.

[†] Depending on pixel footprint, various background features may exhibit polarization.

In recent years, prototype polarimeters have been introduced into experimental field measurements to validate observability predictions. These time-sequential polarimetric designs, when employed in static sensing configurations, have been adequate to validate predicted polarization effects. Unfortunately for many applications of interest involving a dynamically moving sensor platform and/or object of interest, time-sequential polarimetric techniques are precluded due to the practically uncorrectable spatiotemporal mis-registration of the imaged scene (due to relative scene motion) over the duration of the measurement sequence. Such mis-registration creates artifacts that masquerade as polarization signals. The limits of allowable relative motion are quite restrictive since many polarization signals of interest represent polarization levels on the order of only several percent. Thus, spatiotemporal misregistration must typically be controlled to below 1%.

Specifically, for a temporal sampling sequence duration of dt , and a spatial resolution element of linear angular subtense Δq , in order to employ time-sequential polarimetry the relative sensor pointing slew rate $\dot{\theta}$ must satisfy the following constraint: $\dot{\theta} \cdot dt \leq 0.1 \cdot \Delta q$. This is certainly not the case for most military and remote sensing field applications. For example, at a modest $1^\circ/\text{sec}$ platform rotation rate (e.g., due to buffeting), the footprint of an IFOV of $100\mu\text{rad}$ would shift nearly an entire IFOV subtense during a frame period (τ_{int}) of a mere 5msec! Note that for such applications the employment of time-simultaneous polarimetry might not necessitate sampling extremely rapidly (i.e., to attempt near “freeze-frame” sampling), but rather that exactly the same scene content be dwelled upon in the same spatiotemporal manner across all the sensor’s polarimetric channels for the given spatial resolution element.

To date, time-simultaneous polarimeter designs for remote sensing are compromised due to their inapplicability to marginally resolved scene elements, costly and difficult optical configurations, or polarimetric ambiguity from too few “channels”. Time-simultaneous imaging polarimetric channel acquisition is possible at the expense of important drawbacks by employing “microscale channelization”. This technique inserts a pixelated polarizing filter mask of alternating analyzer orientations at an intermediate image plane within the optical train, at a sacrifice of 2-4 in spatial resolution relative to the underlying focal plane array detector spacing/resolution. A more serious drawback is that microscale channelization designs are suitable only when restricted to applications imaging radiometrically and polarimetrically uniform extended scene elements (i.e., elements with radiometric and polarimetric (auto)correlation lengths roughly at least several pixels). Otherwise, due to the lack of spatial registration (coincidence) of channels, a microscale design attempting polarimetric imaging of marginally resolved scene elements will yield unacceptable phantom polarization artifacts due to the unknown and varying amounts of light incident upon each of the channel pixels as the scene dwell is varied.

Time-simultaneity can also be obtained by employing “macroscale channelization” by means of a “quadfocal” optic (e.g., via a segmented mirror), wherein offset images are projected through oriented analyzers and onto a singular focal plane. This preserves spatial resolution and achieves spatial channel coincidence at the expense of a reduced field of regard, the need for custom optics and precise alignment. Alternately, multiple focal planes can be employed at greatly increased expense and heightened alignment difficulties.

Even designs that embrace the time-simultaneity and spatial channel coincidence requirements fall short when too few “channels” are measured. For instance, a design which employs merely “vertical” and “horizontal” linear polarizers (2 channels) in an attempt to deduce the “degree of polarization” will fail for most encountered angles of polarization, particularly yielding a null signal at a 45 degree polarization orientation.

2.2. Constraints on extension of spatio-temporally registered polarimetry to spectral sensing

The extension of spatio-temporally registered polarimetry designs to spectropolarimetry must of course by definition not employ time-sequential spectrum acquisition methods. An example of the latter is the device of US patent 5,131,742 to Schaff (1992) wherein the ordinary and extraordinary diffracted beams propagated through an acousto-optic tunable filter (AOTF) are intercepted for purposes of polarimetry, but wherein the passband of the AOTF must be swept in time to acquire the spectrum.

Compliance with time-simultaneity can typically be accomplished by insertion of a dispersive diffraction grating or prism into the sample beam. For imaging spectropolarimetry, this typically implies the use of an area focal plane detector wherein a line image is spectrally dispersed along the remaining dimension of the detector array. Nevertheless, this approach may be fraught with practical difficulties, as illustrated in the device described in US patent 5,337,146 to Azzam (1994). To accomplish spectropolarimetry it is suggested therein to insert polarizing means between the diffraction grating and the area detectors for two or more of the intercepted diffraction orders. In practice, this configuration would require precise alignment

Figure 1 Lab measurement demonstration of P-SIM in visible regime

and registration of the existent beams as imaged onto one or more focal plane array detectors, potentially precluding compact, rugged, or inexpensive embodiments.

3. POLARIMETRIC SPECTRAL INTENSITY MODULATION (P-SIM)

The most telegraphic means of conveying the P-SIM (Polarimetric Spectral Intensity Modulation) concept is to show its employment within a conventional hyperspectral line (pushbroom) imager. We are presently building a prototype of just such a design for the LWIR dubbed “IRPHSI”, which we will describe herein. It is also possible to insert the elemental P-SIM modulator assembly into other spectral imaging designs to overlay polarimetric capability, and we will briefly suggest an example pertaining to a 2D chromo-tomographic imaging spectrometer (CTIS).

3.1. Overview of IRPHSI Project Underway

The InfraRed Polarimetric HyperSpectral Imager (IRPHSI) concept was originated by Aerodyne Research as part of a Phase 1 SBIR effort under the sponsorship of the U.S. Air Force (AFRL/Hanscom). The sensor simultaneously acquires polarimetric and hyperspectral imagery on a single focal plane array (FPA). The effort to fully design and build IRPHSI, under Air Force Phase 2 SBIR funding, is presently underway. Aerodyne is presently submitting a patent application for the underlying “Polarimetric Spectral Intensity Modulation” (P-SIM) design concept employed within IRPHSI. Our polarimetric hyperspectral imaging technique is equally viable in the visible or near-infrared bands, but our prototype sensor currently under development concentrates on the “thermal” infrared wavelengths spanning 8 to 12 micrometers.

3.2. IRPHSI Design Configuration

The difficulties of introducing snapshot polarimetry into hyperspectral imaging are obviated by employing IRPHSI’s P-SIM design concept. IRPHSI parsimoniously achieves time-space simultaneity without sacrificing spatial resolution, and employs a compact inexpensive configuration. The notional optical layout is shown in Figure 2 and Figure 3. In Figure 2 the key polarimetric spectral intensity modulator assembly 20 is presented, showing its components and their arrangements. A birefringent primary medium 22, in this instance crystalline CdS (Cadmium Sulfide), is the first component to receive the propagating polychromatic waveflux. The waveflux subsequently propagates into a birefringent secondary medium 24. The birefringent primary medium by nature possesses orthogonally resolved fast and slow axes of propagation. The nature of propagation through the medium is that a respectively shorter or longer propagation time delay is imposed upon the

polarization component of the incident wave as resolved with respect to either axis. The primary medium is crafted such that its fast and slow axes lie within a plane substantially normal to the direction of propagation. The characteristics of the primary medium are chosen such that its propagation time delays are minimally dispersive or well tempered functions with respect to optical frequency within the desired spectral range.

The secondary medium is similar in aforementioned characteristics to the primary medium, albeit with two critical differences. First, the predetermined difference between its slow and fast propagation delays is normally to be discernibly different from that of the primary medium. This is typically arranged, if the two media are composed of the same material, by using differing lengths (as measured along the direction of propagation). Otherwise, a combination of length and material disparity is employed. The length of the secondary medium should often be considerably greater than that of the primary medium. Second, the secondary medium must be situated such that its own fast axis 25 is substantially displaced rotationally to form a finite acute (less than 90 degree) angle with respect to the fast axis 23 of the primary medium. Normally, this acute angle is set at 45 degrees.

Waveflux propagated through the secondary medium subsequently propagates through a linear polarizer 26. For optical infrared sensors, wire grid polarizers satisfy this and other predetermined typical criteria. They are fabricated by depositing metal within parallel grooves etched upon transparent planar substrates such as ZnSe. It is critical that the transmission axis 27 of the linear polarizer is oriented substantially rotated to form a finite acute (less than 90 degree) with respect to the fast axis 25 of the secondary medium. Normally, this acute angle is set at 45 degrees.

The IRPHSI sensor is composed by inserting the modulator assembly 20 described above into a slit-based line imaging spectrometer as shown in the layout of Figure 3. The inclusion of the modulator assembly enables this imaging spectrometer to simultaneously perform full elliptical Stokes polarimetry in addition to its normal function. This layout is comprised of input imaging optics 30, typically implemented with a light-collecting primary imaging optic, a field-stop, and collimating lens as illustrated. The imaged waveflux is relayed as a collimated beam through the modulator assembly 20, the output of which is subsequently analyzed by the arrangement of remaining conventional elements 32, 34, 28, and 36. The re-imaging optics 32 produce 2 principal focal planes. A field definition slit 34 is placed at the first (intermediate) focal plane. A dispersive element 28, in this instance a diffraction grating, is placed in the collimated beam region between the first and final focal planes of the re-imaging optics. The spectrally dispersed, 1-dimensionally spatially resolved line image is projected onto a photosensitive areal detector array 36.

With each readout of the photosensitive areal detector array 36, a spectrally and (1-D) spatially resolved image of the spectrometer slit 34 is acquired. To achieve spatial imaging in the direction perpendicular to the slit, sensor platform motion translates the slit across object space in “pushbroom” fashion. Alternately, for stationary platforms, a scanning mirror (not shown) may be engaged. Thus, assuming simultaneous synchronized sampling by all the elements in said photosensitive areal detector array 36 (assured by “snapshot” mode operation now commonly available), the complete sensor performs simultaneous spectropolarimetric 1-dimensional line imaging, while spatial imaging in the second (orthogonal) dimension is obtained in a time-sequential manner.

The effect of the modulator assembly 20 is to impress polarization-dependent modulation modes upon a spatial resolution element’s (hereinafter “pixel”) intensity spectrum. Appropriate signal processing of a pixel’s modulated intensity spectrum (as projected along a row of detector elements as shown, 36) allows recovery of its intensity spectrum and also deduces its full elliptical polarization state (Stokes vector).

3.3. Existing Experimental Confirmation of IRPHSI’s P-SIM Concept

The P-SIM concept has been experimentally confirmed at Aerodyne. The low cost of components for the visible spectrum was exploited by employing an inexpensive P-SIM modulator configuration (quartz waveplates and polaroid) within an off-the-shelf visible line imaging spectrometer. Figure 1 shows the measured areal focal plane response to a uniform line source for various imposed angles of linear polarization (impressed upon a light source via a polaroid film). Observe that the fringe pattern is more complex than a monotonic (though chirped) sinusoid that would otherwise result from a mere waveplate and polarizer typical of birefringent filter designs². Rather, as will be shown in what follows, P-SIM produces a multi-period fringe pattern enabling full elliptical polarimetry.

3.4. Mueller-Stokes Perspective of P-SIM Method

The following Mueller matrix-Stokes vector formulation of the sensor measurement equation provides one of several perspective for revealing the nature of operation. The derivation of the sensor measurement equation follows from expressing the *spectral* Mueller matrix of the modulator assembly and thereby relating its output Stokes vector to the incident Stokes vector.

The Stokes parameters are a method of characterizing the ergodic average (i.e., time average over many cycles of the principal frequency components of the wave) hence conventionally observable polarization state of partially polarized waveflux. The parameters are frequently assembled into a vector and are defined as follows:

$$\begin{bmatrix} I \\ Q \\ U \\ V \end{bmatrix} \equiv \begin{bmatrix} a_1^2 + a_2^2 \\ a_1^2 - a_2^2 \\ 2a_1a_2 \cos \mathbf{d} \\ 2a_1a_2 \sin \mathbf{d} \end{bmatrix}$$

where a_1 and a_2 are the ergodic real-valued orthogonal field amplitudes and \mathbf{d} is the phase lag between instantaneous realizations. The first Stokes parameter is thus the conventional waveflux intensity.

Mueller matrices or scattering matrices, form a convenient method for describing the transformations on the Stokes vector as partially polarized waveflux propagates through a system. The resulting transformed Stokes vector is merely a matrix-vector product. Therefore, the modulated spectral intensity pattern is ascertained to be the first Stokes component (i.e. intensity) of the matrix-vector product formed by frequency-dependent Mueller matrix of the modulator assembly 20 and the incident waveflux Stokes vector. Attending to Figure 2, we can build up the expression for the resultant Mueller matrix of modulator assembly 20 by determining the matrix product of sequentially ordered standard Mueller matrix representations of the series of elements, namely the primary medium 22, secondary medium 24, and linear polarizer 26.

A retarder (delay element) behaves as a frequency-dependent phase-shifter, with denoted (frequency-dependent) phase shift angle \mathbf{f} . A uniaxial birefringent medium behaves as an orientationally selective retarder by virtue of its possessing orthogonally oriented fast and slow axes of propagation. The nature of propagation through the medium is that a respectively shorter or longer propagation time delay is imposed upon the polarization component of the incident wave as resolved with respect to either axis.

The *difference* between these propagation delays can be expressed as a frequency-dependent phase shift angle \mathbf{f} as follows:

$$\mathbf{f} = \frac{2\pi n \Delta n l}{c}$$

where \mathbf{n} is the optical frequency, Δn is the birefringence of the medium (i.e., the difference between the refractive indices of its slow and fast axes) and l is the physical length of the medium (as measured along the propagation direction), and c the speed of light in vacuum. The intent of the design is most directly realized when the birefringence of the medium Δn is nearly constant with \mathbf{n} within spectral range of interest (i.e., minimally dispersive), and this will be assumed in description of operation that follows. The Mueller matrix employed herein for a uniaxial birefringent medium corresponds to its fast axis oriented parallel with the system reference axis (i.e., the axis of reference for aforementioned Stokes vector definition field amplitude component a_1).

Consequently, we form the ordered products of the Mueller matrices corresponding to each element of the modulator assembly 20, accounting for rotation of axes with respect to the system reference axis which is taken to be the fast axis 23 of the primary medium. Denoting the rotation angle of the secondary medium as \mathbf{b} and that of the linear polarizer as \mathbf{q} , the Mueller matrix of 20 is:

$$M_{\text{modulator}} = M_{\text{polarizer}}(\mathbf{q}) \cdot M_{\text{rotation}}(-\mathbf{b}) \cdot M_{\text{uniaxial}}(\mathbf{f}_2) \cdot M_{\text{rotation}}(\mathbf{b}) \cdot M_{\text{uniaxial}}(\mathbf{f}_1)$$

A most useful design configuration for elliptical polarimetry is to configure element orientations to set \mathbf{b} to 45 degrees and \mathbf{q} to zero or 90 degrees. Assuming \mathbf{q} to be zero and solving for the output first Stokes (intensity), we obtain:

$$I_n(\mathbf{f}_1, \mathbf{f}_2) = \frac{1}{4} \begin{bmatrix} I & Q & U & V \end{bmatrix} \begin{bmatrix} 2 \\ 2 \cos \mathbf{f}_2 \\ \cos(\mathbf{f}_1 - \mathbf{f}_2) - \cos(\mathbf{f}_1 + \mathbf{f}_2) \\ \sin(\mathbf{f}_1 + \mathbf{f}_2) - \sin(\mathbf{f}_1 - \mathbf{f}_2) \end{bmatrix}$$

where, with l_1 and l_2 the lengths of the primary medium 22 and secondary medium 24:

$$\mathbf{f}_1 \equiv \frac{2pn\Delta n l_1}{c}$$

$$\mathbf{f}_2 \equiv \frac{2pn\Delta n l_2}{c}$$

Thus, the resultant intensity spectrum I_n is modulated by 4 sinusoidal modulation “fringe” modes: a DC (non- modulated) mode, a “carrier” mode corresponding to the \mathbf{f}_2 term, along with sum and difference frequency (upper and lower “sidebands”) modes corresponding to the $\mathbf{f}_2 - \mathbf{f}_1$ and $\mathbf{f}_2 + \mathbf{f}_1$ terms. A modulation mode’s periodicity is:

$$\Delta n = \frac{c}{\Delta n \cdot l}$$

with the periodicity units in bandwidth (Hz) per modulation cycle. Thus, the 4 modulation mode periodicities are:

DC

$$\Delta n_c = \frac{c}{\Delta n \cdot (l_2)}$$

$$\Delta n_{low} = \frac{c}{\Delta n \cdot (l_2 - l_1)}$$

$$\Delta n_{up} = \frac{c}{\Delta n \cdot (l_2 + l_1)}$$

For an otherwise white optical spectrum incident upon the modulator assembly 20, *sinusoidal* variations as a function of n will appear across the resultant intensity spectrum. For a non-white incident spectrum, the apparent variations will appear other than sinusoidal but nevertheless are determined by the measurement equation derived above. Note that for the given orientation configuration, the identified carrier mode frequency is set by the secondary medium.

3.5. SpectroPolarimetric Data Processing for P-SIM

The fundamental observation that modulator assembly 20 imposes 4 independent modulation modes (DC, carrier, and sidebands) upon resultant intensity spectrum evokes the following expectation. Inversion of the measurement equation given 4 or more n -varying spectral intensity samples should allow solving for the 4 unknown Stokes parameters of the sensor-incident waveflux. Given or providing the appropriate regularization conditions, this is indeed the case. There are a number of conceivable methods that will undoubtedly suggest themselves to those skilled in the art for retrieving the Stokes vector and also the conventional intensity spectrum, at varying spectral resolution, from the transduced modulated intensity spectrum pertaining to a given spatial image resolution element.

3.6. Polarimetric augmentation of CTIS design using P-SIM

Non-scanning computed tomography imaging spectrometry (CTIS) provides a means of 2D imaging snapshot spectrometry ^{ur3,4}. The essential notion is to use crossed transmissive phase gratings or a computer-generated holographic (CGH) disperser within the collimated image beam. Followed by re-imaging optics, this projects spatially/spectrally overlapped regions of various spectral orders. The effect mathematically is essentially to form various projections of the 3D space-spectral image cube onto various oblique 2D planes. These various “slices”, manifested by the various spectral orders projected on the focal plane detector, can be used to tomographically reconstruct the 3D spectral image cube voxels. However, the “missing cone” drawback of such imaging (due to a finite focal plane array, and other practical factors) limits the spectral and spatial resolution of the reconstruction. To add full-Stokes polarimetry to this design without disrupting its snapshot feature, we simply insert the P-SIM modulator into the collimated beam. The resulting spectrum will be modulated, and can be decoded for polarimetry, as evidenced in earlier discussion.

Quantifying key trade-off between IR polarimetric discriminability versus pixel resolution against complex targets

Frank J. Iannarilli, Jr. and John A. Conant

Aerodyne Research, Inc., 45 Manning Rd., Billerica, MA USA 01821

ABSTRACT

The augmentation of passive IR conventional and hyperspectral imaging sensors with polarimetric capability offers enhanced discrimination of man-made and geophysical targets, along with inference of surface shape and orientation. In our efforts to size the design of IR polarimetric hyperspectral imagers to various remote discrimination applications, we have ascertained critical relationships between polarimetric SNR and pixel sizing. This relationship pertains primarily to realms wherein the objects to be sensed will be marginally resolved spatially. The determination of such application-specific relationships is key to the design of effective polarimetric sensors. To quantify this key trade-off relationship, we have employed the latest developmental version of SPIRITS, a detailed physics-based signature code which accounts for the various geometric, environmental illumination, and propagation effects. For complex target shapes, detailed accounting for such effects is especially crucial to accurate prediction of polarimetric signatures, and thus precludes hand calculation for all but simple uniformly planar objects. Key to accurate polarimetric attribute prediction is our augmentation of the Sandford-Robertson BRDF model to a Mueller/Stokes formalism that encompasses representation of fully general elliptically polarized reflections and linearly polarized thermal emissions in strict compliance with Kirchhoff's Law. We discuss details of the polarimetric augmentation of the BRDF and present polarimetric discriminability-resolution trade-off results for various viewing aspects against a ground vehicle viewed from overhead.

Keywords: Optical infrared polarimetry discrimination polarization BRDF reflectance signature

1. OVERVIEW OF IR POLARIZATION PHENOMENA AND OBSERVABLE ATTRIBUTES

The fundamental principle behind polarimetric sensing is the fact that the parallel and perpendicular reflection coefficients are not, in general, equal. Figure 1 shows the difference between the perpendicular and parallel Fresnel (intensity) reflection components, for dielectric ($n=1.3$, $k=0$).

coefficients for a dielectric surface ($n = 1.3$, $k = 0$). The apparent signature of an elemental surface may exhibit a net polarization, the nature of which is determined by the surface optical properties, the surface temperature, the viewing angle of incidence and the effective temperatures and angular distribution of the incident radiation field. The impact of the optical properties can be characterized by the complex index of refraction, the surface roughness, and the "diffusivity". A sound representative model is one that partitions the exhibited behavior between "surface" (i.e., specular) and "volume" (i.e. diffuse) scatter components. The diffuse component (e.g., sub-surface volume multi-scatter) of reflected or emitted light is typically

unpolarized. The diffuse (i.e., rough) character of many natural background surfaces is the underlying reason why such backgrounds exhibit a decided lack of observable polarization. For the "surface" component, the (unscaled) reflectance coefficients for light polarized parallel and perpendicular to the plane of incidence are given by Fresnel's relations, dependent upon the index of refraction. Detailed discussion of the reflectance model is provided later below.

Reflected light will exhibit a net polarization vector (E-field) perpendicular to the plane of incidence, while conversely, emitted light will exhibit a net "parallel" polarization. Depending on the source intensities of surface reflected and emitted radiation, there may be a net partial polarization of observed radiation. The degree of such polarization with respect to the total exitant radiation intensity is herein termed the Degree of Polarization (DoP). For an isothermal surface and surrounding environment, the emitted and reflected polarized components cancel vectorially, yielding zero net DoP. However, with unequal reflected and thermally emitted intensities, which particularly occurs for at least some of an object's surface elements when located within angularly anisotropic radiative environments (e.g., warm earth/cold sky radiance fields), such cancellation is typically incomplete, yielding a finite net DoP. For such situations, the angle of the (E-field) polarization vector with respect to some reference direction is termed the Angle of Polarization (AoP), and depends upon the relative surface orientation. In certain (relatively unusual) configurations, a third polarimetric attribute may be observable, that of the ellipticity of polarization (EoP). Discussion of the various types of polarization descriptors and means of measurement can be found in Collett.¹ In what follows, we will assume negligible EoP, and thus that DoP and AoP correspond to linear polarization.

2. SENSOR DESIGN MOTIVATIONS FOR POLARIMETRIC SIGNATURE PREDICTION

As indicated above, the IR polarimetric observables are strongly dependent on configuration variables. In prior years there had been a vigorous if somewhat restricted debate about whether IR polarimetric observables were so fleeting and evanescent that it was not worth building sensors for their exploitation. Although computational modeling evidence indicated sufficient persistence over much of the typical range of terrestrial environmental conditions, ever-accumulating field measurements provided the decisive corroboration. At this point in time, there is general acceptance of the utility of polarimetric sensing. Nevertheless, the relevance of signature prediction to polarimetric sensing remains strong, particularly for sensor design.

Implied in the earlier discussion regarding the vectorial addition of polarimetric observables (e.g., Stokes vectors) is a fact of fundamental significance for polarimetric sensor (non-imaging) field-of-view (FOV) or (imaging) pixel instantaneous FOV (IFOV) sizing. The polarimetric observables from two differently oriented surfaces may be of significant intensity when measured separately in turn. Nevertheless, when these same surfaces are measured together in combination, the net polarimetric observables may yield negligible intensity, precisely due to vectorial combination. This explains why a polarimetric imaging sensor that measures a sphere that completely falls within a pixel's subtense will register no polarization signal, while a similar sensor with higher resolution pixels that spatially resolve the sphere will register otherwise. Thus, it is evidently of critical importance to match sensor pixel sizing to polarimetric feature spatial scale.

An object such as an aircraft or ground vehicle can be modeled as a collection of elemental surfaces or facets. The computation (prediction) of the net polarization attributes (e.g., polarized radiance, DoP, AoP) of an object, as observed within any given (partially or totally subtending) angular view subtense, is essentially an exercise in the detailed accounting per the phenomenology described above, with the vectorial components due to each surface element within the subtense properly accumulated to yield the net polarimetric signature. However, only a computer model can adequately account for the complex interplay of parameters required to compute such quantities for a complex shape such as a vehicle, especially if these quantities are to be spatially resolved (imaged).

3. IR POLARIZATION SIGNATURE PREDICTION CODE CAPABILITIES

3.1. IR polarization signature prediction using SPIRITS-AC3

SPIRITS (which stands for "Spectral and Inband Radiometric Imaging of Targets and Scenes") is a well-established and validated optical signature prediction code owned by the U.S. Government and principally developed at Aerodyne Research by one of us (J. Conant). Over the past 15 years, it has undergone numerous enhancements for various application versions. The most recent versions are denoted SPIRITS-AC, with "AC" indicating features and modules specifically useful in modeling aircraft signatures. Nevertheless, the code is sufficiently flexible to allow importing of surface temperatures computed by specialized heat transfer codes, which facilitates applicability to various other types of vehicles and objects.

A “polarized” version of SPIRITS, called “POLAR”, was first generated by Aerodyne in 1986. The POLAR code included two separate incompatible BRDF (bi-directional reflectance distribution function) models, for “polar” and “non-polar” use. The polar BRDF routines were based upon the Maxwell-Beard model^{2,3}, while non-polar computations utilized the Sandford-Robertson (“S-R”) model as with other SPIRITS versions. The capabilities of this POLAR model evolved in tandem to those of the SPIRITS model itself, all the while remaining a separate code due to the non-unified BRDF modeling. Although valid for specular, non-metallic coatings, the POLAR code implementation of the Maxwell-Beard BRDF model lacked an explicit coupling between the specular and diffuse components.

To include proper treatment of coatings possessing a diffuse reflectance component as well as metallic (e.g., complex refractive index) coatings, the most current developmental version of SPIRITS has thus been extended to compute both polarized and non-polarized target body radiances, and is denoted as SPIRITS-AC3dr1.⁴ It improves on and supplants previous versions of POLAR (polarized SPIRITS) in two ways: it is based on the latest developmental non-polarized version (AC2Dr2), and it has an improved polarized reflectance-emittance model. This model combines the Sandford-Robertson approach (used previously in SPIRITS) with the Fresnel/Mueller equations, resulting in a model which includes the most important polarization properties, is easy to use, and gives total radiances identical to those of version AC2Dr2. The new version has been given to U.S. Government (JANNAF) control, and is expected to comprise the latest configuration of mainstream SPIRITS.

3.2. Characteristics and advantages of the polarized Sandford-Robertson BRDF treatment

The Sandford-Robertson (“S-R”) model as included within SPIRITS includes emission, transmission, and reflection. Reflectance is divided into quasi-diffuse and quasi-specular portions with separate sub-models. Total reflectance and emittance are analytically coupled to conserve energy, with their relative balance an adjustable function of incidence angle. We model the specular reflections as polarized, while the diffuse reflections are depolarizing. Future upgrades could add in polarization to the diffuse contribution. At present, since we have focussed concern on opaque surfaces, transmissions are taken as neutral; they neither polarize nor depolarize the transmitted light, but merely attenuate all Stokes components by the same factor. A more detailed discussion of how we polarized the S-R BRDF treatment is contained in [4]. An overview is presented below.

In polarizing the S-R BRDF treatment, there were two main constraints we have adhered to. First, we constrain the Stokes 1 element (total radiance) to strictly match that yielded by the (non-augmented) S-R model. In this way we ensure that all previous (non-polarized) SPIRITS tests and data validations remain relevant and repeatable. Moreover, the new SPIRITS-AC3 may be run in either polarized or non-polarized mode, and will give identical results in the total radiance.

The second applied constraint is to meet the requirements of thermal equilibrium (discussed below), keeping a proper balance between polarized emissions and reflections. Our previous polarization studies have shown that in most cases the total polarization state of a 3D object results from a subtle balance of vectorially competing polarized emissions and reflections, modulated by varying surface element orientations. Specular reflectance and emission from a surface are cross-polarized (for unpolarized incident light), and they will cancel to the degree that the surface’s Planck emission matches the incident radiance field. The remaining polarization will be a “small difference of two large numbers”, and thus sensitive to modeling infidelities.

In contemplating the compliance with Kirchoff’s Law, it is important to conceptualize the situation of thermal equilibrium, which dictates that incoherent unpolarized radiation is incident upon the surface. Polarized incident light is by definition non-equilibrium. Since unpolarized incident radiation will reflect as linearly polarized radiation, the emittance must be linearly polarized in such a way as to cancel the reflected polarization and yield a net unpolarized exitance under equilibrium conditions. This also implies that elliptically polarized emission is forbidden. [This is true even though at the microscopic level when a primary reflection followed by a secondary exitant reflection yields elliptically polarized light. In this case, the primary surface will also emit linearly polarized light that exactly cancels the linear polarization of the primary reflection. Thus, the total light exitant from the primary surface onto the secondary surface is unpolarized.] This relationship between directional (polarized) emittance and scattering coefficients is similarly established by Peake.⁵ A more generalized relationship for translucent anisotropic media in non-equilibrium is derived using Landau/Lifshitz fluctuation-dissipation theory in Yueh and Kwok.⁶ A treatment in [7] establishes these fundamental properties of the BRDF from field (coherence) theory.

Unlike other signature models, the polarization predictions of SPIRITS properly include the effects of finite-width lobe specular reflectance, non-Lambertian diffuse reflectance, and polarized directional emittance derived in strict compliance with energy conservation and Kirchoff's Law. Less capable approaches typically attempt to represent surface reflectance merely with a simple Mueller matrix derived directly from the complex refractive index. Such approaches are ill-equipped to account for the effects of angularly variable diffuse reflectance, which complicates the maintenance of Kirchoff's Law compliance for the balance between reflected and emitted polarized light.

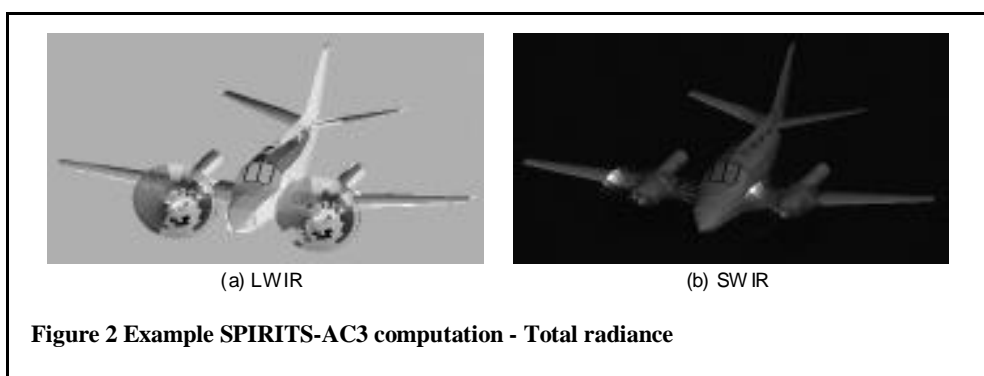

The accuracy of predicted polarized radiance due to specular reflections of extended sources is fundamentally dependent on the accuracy of the source radiance assumed. SPIRITS versions AC2 and above employ a panoramic environmental (earth/cloud/sky) representation with inwelling spectral radiances properly varying in both zenith and azimuth. This level of fidelity (as compared say to simplifications that assume hemispherically isotropic upwelling earth and downwelling sky radiance) is oftentimes critical for polarization signature prediction.

3.3. Examples of SPIRITS-AC3 polarized signature computations

An example computation using SPIRITS-AC3 is shown in Figure 2 and Figure 3. This employed a representation of a Beech Duke commercial aircraft. In this representation the propellers are modeled as a translucent disk with radially varying normal vector, capturing the effect of their time-averaged spin on a staring sensor and also the effect of propeller variable pitch. A set of realistic paints was applied, and a full radiating environment was used. Computations were made in both the LWIR (1000 – 1500 cm^{-1}) and SWIR (4000 – 5000 cm^{-1}) regions to show both thermal-dominated and solar-dominated images.

Figure 2 shows the total (Stokes 1) radiances in both bands. The LWIR image is dominated by thermal emission, which is fairly uniform across the body. Most variation across the image is due to varying amounts of reflected warm earth and cold sky, with reflected earth causing the lighter regions on the sides. The translucent time-averaged propellers reflect either earth or sky depending on their local orientation, which varies radially (propeller pitch) and azimuthally (propeller spin). The SWIR image is dominated by reflected sunlight, with glints from the propellers.

Figure 3 displays the degree of linear polarization ("DoLP"), color-coded from 0.0 (black) to 28% (white) for both bands. The DoLP is largest for facets seen near-grazing angles. Since the primary aircraft paint was given significant extinction (imaginary index) there is no Brewster Angle where a facet (in the SWIR) is 100% polarized; the angle of maximum linear polarization occurs around 80° off-normal, or 10° from grazing. Furthermore, the net DoLP will tend toward a maximum when there is minimal cancellation of the competing emission and reflection. Since the employed set of Sandford-Robertson BRDF model parameters has emittance decrease toward grazing while specular reflection increases, a DoP peak at grazing is to be expected.

4. MULTISCALE POLARIMETRIC SIGNATURE COMPUTATIONS

While SPIRITS-AC3 is an essential tool for computing the apparent Stokes imagery of complex targets, it is inefficient to iterate its computations merely in order to span across various pixelizations (spatial resolutions). Instead, our approach for gauging the impact of spatial resolution is to perform a multi-resolution decomposition of the high-resolution Stokes imagery output from SPIRITS-AC3. At each spatial resolution level, the corresponding Stokes image planes are used to compute images of various polarimetric measures such as DoP. This of course is the physically correct manner of reckoning; merely performing a multi-resolution decomposition on, say, the hi-resolution DoP image itself is incorrect.

The multi-resolution decomposition is performed using an augmentation of the classical (oversampled) Gaussian pyramid.⁸ The “pyramid” terminology is appropriate since each resolution level’s image is decimated by factor 2 (in each dimension) relative to the preceding level. Conceptually “stacking” the various resolution level imagery along a vertical axis yields a pyramid, with the finest resolution level corresponding to the original image (level “0”) at the bottom, proceeding to ever coarser resolutions toward the top. An image at the “i-th” resolution level is formed by lowpass filtering the “(i-1)-th” level image then subsequently decimating the filtered result by factor 2. The low-pass filter is typically a 2D Gaussian kernel – we employed an even-number of taps (6x6).

It can be shown that a pixel at the “i-th” resolution level corresponds to the output of an ever more finely interpolated “effective” filter kernel spanning $2^{i-1} \cdot \text{kernelWidth}$ pixels along a given dimension of the original (level 0) image. Furthermore, the “weight” of the effective interpolated kernel is preserved – we normalized our 6x6 kernel taps to sum to 1.0. The composite “phase” of this effective kernel “laydown” within the original level 0 image can be controlled by selecting the “odd” or “even” samples (for each dimension) at each decimation step. This successive downsampling-with-averaging property of the Gaussian pyramid exactly mirrors the pixel response to a scene for a physical imaging sensor as its IFOV resolution is coarsened.

To statistically assess the impact of varying IFOV size on polarimetric discriminability, we treated each of the non-zero valued pixels (i.e., target & boundary samples) within a given multiresolution level DoP image as dwell samples pertaining to the corresponding IFOV size. At each level, we include in the sample ensemble all 4 sets of sampling “phase”, i.e., the “odd” and “even” samples for each dimension at each decimation step. Although strictly speaking, it is the polarized radiance and not the DoP that determines polarimetric SNR, for our particular example given its fairly high target effective emissivities and warm environmental reflections, SNR is sufficiently proportional to DoP across all total radiance instantiations. When reporting effective IFOV values, we quote the IFOV as the full-width-half-maximum (FWHM) of our effective (Gaussian) kernel, which we take to be half its total width. Its total width spans ± 2.5 standard deviations (s.d.), so the FWHM spans 2.5 s.d. (± 1.25 s.d.).

We took care in our implementation of such computations to preclude careless missteps that might tarnish the results. The lowpass filtering was performed using FFTs, which implies performing a circular convolution. To preclude the associated wraparound and edge effects, we padded the Stokes imagery, placing the target in the center of the pad. Pad values set to the background radiance were employed for s1 imagery (total radiance), while zero-valued pads were employed for s2-s4 (this assumes unpolarized background). Since the successive decimation performed by the Gaussian pyramid operations would eventually cause enough pad decimation to threaten wraparound effects, we adaptively re-padded during the “ascent” of the pyramid. Padding was maintained so that the distance between the target boundaries and the image borders was always

greater than the kernel width. One might dub this augmentation of the pyramid computations as the “interrupted Gaussian pyramid”. For efficiency of coding, all implementation was performed in MATLAB.

5. POLARIMETRIC OBSERVABILITY VERSUS IFOV SIZE – EXAMPLES

We model a military ground vehicle, which for expedient modeling purposes we assume is uniformly coated with a typically high emissivity specular paint. The inquiry regards observers above the ground at the following viewing geometries. Observers are swept in azimuth about the vehicle in steps of 40 degrees starting from 0 degrees (head-on), for the following discrete zenith angles: 30, 45, 60, 75, and 85. Zenith angle is measured between the local vertical (at the vehicle)

and the vector from vehicle to observer; thus 0 degrees corresponds to a directly overhead observer, while 90 degrees is a horizontally viewing observer. Signatures were computed for the 8-12 micrometer band from a range of 10km through a clear sky U.S. Standard Atmosphere, rural haze, with multiple scattering as computed by MODTRAN. The vehicle was quiescent with temperatures computed for a sunny diurnal cycle point of 1500 local time.

A number of competing factors confound simplistic expectations regarding the dependence of the distribution of pixel DoP on zenith, azimuth, and varying IFOV size. Although incidence angle, thus Fresnel disparity hence elemental DoP, increases with zenith for horizontally oriented surfaces, it decreases for those vertically oriented. Furthermore, as the Fresnel disparity of horizontally oriented surfaces increases with zenith, their projected area decreases as the reciprocal of cosine(zenith). Thus, a statistical analysis of the behavior of DoP with the factors zenith, azimuth, and IFOV size is warranted and presented below.

2D scatterplots of DoP versus IFOV lineal subtense (1 plot for each given zenith) are shown in Figure 4 through Figure 8. Regression analysis revealed no clear trend with respect to azimuth angle (even when considering trimmed quantiles), so it is a hidden factor in what we present here (although azimuth induces a slight systematic variation on realized IFOV values due to the image formation operations within SPIRITS). Each point plotted represents a pixel from within each of the 4 grid sets of pixels that fall across the target for a given IFOV size. A grid set corresponds to 1 of 4 possible dyadic sampling phases (e.g., northeast, northwest, southeast, or southwest shift by half an IFOV width). All grid set pixels are plotted, even those with meager target fill factors (e.g., those that barely include the target edge). Thus, for nearly all IFOV bins the DoP sample values will span a range extending down to near zero. Detection will be dependent largely on high fill factor pixels with correspondingly higher DoPs (i.e., not diluted by unpolarized background). Therefore, the most relevant “response surface” is what one may visualize as “draping” across the tops of the “spikes” of samples within the scatterplots.

One prominent robust trend is (visually) evident from inspection of the scatterplots. For a fixed zenith angle, the observable DoP values decrease at least superlinearly and nearly quadratically with lineal IFOV subtense. This makes sense in that the projected area increases quadratically. For this vehicle and scenario, the highest DoPs occur for zeniths of 75 and 85 and, relative to these, are somewhat lower for zeniths of 30, 45, and 60. Interestingly, the maximum DoPs achieved appear to be lowest for 60 degree zenith, with an increase in DoP as the zenith value approaches the extremes of zenith. This may be related to the fact that the neighborhoods near the extremes of zenith (0 and 90) represent the best opportunity for near-

grazing incidence viewing of horizontal or vertical surfaces (hence maximal Fresnel disparity), although as earlier remarked this competes with other effects.

An IFOV (“FOV” in the plot figures) of 400 microradians (0.0004) corresponds to a projected length of 4 meters (lineal) at a 10km range. The size of the vehicle is nominally about 4m width by 7m length by 3m height. An IFOV projected footprint of between 0.5m-1.0m (lineal) (50-100 microradians) appears to be about the coarsest sizing that maintains DoP at or greater than 5% (corresponding roughly to 10:1 polarimetricSNR), before the DoP drops precipitously to negligible noise-equivalent (e.g., 0.5%) levels. (Note: the axes of the plots are displaced outward from the data origin for clarity).

Figure 7 Scatterplot of DoP versus IFOV for zenith=75

Figure 8 Scatterplot of DoP versus IFOV for zenith=85

6. CONCLUSION

These results, though rendered for a singular scenario and certainly not exhaustive, should infuse a cautionary approach into polarimetric sensor design for remote sensing and surveillance. Specifically, we demonstrate that the spatial subtense of the detector(s) is a critical design parameter – if their sizing is chosen carelessly, a negligible polarimetric signal may result when deployed against the applications of interest. These IFOV size sensitivity results need to be validated by comparison with actual measurement data. Nevertheless, a well-validated polarimetric signature prediction model appears slated to play an essential role in careful polarimeter designs of the future.

In this work we consider the solution of multiple linear systems of equations of the form

$$Ax^{(j)} = b^{(j)}, \quad j = 1, \dots, J,$$

where $A \in \mathbb{C}^{n \times n}$ is large, sparse, and non-Hermitian and the $b^{(j)}$'s are all available simultaneously. Such problems arise, for instance, in the numerical solution of frequency-domain electromagnetic wave scattering; in this case, the right hand sides might correspond to different incident fields on the scatterer induced either by plane waves incident at various angles or by excitation sources at different locations. We propose a new technique, based on the quasi-minimal residual (QMR) algorithm, to solve these types of problems. Our approach is efficient in both computation time and storage.

The naive approach of solving each of the J linear systems independently using a Krylov subspace method does not take advantage of the fact that the $b^{(j)}$'s, and hence the $x^{(j)}$'s, may be closely related due to the underlying physical nature of the problem. By closely related, we mean that the solution to the j th system has large components in the directions of the Krylov subspace generated from one of the other systems. Projection-type techniques for both the Hermitian and non-Hermitian cases that specifically exploit such shared information have been proposed (e.g., see [?, ?] and the references therein).

Another alternative is to use a block algorithm, such as block QMR [?, ?], to solve the systems simultaneously. However, this approach can be more expensive in terms of storage than projection techniques because the length of the recurrences to update the iterates depends on the number of right hand sides, or, in the case of deflation [?], the number right hand sides corresponding to the deflated Krylov subspaces. Further, the residuals themselves are not available at every iteration. Also, if a deflation technique is used, a deflation tolerance must be specified in advance, and we have found in experiments that the performance and convergence of the systems depends in an unpredictable way on this value. Therefore, we pursue the idea of a projection-type technique and then present a block variant of our algorithm that exploits good properties of the block QMR algorithm while preserving the basic properties of our projection-type technique.

The idea of a projection-type technique is to choose one of the J systems to be the “seed” system and apply some type of Krylov subspace method to it. For the non-Hermitian case, choices include conjugate gradient for least squares (CGLS), biconjugate gradient (BiCG), conjugate gradient squared (CGS), and generalized minimal residual (GMRES). As the relevant subspaces are generated, the approximations to the other systems are simultaneously updated by projecting the residual onto a particular subspace and by either enforcing a Galerkin-type condition [?, ?] or by minimizing the projected residual [?]. Our algorithm is similar to the project-minimize approach but has certain advantages over the algorithm in [?]; namely, we do not need to store the basis vectors, we do not need to predetermine a subspace dimension, and the approximate solutions and residuals are cheaply computed and available at every stage of the algorithm because they are updated with short-term recurrences.

Our algorithm proceeds as follows. First, we select one system, say system

j , to serve as “seed” and apply QMR (without lookahead) to the seed system. In the following, we use $r_0^{(j)}$ to denote the initial residual to system j given the starting guess $x_0^{(j)}$ and $r_k^{(j)}$ to denote the residual of system j after k iterations. As QMR progresses to the $k+1$ st iterate, it generates bi-orthogonal bases for two k -dimensional Krylov subspaces, $K_{k+1}(A, r_0^{(j)})$ and $K_{k+1}(A^T, r_0^{(j)})$. We denote the respective bases by the columns of V_{k+1} and W_{k+1} . By bi-orthogonality, $W_{k+1}^T V_{k+1} = D_{k+1} = \text{diag}(\delta_1, \dots, \delta_{k+1})$. For the seed system, the k th iterate is obtained by minimizing the norm of a quasi-residual, which amounts to solving a least squares problem involving a $(k+1) \times k$ tridiagonal matrix. That quasi-residual can also be thought of as a projected residual; that is, if $r_k^{(j)}$ denotes the k th residual of the seed, the k th iterate is taken to be $x_0^{(j)} + V_k z_k^{(j)}$, where $z_k^{(j)}$ denotes the vector in \mathcal{C}^k which minimizes the norm of $D_{k+1}^{-1} W_{k+1}^T r_k^{(j)} = D_{k+1}^{-1} W_{k+1}^T (r_0^{(j)} - A V_k z_k^{(j)})$.

We extend this idea to solve the remaining systems. Thus, if $r_k^{(i)}$ denotes the k th residual of the i th non-seed system, the corresponding k th iterate is determined to be $x_0^{(i)} + V_k z_k^{(i)}$ where $z_k^{(i)}$ minimizes the norm of $D_{k+1}^{-1} W_{k+1}^T r_k^{(i)}$. Alternately, the iterates to the non-seed systems can be thought of as minimizing a quasi-minimal residual. After the seed system converges, the current iterates are used as starting guesses and the process is repeated by selecting a new seed from among those that have not converged. The whole process repeats until all the systems have converged. Although it is not obvious from this discussion, we note that no extra Lanczos vectors need to be stored to form the k th iterates of the non-seed systems. We expect our algorithm to have better convergence behavior than BiCG-projection approaches just as QMR behaves more stably than BiCG on a single problem.

The dominant cost in our algorithm is the total number of matrix-vector products. In the worst case, if the solutions have very little shared information, we expect the cost to be comparable to the method of solving each system separately. However, if the Krylov subspace generated by the seed and the Krylov subspace generated by a non-seed are close, we expect that only a few restarts, relative to the number of right hand sides, will be necessary, and thus significantly reduce the number of matrix-vector products computed overall. Along the lines of the analysis in [?], we show that under certain conditions, when the process is restarted with a new seed, the convergence rate of the residual of that seed system behaves as if the extreme ends of the of the spectrum of A are cut off. We are currently working on bounds for the remaining residuals after each restart. Indeed, our numerical results indicate that the computational savings of our algorithm over the approach of solving each system separately can be significant.

As mentioned, the performance of the single seed projection-type algorithms relies on presence of common information among the right hand sides. If little such information is found, one way found to generalize our algorithm to address this difficulty is to take m ($1 < m < J$) systems as seed, say those with indices in I_s , and use block QMR to solve the seed systems. Then, as with the single

seed algorithm, we project the residuals of the non-seed systems and solve the corresponding minimization problems. Thus, the Krylov subspace in which approximate solutions are sought is the km dimensional subspace

$$K_{km}(A, B_s) = \text{span}\{B_s, AB_s, A^2B_s, \dots, A^{k-1}B_s\}, \quad B_s = [b^{(i_1)}, \dots, b^{(i_m)}], \quad i_m \in I_s.$$

We use the implementation in [?], which incorporates deflation to drop converged seed systems and to delete (nearly) linearly independent vectors in $K_{km}(A, B_s)$ and $K_{km}(A^T, B_s)$. Methods for selecting optimal choices for m and I_s are topics for future research.

Therefore, if the right hand sides of the seed systems are not very closely related, they must each be contributing unique information to the Krylov subspace, and we expect convergence of the seed systems to occur for small k . Further, we expect that initial guesses of non-seed systems obtained by projection onto this subspace will be better. As long as the number of seed systems is not too large, there are still short term recurrences which generate the solution estimates at each iteration. We are currently exploring the theoretical convergence properties of our multiple seed approach.

ABSTRACT FOR the SIAM ANNUAL MEETING in TORONTO 1998

Ill-conditioned matrices with Toeplitz-type structure arise from the discretization of certain ill-posed problems. We use a preconditioned Krylov subspace method to compute a regularized solution to this linear system given noisy data. Our preconditioner is a rank- m approximation to the Cauchy-like matrix obtained by applying a fast, symmetry-preserving orthogonal transform to the original system. We show that the preconditioner has desirable properties, give a method for applying it quickly, and illustrate its effectiveness on examples.

ABSTRACT FOR SIAM ANNUAL MEETING IN Atlanta, 1999

We consider the solution of large, sparse, non-Hermitian, linear systems with multiple right hand sides. We use QMR to solve the seed system and generate bi-orthogonal Krylov subspaces; approximate solutions to non-seed systems are generated by minimizing their appropriately projected residuals. The process is repeated by selecting a new seed from among the non-converged systems and using previously generated approximate solutions as initial guesses. Convergence theory is given and algorithmic efficiency is illustrated on examples.

ABSTRACT FOR PLEMMONS BIRTHDAY CONFERENCE, 1999

Discrete ill-posed problems in the form of large linear systems or least squares problems occur in a variety of applications. Due to the presence of noise, regularization methods must be used to determine a solution that approximates the noise-free solution. A wise choice of regularization parameter, which controls conditioning, is crucial to obtaining a good approximate solution. If the dimension of the discrete problem is large, however, selecting a parameter and solving the regularized problem can be costly. For this reason, we compute an approximate solution by projection onto a smaller dimensional subspace via Krylov subspace-based iterative methods. We show how techniques designed for choosing the regularization parameter for the original problem can also be used effectively on a regularized form of the projected problem. We prove some results on the approximate equivalence of this approach of regularizing after projection to other forms of regularization, which operate on the larger problem directly. The success of these techniques and the computational savings is illustrated in examples.

FOR TALK AT UMASS DARTMOUTH, 1999

Many problems in image processing require the solution of a linear system or least squares problem resulting from the discretization of a first kind integral equation. The exact solution to such problems is often hopelessly contaminated by noise, since the discretized problem is very ill conditioned and noise is usually present in the data; hence, regularization must be employed to approximate a solution. In this talk, we will consider a wavelet-based regularization scheme for use in linear image restoration problems. We introduce the L-hypersurface method for determining the multiple regularization parameters associated with our regularization scheme. Since the computational cost of selecting parameters by means of the L-hypersurface can be prohibitive, we also explore cost efficient variants. The effectiveness of our regularization approach and parameter selection techniques will be illustrated on several examples.

Hyperspectral Imaging Using AOTF and NIR Sensing of Buried Objects and Landmines

Abstract

The detection of landmines and buried objects requires methods that can cover large areas rapidly while providing the required sensitivity to detect the optical and spectroscopic contrasts in soil properties that can reveal their presence. These conditions on contrast and coverage can be met by capturing images of the soil at wavelengths which are sensitive to the properties modified by the presence of buried objects. In this work we investigate both imaging and scanning methods which may have some utility for the detection problem. In the imaging approach, we capture hyperspectral reflection images using an acousto-optic tunable filter (AOTF) and fluorescence images using a long-pass filter. For the scanning method, we acquire data point-by-point over a two-dimensional grid with a single emitter/detector pair. The results illustrate the potential of these two approaches for detection of landmines and buried objects.

I. Introduction

Indirect methods of detecting buried objects involve looking for differences between undisturbed soil and soil directly above a buried object. The detection of landmines and buried objects requires methods that can cover large areas rapidly while providing the sensitivity to the contrasts in soil properties that can reveal the presence of foreign objects. The conditions on coverage can be met by acquiring images of large areas or rapidly scanning over the ground. The contrast is provided by acquiring the data at specific wavelengths or over continuous spectral bands which are particularly sensitive to the properties affected by the presence of buried objects. In this work we look at both imaging and point-by-point (scanning) methods which can be adapted for use in the detection problem. The images were acquired by a charge-coupled device (CCD). Two types of images were captured: (1) narrowband reflection images using an acousto-optic tunable filter (AOTF) and (2) fluorescence images using a long-pass filter. The scanning method employed a near-infrared (NIR) emitter/detector pair where data were captured point-by-point over a two-dimensional grid.

II. Imaging-Based Methods for Object Detection

IIa. Reflection Imaging with an Acousto-Optic Tunable Filter

By taking two-dimensional images of a target zone, a large area can be spectrally mapped quickly given that the contrast between the background soil and burial sites are sufficiently strong to allow rapid detection. One method of increasing contrast is to image at/over wavelengths where the differences in reflection or fluorescence properties are maximized. These types of images can be captured rapidly by using an acousto-optic tunable filter (AOTF) for wavelength discrimination. The AOTF is

a narrowband optical filter with a electronically-selectable passband and a two-dimensional aperture. It can quickly jump between remote wavelengths or be rapidly scanned across some continuous spectral range. Band-limited (i.e., a spectral range wider than the resolution width of the filter) imaging can be performed by scanning the AOTF across a specific range of

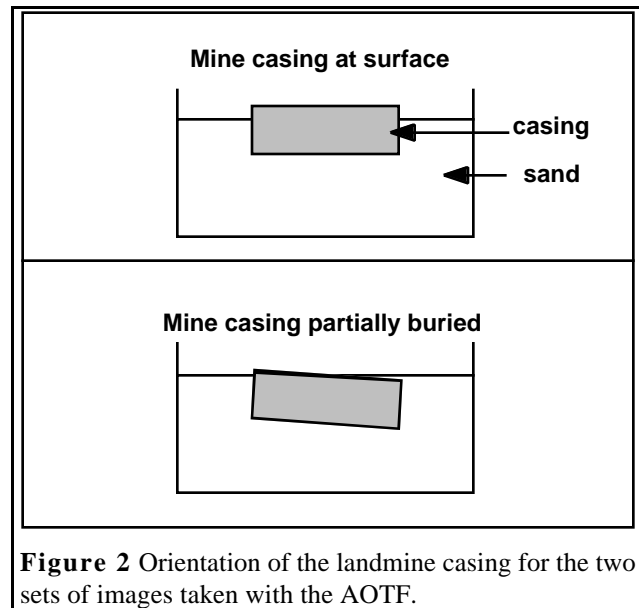

light is discriminated by the TeO₂ AOTF used here.

In this work our imaging system was limited to wavelengths shorter than 700 nm. Thus to demonstrate the capabilities of an AOTF-based system to make wavelength-resolved images, we have examined a landmine casing both above and partially buried in sand (see Figure 2) illuminated by an incandescent lamp and imaged at wavelengths from 525 to 700 nm. A white-light image of the casing is shown in Figure 3. The imaging system is diagrammed in Figure 4 and employs a TeO₂ AOTF (Brimrose, Inc. tunable from 450 to 700 nm), a thermoelectrically cooled CCD (Santa Barbara Instruments, Model ST-6) and a camera lens with adjustable aperture and focus. At each wavelength, in addition to the landmine casing, an image of a white card was also recorded along with the landmine casing for use in data normalization. The normalization process is diagrammed in Figure 5.

wavelengths while exposing the image-capturing elements (e.g., film or charge-coupled device array (CCD)). Our laboratory has previously reported on the use of AOTF/CCD based systems for hyperspectral imaging[1-3].

The AOTF operates by propagating ultrasonic waves through an anisotropic crystal. The strains induced by the ultrasound act to spatially modulate the indices of refraction of the crystal. The device is essentially a three-dimensional grating whose spacing can be tuned by changing the wavelength of the ultrasound in the crystal. Since the AOTF has no moving parts and can be rapidly moved to the desired wavelength, it is ideal for use in portable instrumentation where spectral selectivity and timely feedback are required. Figure 1 shows the how the

The normalized images for the exposed casing are displayed in Figure 6. The casing has five indentations on its surface (four around the rim and one arrow-shaped) which were filled with sand in the wavelength-resolved images. The best images in

terms of clarity and contrast between the sand and casing are the three images taken at 600 nm, 625 nm, and 650 nm respectively. The images of the partially buried casing, as displayed in Figure 8 (Figure 7 gives the orientation of the casing as seen in Figure 8), showed similar results. For these, the 625-nm and 650-nm images display the best contrast. The resulting contrasts in these reflected-light pictures are of course related to the respective colors of the casing and sand. The casing is mostly green and as one moves to longer wavelengths (starting from 525 nm) the casing reflects less light while the background sand reflects more evenly across the spectrum. Thus the contrast between the two increases as one moves from green wavelengths to the red end of the spectrum. Future work will involve investigating local reflection properties of the soil at NIR wavelengths. By performing narrowband or wavelength-resolved imaging, the contrast in soil properties can be maximized.

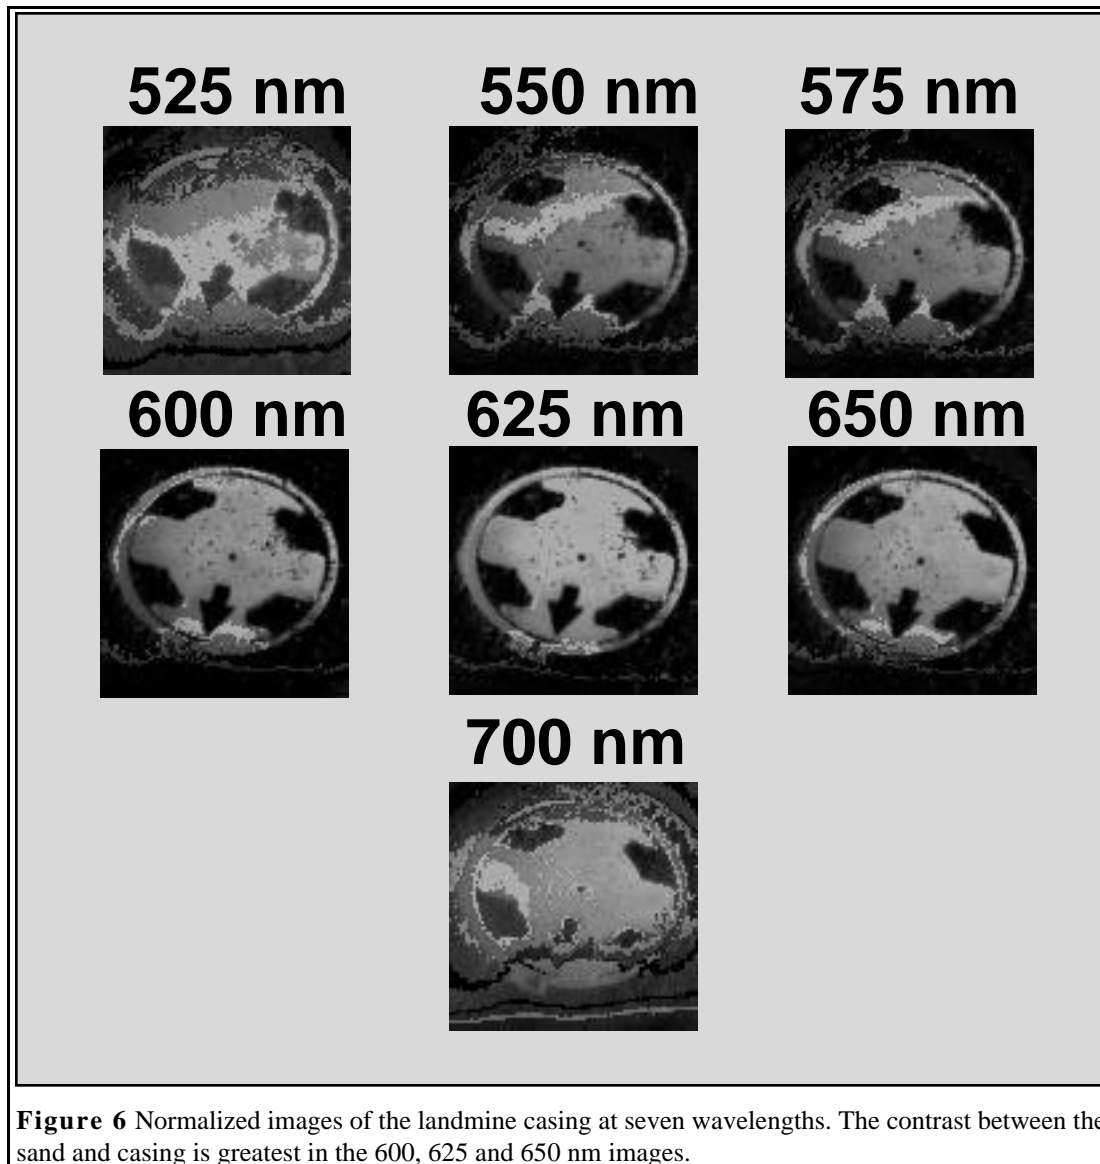

Figure 6 Normalized images of the landmine casing at seven wavelengths. The contrast between the sand and casing is greatest in the 600, 625 and 650 nm images.

Iib. Fluorescence Imaging

In addition to reflected light, we also captured images of the fluorescence emission from the partially-buried object. In this mode, the AOTF was replaced by a 525-nm long pass filter, the focusing lens/camera were axially aligned with the collection lens and the object was illuminated by the 488-nm line of an Argon laser. The captured image is shown in Figure 9. The high contrast between the casing and sand is readily apparent. If a condition of the soil above a buried mine can be detected via fluorescence, this method could be useful in low-light situations where the fluorescence can be measurably detected over ambient reflected light.

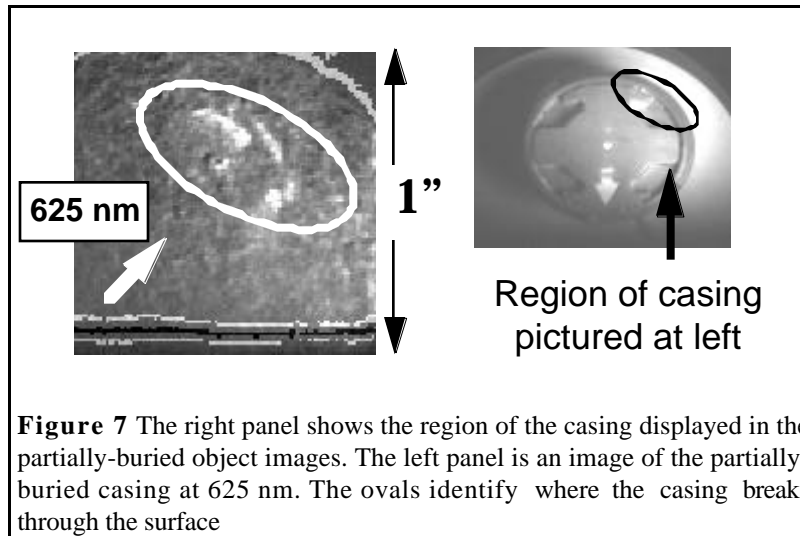

Figure 8 Normalized reflection images of the partially-buried landmine casing at seven wavelengths. The degree of contrast between the sand and casing is greatest in the 625 and 650 nm images.

Exposed portion of casing

Figure 9 Fluorescence image of the partially-buried landmine casing. The sample area was illuminated with the 488 nm line of an Argon laser. A 520 nm long pass filter was used to remove the background.

III. Point-by-Point Scanning in the NIR

In contrast to the direct imaging methods, we also performed a point-by-point reflection-mode scan in a 2-D grid pattern at NIR wavelengths over the surface of sand with wet and dry areas. The idea behind this experiment is that the soil above the buried object may contain less moisture - the flow of moisture being drawn up to the surface (due to concentration gradients stemming from surface evaporation) may be affected by the presence of the object. A casing for a landmine was buried under 5 mm of material in a tray that measured 30x16x8 mm (LxWxD). In order to simulate the dry and wet areas found in the field, a piece of plastic wrap was used to separate the dry material from the wet. Using an infra-red emitter/detector matched pair operating at 915 nm, a light-emitting diode (LED) and a photodetector were mounted side-by-side on perforated board and soldered in place. The orientation was chosen to maximize the detection of reflected IR from the infrared LED. The photodetector has a sensitive area of about 1 mm² while the LED has a collimating lens mounted in place and a radiant power of 0.5 mW. The detector and experiment are depicted in Figure 10.

The photodetector was used in the passive mode and voltages were measured with a digital multi-meter. The device was positioned using an optical rail system marked in mm. The LED and photodetector were held about 30 mm above the surface of the soil and a reading was taken, in a darkened

Figure 10 Diagram of the sensor and the experimental arrangement used for the IR scan.

Figure 11 Result for the IR scan of the buried object. The x and y axes are position and the z-axis is the photodiode voltage in linear units.

room, every 20 mm in the x and y direction. The surface scanned in this procedure covers a 12x20 cm area. The resulting image is illustrated in Figure 11.

The experiment provided an image of medium resolution where the wet sand reflected enough radiant energy to produce a signal on the order of 27 - 40 mV and the dry sand that of 50 - 60 mV. The variation of the signal at any given point was about one millivolt. The device was able to differentiate between wet and dry material and produce an image that roughly corresponds with that of the buried landmine. Further work will focus on improving the sensor and more accurately simulating field conditions in the laboratory.

Conclusion

In this paper, we have reported on some preliminary work evaluating methods that could be used in the detection of buried objects. We examined imaging techniques using both reflected and fluorescent light as well as point-by-point scanning with a single infrared emitter-detector pair. Each of the methods shows some promise and will be evaluated under more stringent conditions in the future.

Abstract

The sand above a shallow buried object can be differentiated from the surrounding sand by detecting the difference in relative water content. Moist sand absorbs more near-infrared (NIR) incident light than dry sand. A light emitting diode operating at 900 nanometers and a photodiode sensitive to NIR radiation formed the emitter/detector pair used in this study. The pair were mounted side-by-side and scanned over a surface in a two-dimensional grid as readings were collected point-by-point. The results indicated that this simple NIR emitter/detector pair discriminated between sands of varying water content and possessed an imaging resolution of 4 millimeters.

I. Introduction

Remote detection of a shallow-buried-object requires identifying a property to distinguish the undisturbed soil and the soil directly above the buried object. One characteristic that may be exploited for such differentiation is the water content of the surface soil. The water content of the soil directly above a buried object can differ from that of undisturbed soil and the difference can be detected using near-infrared reflectance. The detection of landmines and buried objects requires methods that can cover large areas rapidly while providing required sensitivity to detect the optical and spectroscopic contrast in the soil properties that reveal their presence. These conditions on contrast and coverage can be met by capturing images of the soil at wavelengths which are sensitive to the properties modified by the presence of buried objects. Eventually these techniques can be extended to rapidly scan large areas by using NIR photography. Previous work has shown how powerful an imaging system is in detecting buried objects [1]. The work in this paper illustrates the usefulness of the NIR optical region for detecting buried objects and leads directly to NIR imaging techniques.

II. Experimental

In this study, a probe was constructed to examine the ability of NIR reflectance to detect differences in the moisture content of sand. The emitter and detector were mounted side-by-side on perforated circuit board with a current limiting 1K resistor and a 9V battery for the source. The detector was used in the passive mode and had a 12 millimeter long opaque tube affixed to its casing. This tube protected the photodiode from side scatter of the LED and enhanced the image resolution. Light reflected off of the sand surface was captured by the photodiode, which generated a voltage level that was read by a digital multimeter.

Sand (Quikrete Play Sand) was placed into a plastic tub that measured 13X7X3.5 inches. Plastic petri dishes measuring 10 millimeters high and 35 millimeters in diameter were placed in the sand so that their tops came flush with the surface. On the average, one of these petri dishes holds 13.3 grams of sand. Three of these dishes were placed in the tub and various amounts of

water were added to each dish. The emitter/detector pair was mounted onto the end of an optical rod and this mounted onto an optical rail scored in millimeters. The configuration positioned the pair to be looking down onto the surface. This experimental configuration was used to optimize the distance between the surface and the emitter/detector pair to determine the response of the device to various amounts of water in sand and the resolution of the optimized system.

Resolution was determined by finding a bright reflective surface (white paper) and a good absorber (black paper) and mounting them to produce a sharp boundary perpendicular to the axis of travel of the emitter/detector pair. A step size of 2 millimeters provided sufficient accuracy to determine the imaging resolution of the system. The resolution of the detector was adjusted by placing a black plastic tube over the active element to create a limiting aperture. By increasing (decreasing) the length of the tube, the resolution is increased (decreased) as well. A longer tube length, however, is also accompanied by a decrease in signal. We determined the resolution of a 12 millimeter tube to be on the order of 4 millimeters (Figure 1). We found 4 millimeter resolution gave us a reasonable balance of spatial sensitivity and signal-to-noise. The final experimental configuration is illustrated in Figure 2.

Figure 2: Schematic of experiment for determining areas having higher water content than surrounding sand.

The scans were made in a darkened room and the device was moved in 5 millimeter increments in both directions. The sand was used as is; there were no special preparations made such as baking or washing. To determine the amount of water per gram of sand three petri dishes were chosen at random, tared, filled with sand (overfill and scrape level method), and weighed when filled. Each was weighed filled three times generating nine data points. The weights were consistent as seen in table 1.

Table 1

	Petri Dish 1	Petri Dish 2	Petri Dish 3
Net Weight 1	13.26 g	13.66 g	12.96 g
Net Weight 2	13.15	13.63	13.02
Net Weight 3	13.02	13.54	13.39
Mean \pm St. Deviation	13.14 \pm 0.12 g	13.61 \pm 0.06 g	13.12 \pm 0.23 g

All nine results give a mean weight of 13.29 ± 0.27 gram. In preparing this proof-of-principle experiment, it was desirable to maintain a constant distance between the detector and the surface of the sand. In accomplishing this, material was moved into and out of the petri dishes several times as the surface and the dishes were scraped over by a steel ruler. The leveling procedure makes it impossible to weigh a known amount of material into a petri dish. However, the standard deviation of the weights and the consistency between dishes shows that relatively little error was introduced by not weighing the sand in each dish. Figure 3 gives a graph of the response of the emitter/detector pair when viewing sands containing various amounts of water. Dry refers to untreated sand. The unit (milliliters/gram) given in the graph refers to the amount of water added to untreated sand.

Figure 3: Response of System to Soils Containing Various Amounts of Water

mL / gr	Mean	St. Dev.	Data 1	Data 2	Data 3	Data 4	Data 5
(Dry) 0	15.5	0.122474	15.6	15.5	15.3	15.5	15.6
0.037	13.26	0.320936	13.3	13.4	13.5	12.7	13.4
0.075	11.8	0.291548	11.4	11.9	11.8	12.2	11.7

0.188	10.58	0.130384	10.5	10.6	10.7	10.7	10.4
0.226	10.22	0.083666	10.2	10.3	10.3	10.1	10.2

Figure 4 illustrates the image resulting from a point-by-point scan of the surface. The petri dishes contained sands of higher water content than the surrounding sand. This image was produced by moving the detector in 5 millimeter increments. A grayscale was assigned to the numeric values so that the dry sand produced a light gray pixel and the wettest sand produced a black pixel.

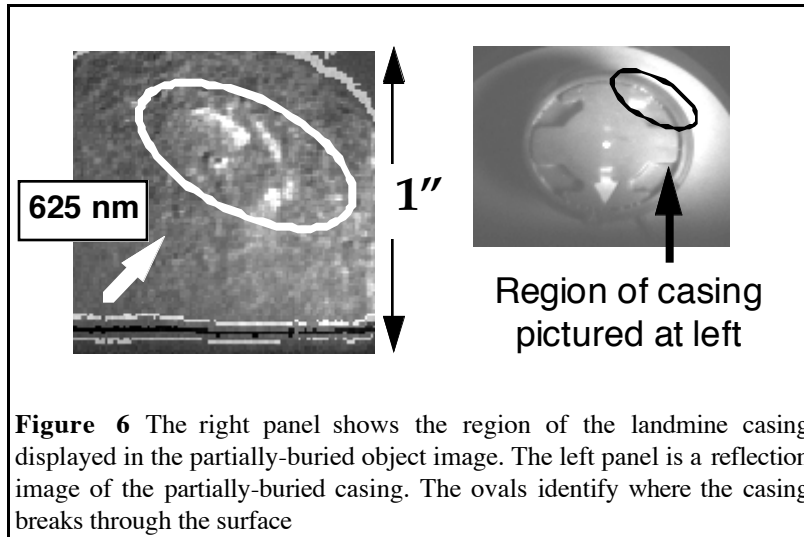

The data may be represented in a three-dimensional form (Figure 5). The regions of higher water content are illustrated as having greater height and the variation in the dry sand is illustrated in the baseline. The values of the z-axis are in descending order to produce peaks where there is greater water content. The value of the signal is smaller in these regions.

Figure 4: Two-Dimensional Representation: Response of the NIR Detector to Sand With Various Water Content. The x and y axes represent the distance in millimeters and the gray scale is the voltage in millivolts.

Figure 5: Three-Dimensional Representation of Wet/Dry Sand. The x and y axes represent the distance in millimeters and the z-axis is the voltage in millivolts.

III. Imaging Approach

By taking two-dimensional images of a target zone, a large area can be spectrally mapped quickly given that the contrast between the background soil and burial sites are sufficiently strong to allow rapid detection. The idea is to increase contrast by collecting images at/over wavelengths where the differences in reflection or fluorescence properties are sufficiently large. To illustrate the application of imaging methods to the landmine detection problem, images of the fluorescence emission from a landmine casing partially buried in sand were captured. The 488-nm line from an Argon laser illuminated the object and a CCD camera captured the image through a 525-nm long pass filter. The orientation of the casing is shown in Figure 6. One of the captured images is shown in Figure 7. The high contrast between the casing and sand is readily apparent.

IV. Conclusion

In this paper, we have reported some preliminary work evaluating methods that could be used in detection of buried objects. We showed the signal of the NIR detector to be sensitive to water content of sand. We illustrated that such a device can produce images of regions having different moisture. This study illustrates the potential of an NIR imaging system to detect buried objects. Such a system could be composed of a charge-coupled device (CCD) in combination with a device to select a specific wavelength of light (e.g. an acoustic optical tuning filter).

FDTD Wave Propagation in Dispersive Soil Using a Single Pole Conductivity Model

Carey M. Rappaport, Shuang Wu and Scott C. Winton
Center for Electromagnetics Research, Northeastern University, Boston, MA

Abstract—In FDTD modeling of lossy, dispersive soil for subsurface imaging and detection applications, the electric flux and the current are convolutions of $E(t)$ with $\epsilon(t)$ and $\sigma(t)$ respectively. To avoid these memory-intensive computations, the convolutions can often be accurately and simply modelled as second order difference equations. In particular, by matching the corresponding Z -transform of the E-field/current relation to frequency-dependent conductivity results in a ratio of polynomials in Z^{-1} (where $Z = e^{j\omega\Delta t}$). A good fit to measured soil data over two decades in frequency is possible using only a single pole, two zero conductivity model. Compared to a similarly accurate three-term Debye model, this one-pole model requires one-third the storage of previously computed field values.

Index terms—FDTD, Soil Modeling, Dispersion, Mine Detection

I. BACKGROUND

There is growing interest in simulating wave propagation for underground microwave and RF sensing and imaging applications. Soil is a good candidate for the finite difference methods since it is usually inhomogeneous, lossy, and has an irregular surface boundary. It has been challenging to accurately compute wideband wave behavior in realistically modelled soil because of its dispersive nature, requiring either many individual frequency domain calculations or a robust deconvolution of $E(t)$ from $D(t)$ in the time domain. A simple dispersive variant of the FDTD algorithm which includes the effects of frequency-dependent conductivity and dielectric constant enables the use of this prevalent and efficient modeling method.

The conventional approach to modeling dispersion in soil approximates the frequency domain dispersive complex dielectric constant with rational functions (Debye or Lorentz models) of $j\omega$ [1,2], multiplies the constitutive relation by the denominator and inverse Fourier transforms the result. We improve on this method by modeling solely the conductivity as a simple rational function of the Z -transform [3,4], based on the observation that the frequency variation of the real dielectric constant does not significantly affect either the real propagation constant β or the decay rate α . By modeling σ in terms of powers of the Z -transform variable Z^{-1} (which readily transforms to time delays), the conversion of the generalized dispersive Ohm's Law $\mathbf{J}(Z) = \sigma(Z)\mathbf{E}(Z)$ to the time domain is particularly straightforward.

II. MODEL FORMULATION

To preserve the conceptual elegance and simplicity of the FDTD method, it is important to keep the media model to at worst second-order. In previous reports, a quite satisfactory two-pole, two-zero rational function conductivity model was presented. This current work shows that a model with a single pole can often be just as good. The right hand side of Ampere's Law $\nabla \times \mathbf{H} = \partial \mathbf{D} / \partial t + \mathbf{J}$ Z -transforms to: $[(1 - Z^{-1}) / \Delta t] \epsilon_0 \epsilon_{Av} \mathbf{E} + \sigma(Z) \mathbf{E}$ (where it is assumed that ϵ_{Av} is frequency independent). The time-dependent conductivity may thus be modelled as

$$\sigma(Z) = \frac{J(Z)}{E(Z)} = \frac{b_0 + b_1 Z^{-1} + b_2 Z^{-2}}{1 + a_1 Z^{-1}} \quad (1)$$

Both the real and the imaginary components of $\sigma(Z)$ depend on the frequency sampling interval Δt and the coefficients of the rational function (a_1 , b_0 , b_1 , and b_2). The imaginary component corresponds to an effective permittivity. This model is implemented by fitting $\text{Re}\{\sigma\}$ to measured conductivity and $\text{Im}\{\sigma\} / \omega \epsilon_0$ to measured real dielectric constant less an average value ϵ_{Av} . To simultaneously solve for b_0 , b_1 , and b_2 , an initial guess is made for a_1 . The conductivity and dielectric constant at three representative frequencies for the measured data and the model are equated. Further simple optimization is performed by trial and error, varying either a_1 or one of the three frequencies. Complex wave number $k(\omega)$ is then calculated from both the model and the measured data, and the real propagation constant β and the decay rate α are derived from $k = \omega / c \sqrt{\epsilon_{Av} - j\sigma / \omega \epsilon_0}$.

Once the a and b parameters of σ have been determined, integration into the FDTD algorithm is straightforward. If the temporal average of the current density \mathbf{J} is used, Ampere's law in the Z domain becomes:

$$\nabla \times \mathbf{H}(Z) = \epsilon_{Av} \frac{1 - Z^{-1}}{\Delta t} \mathbf{E}(Z) + \frac{1 + Z^{-1}}{2} \sigma(Z) \mathbf{E}(Z) \quad (2)$$

Using (1) in (2) and noting that Z^{-1} corresponds to the time index shift $n \rightarrow n - 1$, the E-field update equation for a 2-D Transverse Magnetic ($\mathbf{E} = \hat{z} E_z$) simulation is:

$$E_z^{n+1} = \frac{1}{\epsilon_0} (-e_1 E_z^n - e_2 E_z^{n-1} - e_3 E_z^{n-2} + \Delta H) \\ \Delta H = \frac{\Delta t}{\epsilon_{Av}} \left(-I_x^{n+\frac{1}{2}} - a_1 I_x^{n-\frac{1}{2}} + I_y^{n+\frac{1}{2}} + a_1 I_y^{n-\frac{1}{2}} \right) \quad (3)$$

where $e_0 = 1 + b_0 \Delta t / 2 \epsilon_{Av}$, $e_1 = a_1 - 1 + (b_0 + b_1) \Delta t / 2 \epsilon_{Av}$, $e_2 = -a_1 + (b_1 + b_2) \Delta t / 2 \epsilon_{Av}$, $e_3 = b_2 \Delta t / 2 \epsilon_{Av}$ and I_x and I_y are the spatial first differences of the H_x and H_y fields with respect to y and x (spatial indices have been suppressed for clarity).

The one-pole model of $\sigma(Z)$ requires storing I_x and I_y (and I_z in a three-dimensional simulation) a single additional time compared with non-dispersive FDTD. For each additional conductivity pole, this same amount of storage space must be additionally allocated. Fig. 1 shows the fit of the model (at $\Delta t = 20$ ps) to the conductivity and dielectric constant data measured from Puerto Rican clay loam (PRCL) with 1.4 g/cm^3 density and 10% moisture [5]. The difference between the imaginary conductivity of the model and the measured ϵ (lower panel) is used to determine the constant real soil permittivity ϵ_{Av} . Fig. 2 shows the fit of the full model to β and α . The maximum amount of error is less than 20%, which is close to the measurement error of the soil sample.

Fig. 1. (a) Measured (circles) versus single pole model (continuous curves) of $\sigma(Z)$: (a) real conductivity and (b) imaginary conductivity (real relative dielectric constant) for Puerto Rican clay loam, 10% moisture, 1.4 g/cm^3 density [5]. The constant real dielectric constant ϵ_{Av} is the average difference between the curve and the measured circles of (b).

The use of the average value of the current density is well established and produces accurate results. However, using only the present value of the current density in the update equation results in the savings of another storage location. To facilitate this savings without sacrificing accuracy, $\sigma(Z)$ is multiplied by $(1 + Z^{-1})/2$ and a new set of model parameters is determined to fit this

product over the frequencies of interest. In this case, (3) is additionally simplified with $e_0 = 1 + b_0 \Delta t / \epsilon_{Av}$, $e_1 = a_1 - 1 + b_1 \Delta t / \epsilon_{Av}$, $e_2 = -a_1 + b_1 \Delta t / \epsilon_{Av}$, and $e_3 = 0$, and this dispersive model requires only one additional storing of each field value compared to non-dispersive FDTD. This compares with two field storings for the (2,2) model and three field storings for the comparably accurate three-term Debye model.

Similar modeling for several different types of soil with widely varying density and moisture [5,6] at $\Delta t = 20$ ps is summarized in Table 1. All models have wave numbers in agreement with measured values within 20%.

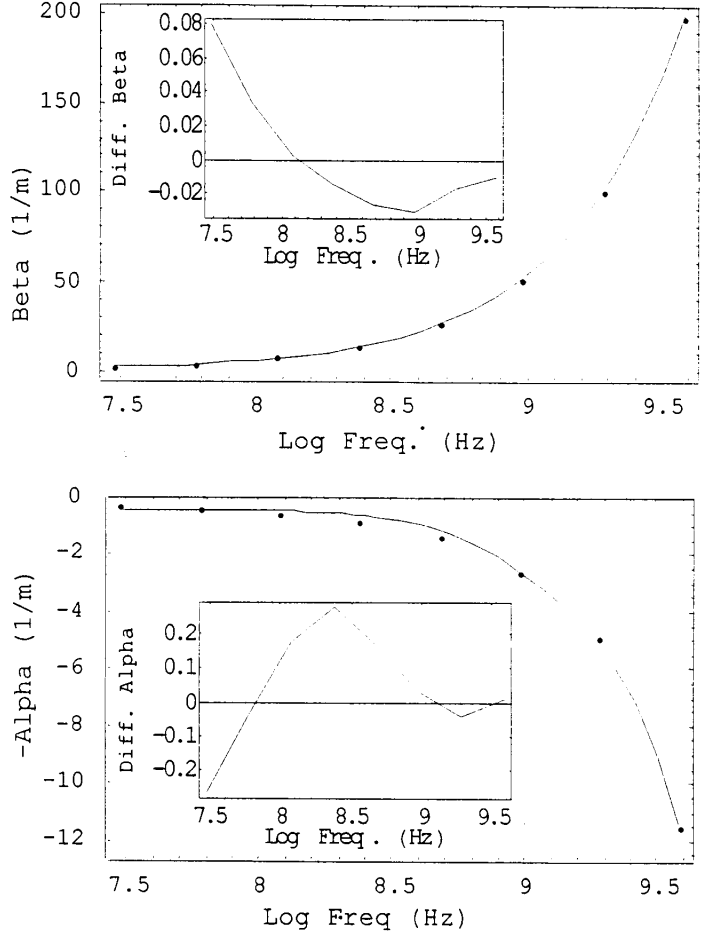

Fig. 2. Measured (circles) versus model for single pole model of $\sigma(Z)$ with constant ϵ_{Av} (continuous curves): (a) Real and (b) imaginary parts of wave number for Puerto Rican clay loam, 10% moisture, 1.4 g/cm^3 density [5] as a function of frequency. Insets show normalized error for this model.

III. STABILITY CONSIDERATIONS

The Courant stability analysis in [3] shows that in a source-free homogeneous medium, the time-space transform of the wave equation for a plane wave ($\Delta x = \Delta y = \Delta z = \Delta$) is:

$$(Z - 1)F(Z) = -4r^2 s^2 \quad (4)$$

where from (2), $F(Z) = \epsilon_{Av}(1 - Z^{-1}) + (\Delta t/2\epsilon_0)(1 + Z^{-1})\sigma(Z)$, and $r = c\Delta t/\sqrt{\epsilon_{Av}}\Delta$, and $s^2 = \sin^2 k_x\Delta + \sin^2 k_y\Delta + \sin^2 k_z\Delta$ with maximum value of s equal to the spatial dimension of the FDTD simulation. Expressing $F(Z)$ in rational form:

$$F(Z) = \epsilon_{Av} \frac{(e_0 + e_1 Z^{-1} + e_2 Z^{-2})}{1 + a_1 Z^{-1}} \quad (5)$$

Using (4), (3) becomes a third order polynomial in Z^{-1} . The solution to this equation yields one real root and two complex roots that are a function of Δ . Stability requires $|Z| < 1$. For Δ within the range of 4.6mm to 120mm, all three roots are within the unit circle.

NUMERICAL TEST CASES

Several numerical experiments were performed to validate this method. The simulations were run in one dimension for simplicity. The choice of Δt is critical since it defines the model, determines the range of usable frequencies and determines the limits on Δ through the Courant condition. For these experiments, the spatial increment was 2.5 mm. The incident field is a modulated gaussian pulse, used to excite many frequencies simultaneously. The modulation frequency is 3 GHz for the Alicia and A.P. Hill soils and 1.5 GHz for the PRCL soil sample.

In order to compare the results of the FDTD simulations with the measured data, the frequency-dependent wave number k must be extracted. Fast Fourier Transforming the time domain fields gives

$$k_{\text{FDTD}} = -\frac{1}{j\ell} \ln \frac{E_z(\omega, \ell)}{E_z(\omega, 0)} \quad (6)$$

Fig. 3 shows the real and imaginary parts of the wave number versus frequency for measured values and either the "Time-Averaged" or "Model-Averaged" k_{FDTD} . These latter "Model-Averaged" simulations use only the current value of the conduction current J^n . The parameters in Fig. 3 correspond to the three separate sites of Table 1. Both the real and imaginary wave numbers agree well for each soil, for both types of models across the entire two decades of bandwidth from 45 MHz to almost 4 GHz. It should be noted that the "Time-Averaged" FDTD computation is more robust, with less sensitivity to excitation function and Courant number.

CONCLUSIONS

A minimal-storage time-domain model for frequency-dispersive soil based on a constant real dielectric constant and a (2,1) rational function of Z^{-1} conductivity function has been developed and tested. By pre-multiplying the measured conductivity data by the Z-transform of the time average function, the resulting model avoids requiring conduction current time averaging in Ampere's law. Without this time averaging,

TABLE I
ONE-POLE CONDUCTIVITY PARAMETERS

Puerto Rican Clay Loam: $m = 10$, $d = 1.4^\dagger$					
av?	a_1	b_0	b_1	b_2	ϵ_{Av}
no	-0.88	0.91625	-1.67662	0.761072	4.18775
yes	-0.9	0.7983	-1.4695	0.67176	4.282
A.P. Hill, Firing Point 22: $m = 19.3$, $d = 1.527$					
no	-0.975	1.51947	-2.97284	1.45362	5.25834
yes	-0.97868	1.5473	-3.036	1.4888	4.7731
Bosnia, Test site Alicia: $m = 25.3$, $d = 1.263$					
no	-0.925	1.76106	-3.32102	1.56193	5.03815
yes	-0.93	1.6325	-3.0827	1.4521	4.9831

$^\dagger m$ is percent moisture content of the soil, d is soil density (g/cm³).

a one-pole conductivity model requires just one additional store of electric and magnetic field compared to the non-dispersive FDTD algorithm. This is half the required additional storage of the previously reported (2,2) model, and even less than standard Debye and Lorentz models. In addition, fitting parameters to a single, real conductivity function — rather than to both parts of a complex permittivity function — is quite advantageous.

Numerical simulations on measured data show that this simple model is efficient and accurate across a wide frequency band for both real and imaginary parts of wave number, giving good predictions of velocity and decay rate. A stability analysis shows that the model is stable for one, two, and three dimensions, for a wide range of grid spacings.

IGARSS, Honolulu Hi, July 2000

Outline

- Problem: Why is it important to characterize the nearfield rough surface effects on impulse GPR signals?
- Modeling methodologies
- Features of ground surface clutter signal
- Separating surface clutter from target signal.

* Demining MURI Supported by ARO

Effect of Ground Roughness on Ground Scattered Pulse

Rough Ground Clutter Signal Characterization

- Signals from rough ground vary considerably
 - Pulse shape depends on roughness and T/R position [DISTORTION]
 - Peak depends on particular T/R position [SHIFT]
 - Overall amplitude varies [SCALING]
- Monte Carlo simulation can model these relevant features
 - 2D FDTD model
 - Real measured impulse GPR excitation and dispersive soil
 - 500 different rough surface realizations

Impulse Ground Penetrating Radar Specifications

Simulation Space

Measured Incident Pulse

Rough Surface Statistical Specification

Gaussian PDF for surface height z with zero mean and rms height = s_h :

$$p(z) = \frac{1}{s_h \sqrt{2\pi}} \exp\left(-z^2 / 2s_h^2\right)$$

Surface height auto-correlation function for surface points x_1, x_2 :

$$R(x_d) = \frac{\langle f(x_1)f(x_1 + x_d) \rangle}{s_h^2}, \quad x_d = x_2 - x_1$$

$$R(x_d) = \frac{1}{s_h^2} \int_{-\infty}^{\infty} W(K_x) \exp(iK_x x_d) dK_x$$

W is the surface profile spectral density function

Rough Surface Statistical Specification (con'd)

For Gaussian spectrum W:

$$R(x_d) = \exp\left(-\frac{x_d^2}{l_c^2}\right)$$

Gaussian joint PDF for surface heights (z_1, z_2) with zero mean and rms height = s_h :

$$p(z_1, z_2) = \frac{1}{2ps_h^2 \sqrt{1 - R^2(x_d)}} \exp\left(-\frac{z_1^2 - 2R(x_d)z_1z_2 + z_2^2}{2s_h^2(1 - R^2(x_d))}\right)$$

Raw Computed Signals

Rough Surface Parameters: $s_h = 3\text{cm}$, $l_c = 10\text{cm}$, ($s_s = 23^\circ$)

Alignment of Randomly Delayed Signals

Given two signals S_0 and S_1

1) Shift by t :

2) Scale by A :

Cross-Correlation Signal Alignment

Normalized cross-correlation functions between flat 'f' and rough 'i' surface:

$$C_{fi}(m) = \sum_{n=1}^{N-|m|} S_f(n) S_i(n+m) / \sqrt{\sum_{n=1}^N |S_f(n)|^2} \sqrt{\sum_{n=1}^N |S_i(n)|^2} \quad \text{For } m > 0$$

$$C_{fi}(m) = C_{if}(-m) \quad \text{For } m < 0$$

Relative Scaling:

$$A_i = \sqrt{\sum_{n=1}^N |S_i(n)|^2} / \sqrt{\sum_{n=1}^N |S_f(n)|^2}$$

where $i = 1, 2 \dots M$.

M = number of surface realizations.

N = number of time steps in each signal.

Alignment Example

For realization # i (e.g.# 378):

Shift= $t_i = 22$ Dt, Scaling factor= $A_i = 0.88$

For $i=1,2,\dots,500$: Signal Statistics: 1- Average Shift= \bar{t}

2- Average Scaling= A

Determining Differential Target Delay from Detected Ground Clutter Delay

- If ground surface height varies, amount of soil between air and nominal target depth varies
- For a given target depth, longer path in air implies shorter path in soil; earlier target signal arrival.
 - Earlier arrival proportional to differential soil propagation velocity
- Verify this effect by comparing ground-only signals with ground-and-target signals:
 - Align ground clutter signals to find τ_{gnd}
 - Align ground-and-target signals each with ground-only signal subtracted w.r.t. target peak to find τ_{mine}

Correlation of Ground Surface Delay and Target Delay

$\sigma_h = 3 \text{ cm}$

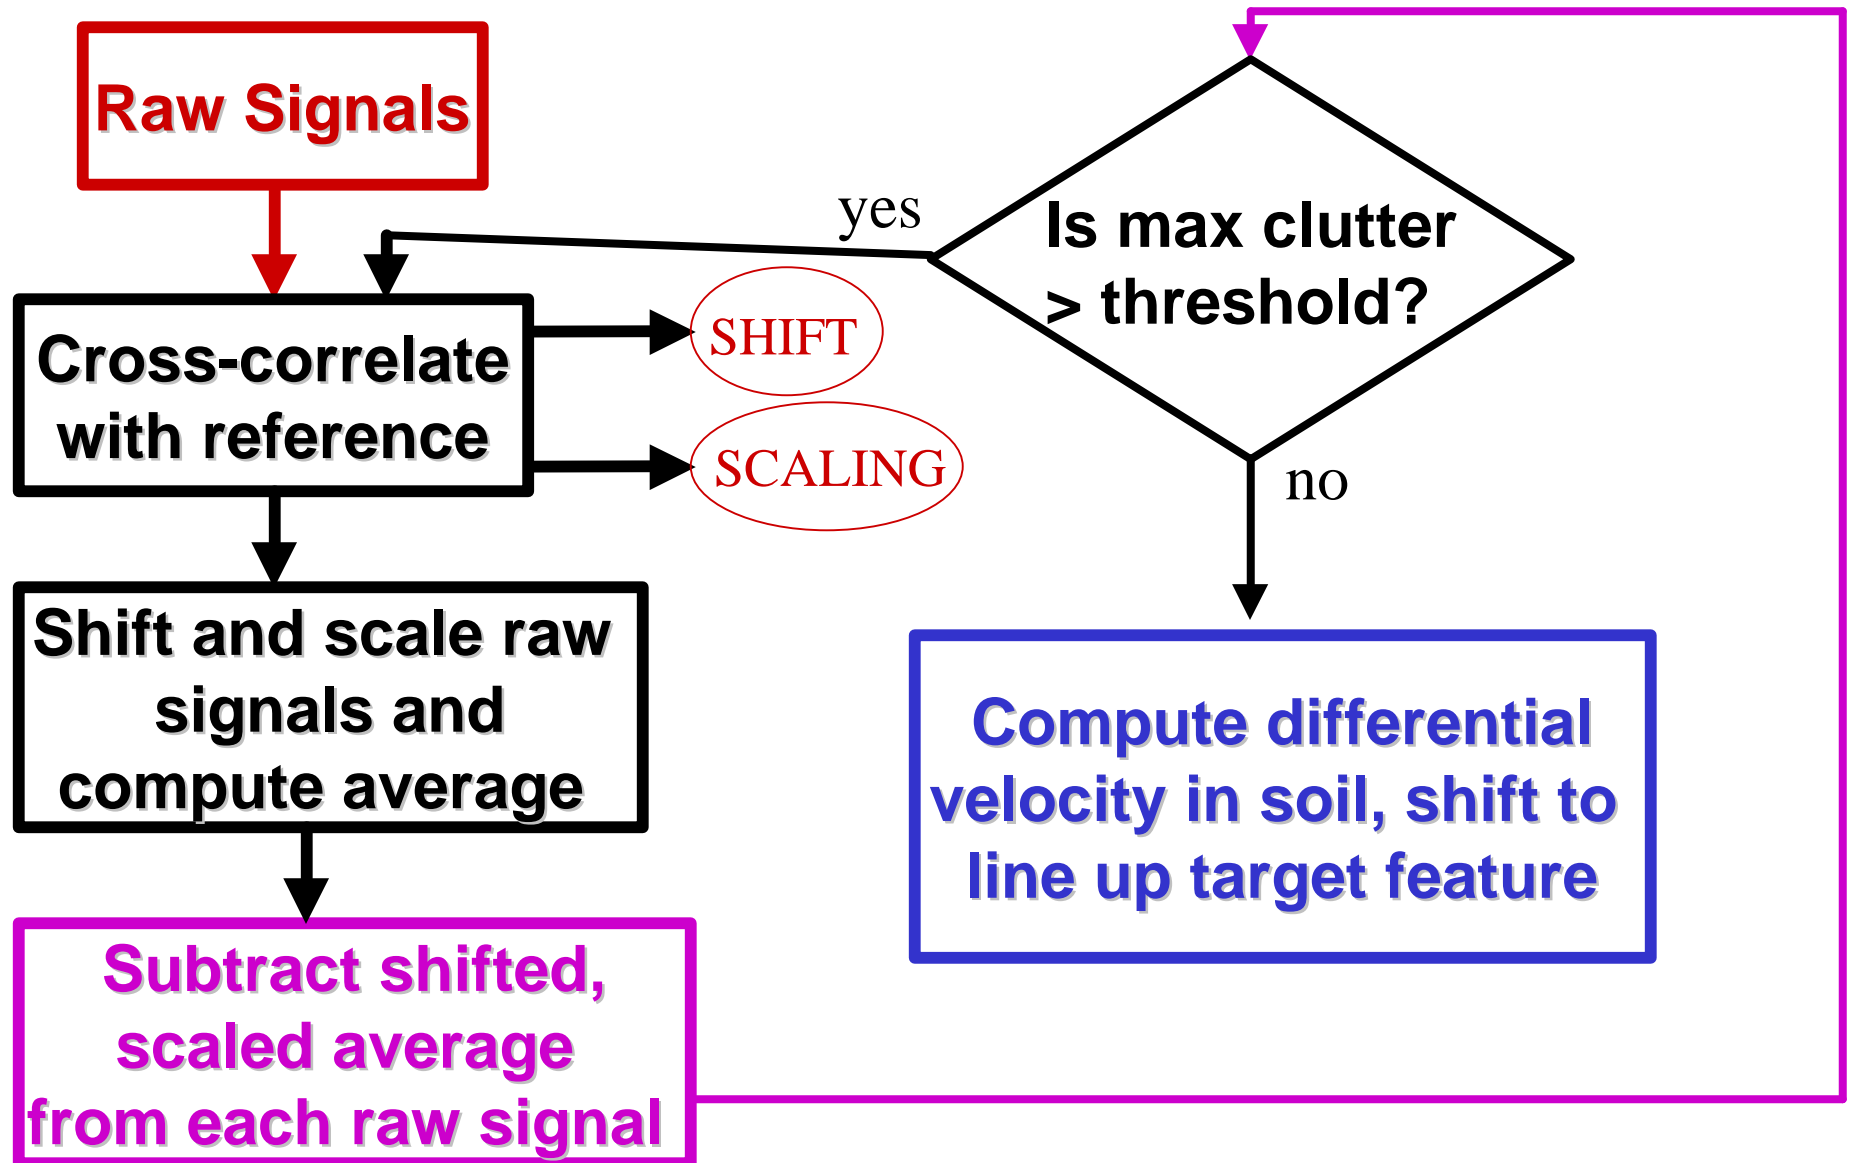

$\sigma_h = 2 \text{ cm}$

$L_c = 10 \text{ cm}$

$L_c = 3 \text{ cm}$

Separating Mine Response from Ground Clutter

Original Signal Averages Obscure Mine Signal

Original Nomine Signals with $\sigma_h = 3\text{cm}$ $l_c = 10\text{cm}$

Original Mine Signals with $\sigma_h = 3\text{cm}$ $l_c = 10\text{cm}$

Single Ground Clutter Signal Removal

Double Ground Clutter Signal Removal

Realigning Signals to Presumed Mine Position

Average Mine Scattered Signals

$\sigma_h = 3$ cm

$\sigma_h = 2$ cm

$L_c = 10$ cm

$L_c = 3$ cm

Conclusions

- Rough ground clutter can be effectively analyzed in terms of:
 - Signal time delay
 - Signal amplitude increase/reduction
 - Pulse distortion
- Signal distortion and time delay depend directly on both surface roughness and roughness scale.
- Target signals are difficult to separate from ground clutter signals because they are small and occur near clutter peaks.
- Identifying and removing the ground signal -- and realigning with the propagation time of a given soil -- enhances the target signal.

Dual Frequency Microwave-Enhanced Infrared Thermography

Abstract

Humanitarian landmine detection and clearance is one of the most challenging, difficult and time-consuming tasks to be completed with existing technologies. Infrared (IR) Imagery images differences in heat transfer on the surface of the soil due to a buried object. Based on sunlight heating, it is only useful at certain times. Microwave heating has been proposed to enhance the thermal signature, but it is limited by surface roughness.

We have proposed a method called *Dual Frequency Microwave Enhanced Infrared Thermography*. Heating with microwaves instead of natural sunlight leads to a number of advantages, such as more efficient heating, more feature parameters like frequency, modulation and incident angle. Moreover, two different frequencies are used consecutively, and the heating image subtracted to minimize background noise introduced by the rough, irregular surface of the ground itself, and vegetation covering the ground. The dependence of scattered fields on frequency makes this possible.

A 2-D computational model of this method has been developed to simulate real-world landmine detection. The model includes two main parts: a microwave model to get an image of absorbed power density and a 2-D thermal diffusion model to get temperature distribution on the surface of the ground. Finally, to evaluate the performance of a system using this method, ROC (Receiver Operational Characteristic) curves are used.

Microwave-Enhanced Infrared Thermography

ABSTRACT

Microwave heating of the ground can enhance infrared signatures of buried objects. The extent of the enhancement depends upon many parameters including wavelength, polarization, angle of incidence, and properties of the soil and the object. We show that angle of incidence and dielectric properties of the object are important, with some analytical and experimental results.

Key Words: Microwave heating, infrared imaging, landmine detection.

1. INTRODUCTION

We have previously reported analytical and experimental results showing that microwave heating of the ground can produce enhancements of the infrared signature of buried objects [DiMarzio, *et. al.*, Sept. 1998]. While diurnal variations in natural heating provide some useful signatures, the microwave heating offers the opportunity to enhance the signals by heating the soil below the surface and the object itself. Two mechanisms contribute to the unique signatures of buried objects. The first, evident at short times, is a modification of the electromagnetic field of the microwave source by the presence of an object with dielectric properties which contrast with those of the ground. This results in changes in the heating pattern of the soil including that near the surface, and appears almost immediately. At later times, an image appears which is quite useful for identifying

the shape of the buried object. This signature depends on the difference in absorption of microwaves between the object and the background, and on the contrasting thermal properties. This signature remains for many minutes after heating is ceased. The combination of these two signatures offers a powerful new tool for the detection and characterization of buried mines and mine-like objects.

2. VARIATION WITH ANGLE AND POLARIZATION

One of the most obvious discriminants is the combination of angle of incidence and polarization. The two-dimensional model was run with a dielectric mine and different angles of incidence for TE and TM polarizations, all at 2.54 GHz. Figure 1 shows some of the results for different angles with TM polarization. The color scale shows the amount of absorbed power. The axes in each plot are spatial, with the vertical representing depth and the horizontal representing transverse position. The microwave energy is incident as a plane wave from the top left at the indicated angle with respect to the vertical. The major result is that the absorbed power decreases with increasing angle as a result of the changing Fresnel reflection at the surface. However, a smaller effect is also noted, in that the region of maximal absorption moves away from the beam with increasing angle. The absorption is almost entirely in the soil rather than in the mine, which has a lower absorption coefficient. The soil heating pattern at the surface is rather complex, resulting from an interference pattern between the incident beam and the scattered one. In a cluttered environment, this heating pattern may make it difficult to detect buried objects directly using the microwave-enhanced infrared signatures. On the other hand, the pattern provides information about the field distribution, which may prove useful in conjunction with imaging using ground-penetrating radar.

A similar result was obtained with the model using TE polarization. Differences do exist between the two, but they are in all cases less than 10 percent of the total, and are much less than that at the surface. Thus these differences would make unreliable indicators of buried objects. A slight advantage exists for TM polarization as a result of the decreased Fresnel reflection at the surface at angles near the pseudo-Brewster angle. However, this effect is not very strong in materials such as soil with high absorption. While the reflectivity for TM polarization does reach a minimum at the pseudo-Brewster angle, the minimum is not very deep, and the ratio of Fresnel reflection between TM and TE polarization is not far from unity. Because the dielectric constant is high, the wave bends strongly toward the normal, and the interaction of the wave with the target is similar for the two polarizations. This result would change for targets without circular symmetry in a three-dimensional model, but it is unlikely that the difference could be exploited effectively to distinguish between mines and other objects under the surface.

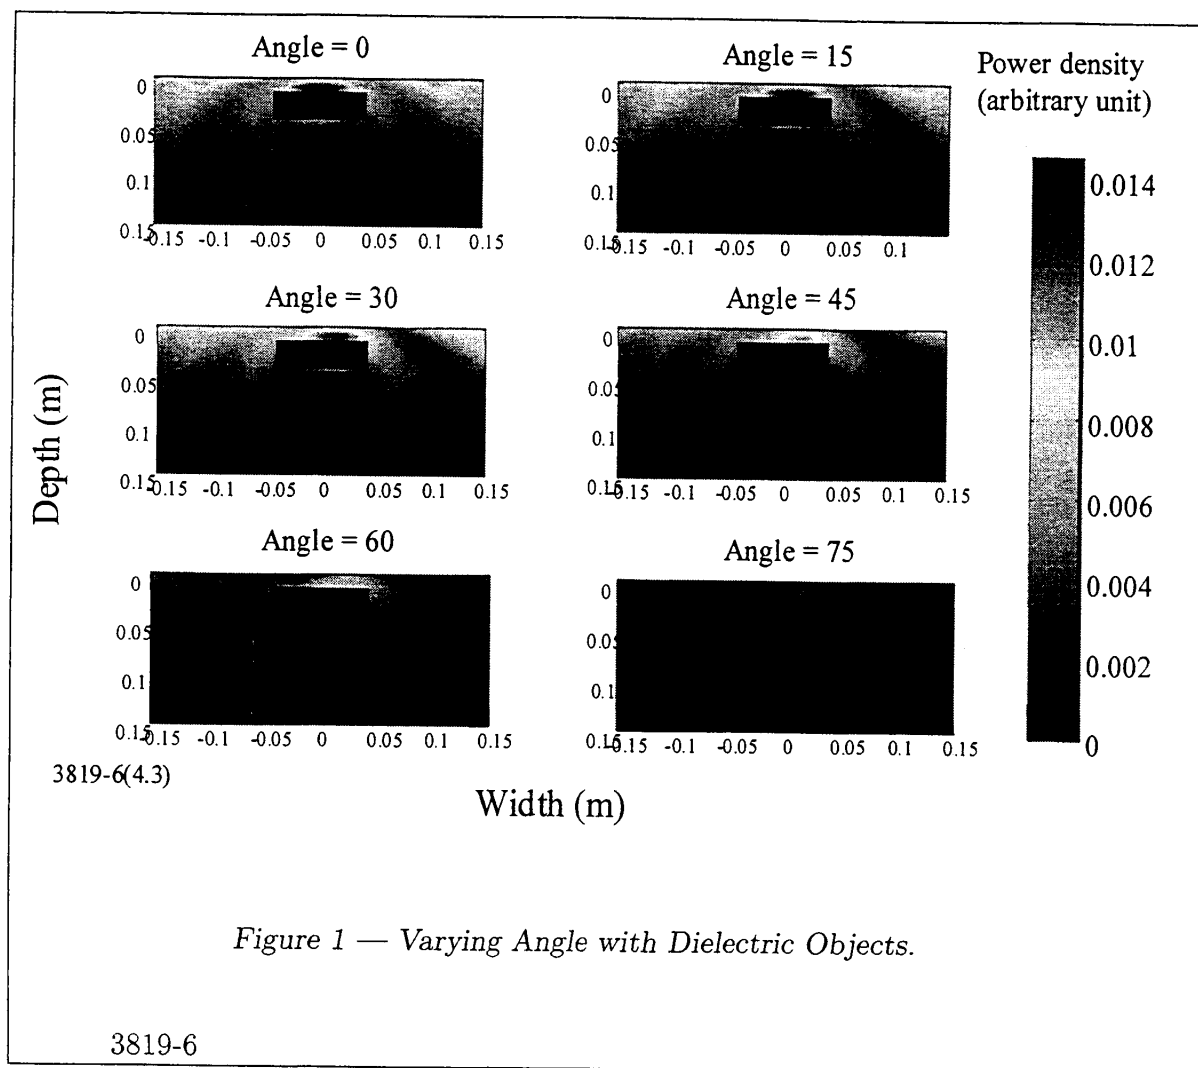

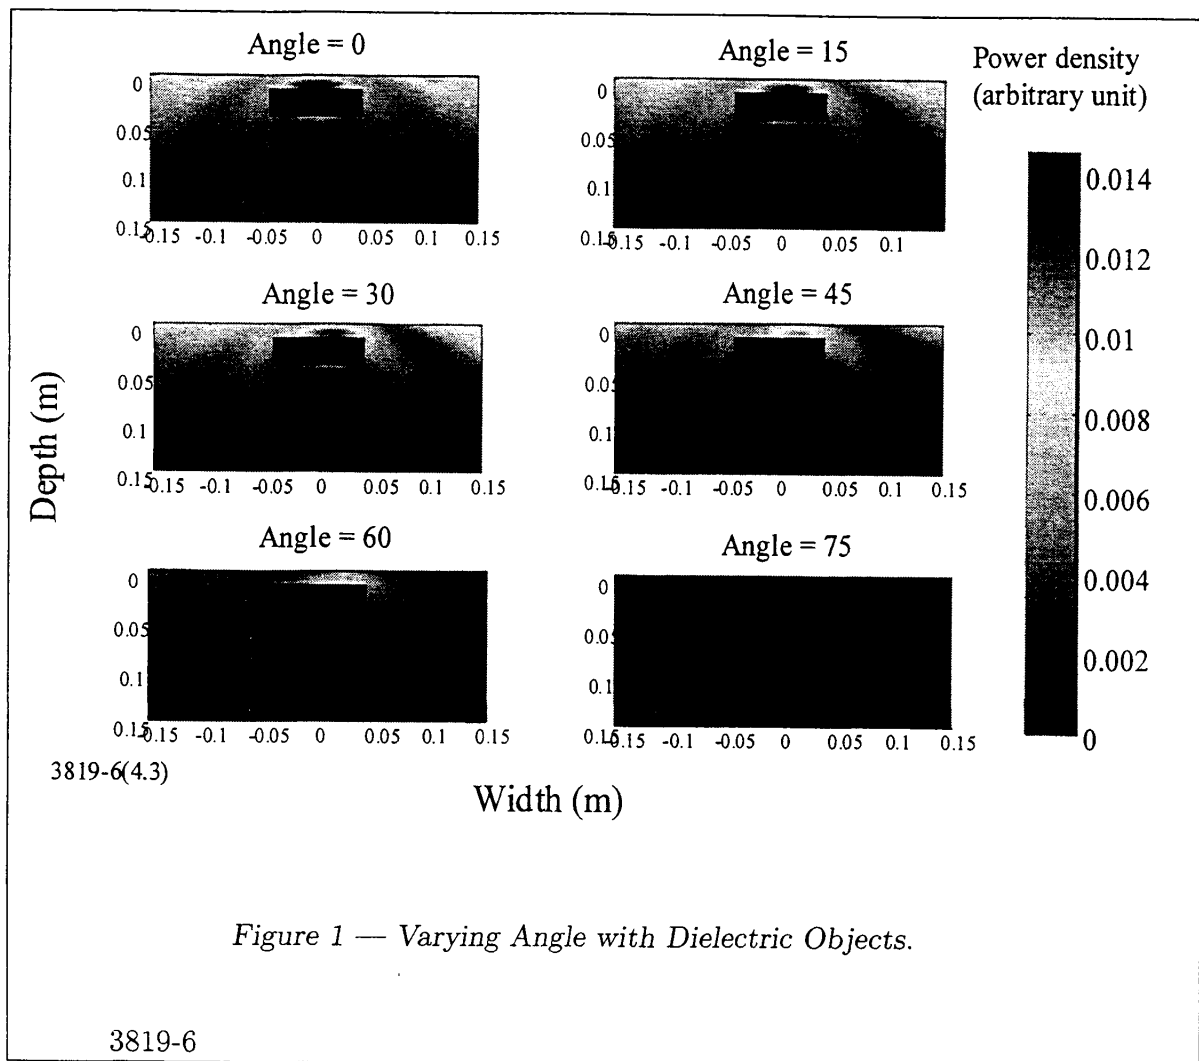

Figure 1 — Varying Angle with Dielectric Objects.

3. VARIATION WITH MICROWAVE ABSORPTION

Results similar to those of Figure 1 were obtained with absorbing targets, but the energy was absorbed primarily in the target rather than the background. This results in a considerably different time history than is observed for the dielectric mines. Figure 2 shows three different objects, having low, medium, and high absorption. The top images are in the same configuration as those in Figure 1, and show the distribution of absorbed power. The bottom images show how surface temperature varies with time. The horizontal axis is the same as in the top figures, and the vertical axis represents time. The color shows the temperature at the surface.

For all objects, heating begins immediately with the application of power at the top of the time axis, and the interference pattern is readily evident. In a three-dimensional

3. VARIATION WITH MICROWAVE ABSORPTION

Results similar to those of Figure 1 were obtained with absorbing targets, but the energy was absorbed primarily in the target rather than the background. This results in a considerably different time history than is observed for the dielectric mines. Figure 2 shows three different objects, having low, medium, and high absorption. The top images are in the same configuration as those in Figure 1, and show the distribution of absorbed power. The bottom images show how surface temperature varies with time. The horizontal axis is the same as in the top figures, and the vertical axis represents time. The color shows the temperature at the surface.

For all objects, heating begins immediately with the application of power at the top of the time axis, and the interference pattern is readily evident. In a three-dimensional

example, this pattern would result in rings around the object. When the power is turned off at time zero, the ground containing the low-absorption object begins to cool almost immediately.

For the more absorbing objects, the surface temperature continues to rise after the power is turned off, as heat from the object is conducted toward the surface. Figure 3 shows a typical temperature time history from the model for the most absorbing object shown in Figure 1, and below that, experimental results for a hockey puck, 76 mm in diameter and 25 mm thick buried in dry sand. The temperature of the surface continues to rise for 10 minutes after the power is turned off. Each graph on the right shows the temperature as a function of time for a column near the center of the corresponding color plot.

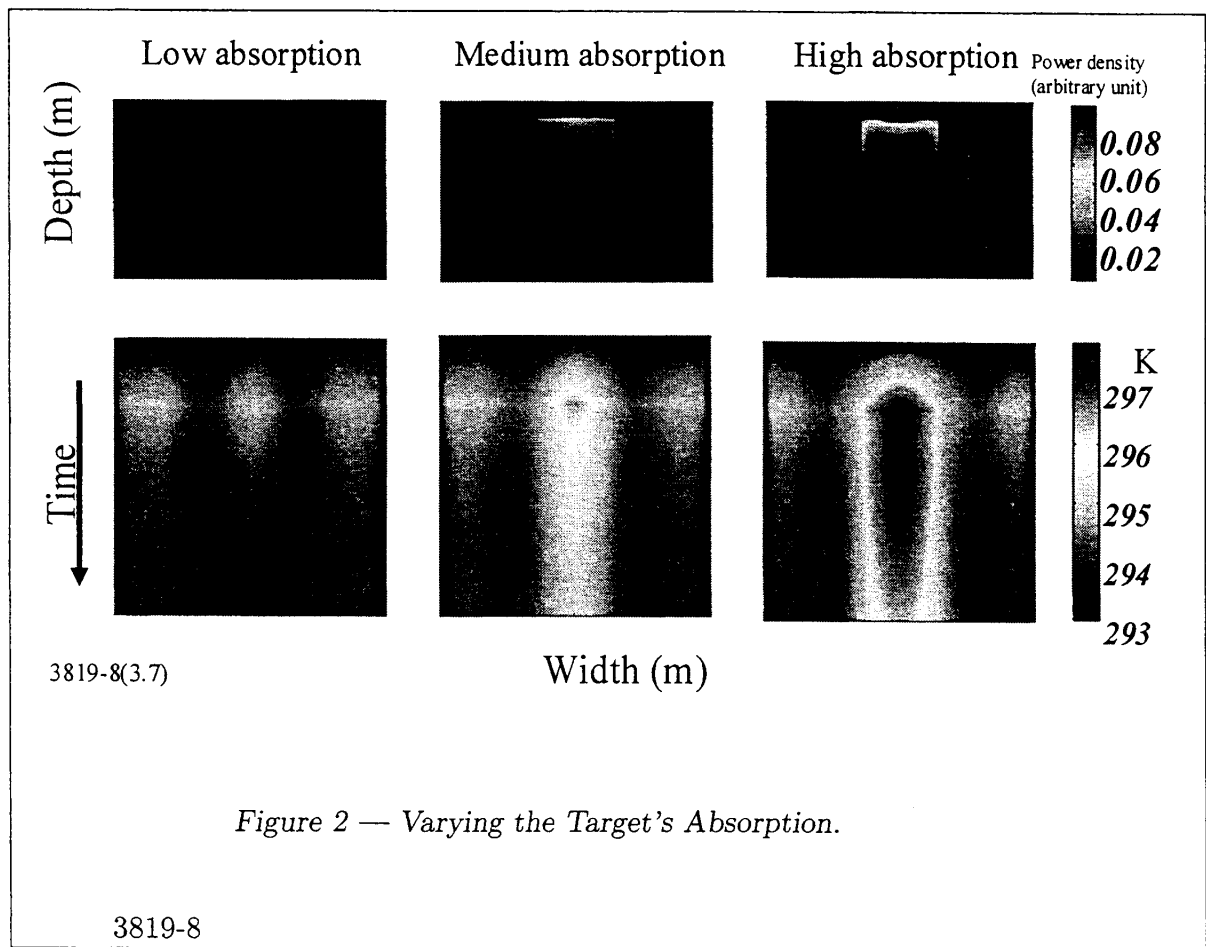

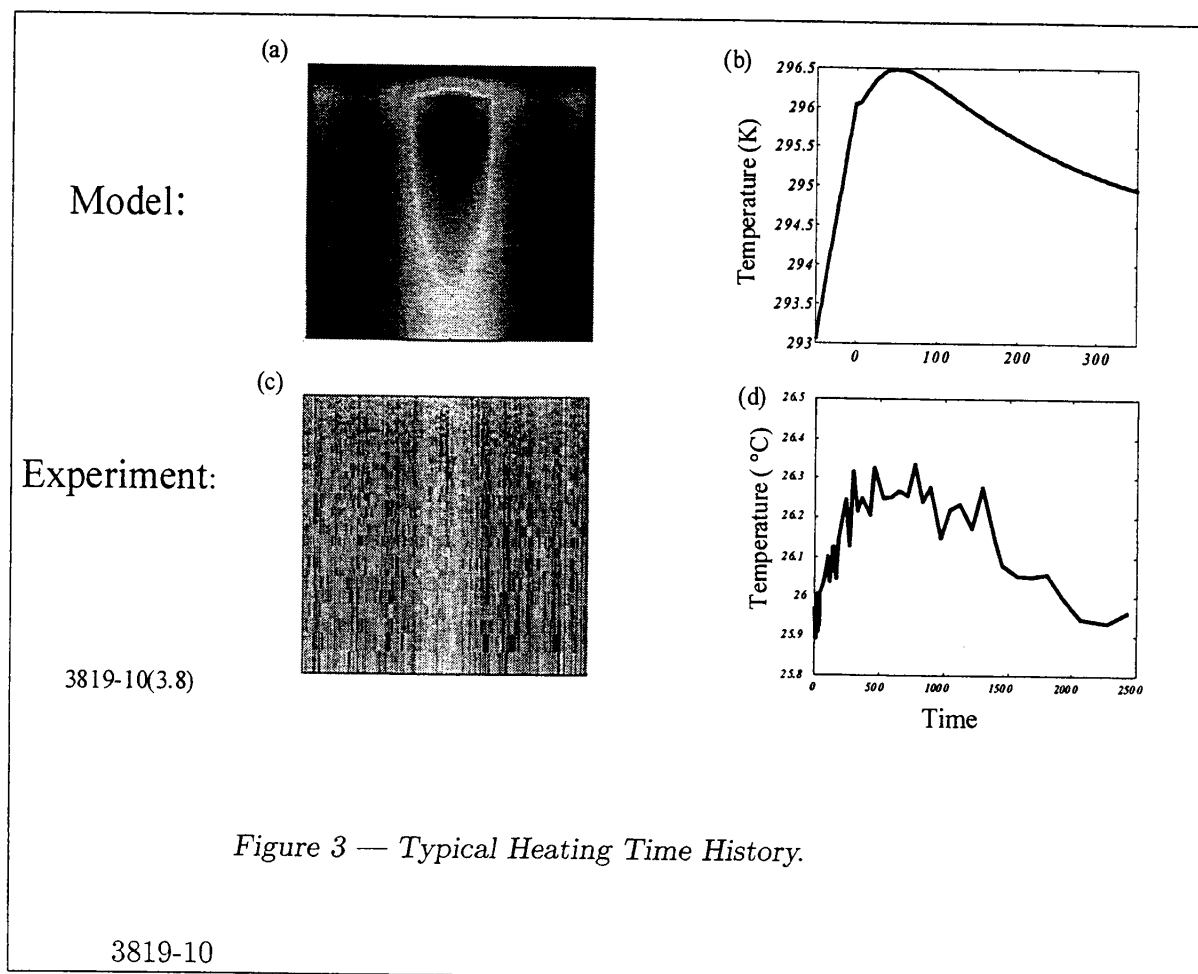

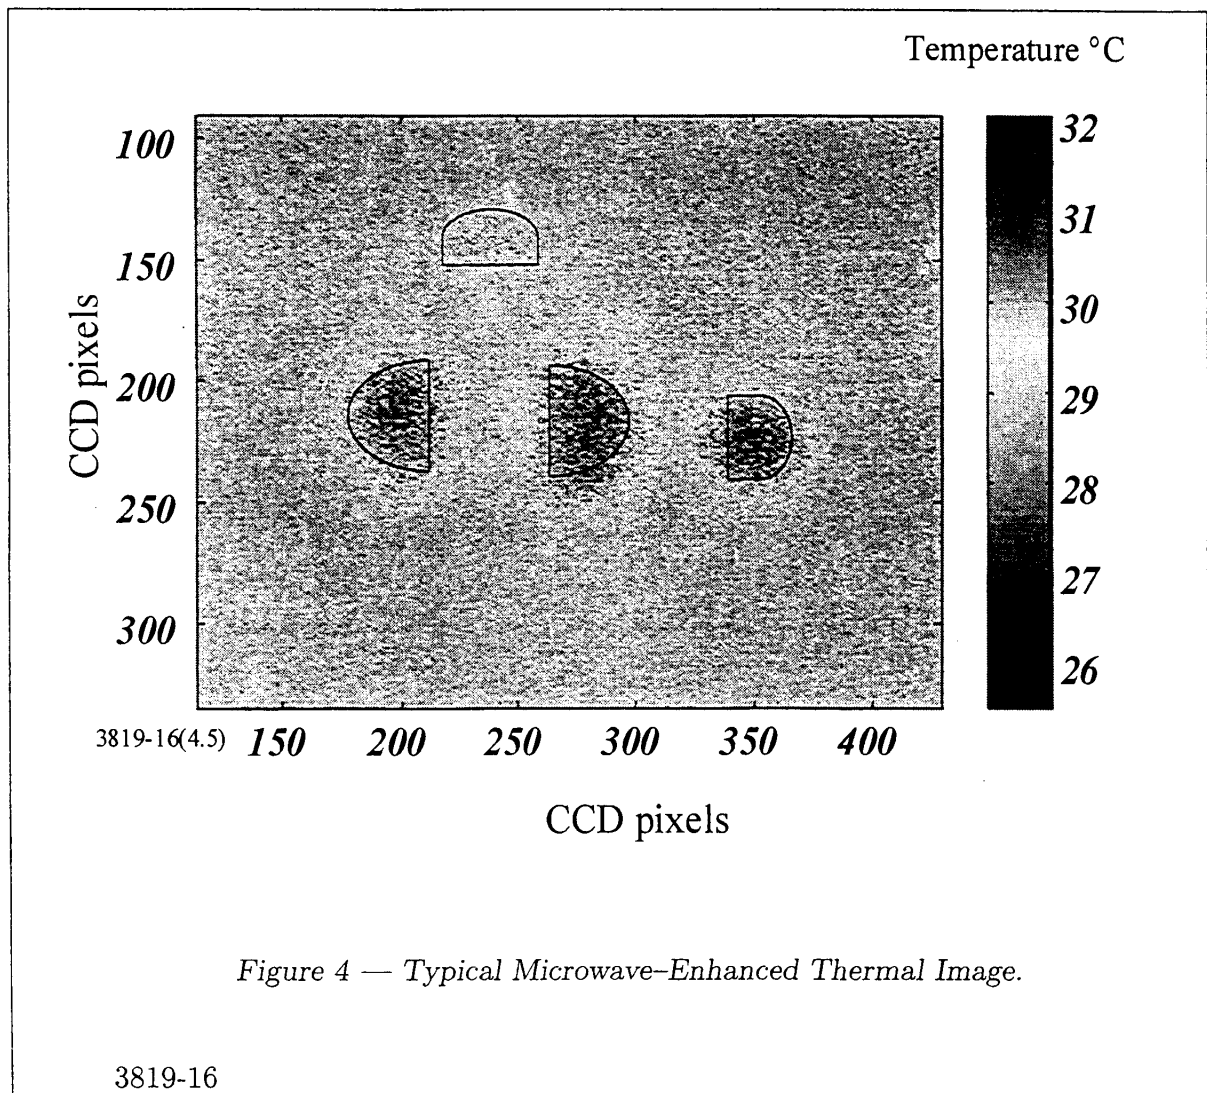

Figure 2 — Varying the Target's Absorption.

4. IMAGING THE TARGET SHAPE

Finally, we examine our ability to recognize the shape of buried objects. For this purpose, we cut hockey pucks into distinguishable shapes and buried them at a depth of about 1 centimeter in dry sand. Figure 4 shows a sample infrared image, overlaid with a line drawing of the objects. We note that the semi-circular shape of the half pucks is evident. One of the small segments shows a rather weak signature, and the other shows a stronger one. Location and aspect ratio are easily determined, although the subtle changes in shape are not readily distinguishable in this picture. We conclude that shape information can be obtained on objects with dimensions of a few centimeters. We anticipate that this information could help eliminate false alarms caused by rocks, roots and other natural buried objects.

5. SUMMARY

We conclude that microwave-enhanced infrared thermography produces useful signatures for the detection of buried mines and minelike objects. Signatures exist and change over a period of minutes after microwave illumination. Initial signatures show information about electromagnetic wave propagation in the vicinity of the object while later ones reveal more about its thermal properties. These images, particularly at the later times, provide useful shape information about objects which are more than a few centimeters in size.

Laser Induced Acoustic Imaging of Underground Objects

Wen Li, C. A. DiMarzio, S. W. McKnight, G. O. Sauermann, E. L. Miller
Center for Electromagnetics Research, Northeastern University, Boston, MA 02115

ABSTRACT

This paper introduces a new demining technique based on the photo-acoustic interaction, together with results from photo-acoustic experiments. We have buried different types of targets (metal, rubber and plastic) in different media (sand, soil and water) and imaged them by measuring reflection of acoustic waves generated by irradiation with a CO₂ laser. Research has been focused on the signal acquisition and signal processing. A deconvolution method using Wiener filters is utilized in data processing. Using a uniform spatial distribution of laser pulses at the ground's surface, we obtained 3D images of buried objects. The images give us a clear representation of the shapes of the underground objects. The quality of the images depends on the mismatch of acoustic impedance of the buried objects, the bandwidth and center frequency of the acoustic sensors and the selection of filter functions.

Keywords: Photo-acoustic, Laser-induced, Acoustics, Buried object detection, landmine detection, pavement quality.

I. INTRODUCTION

This paper investigates the photo-acoustic process, in which the optical energy is converted into acoustic energy. This phenomenon has been observed as early as the 1960's when sound pulses were produced on absorption of pulsed ruby-laser radiation^[1].

When a laser pulse hits the surface of a medium (solid or liquid), several processes occur in a short time, including reflection, absorption (with side-effects such as optical to thermal energy conversion), heat conduction, medium expansion and contraction. Although we have not constructed an exact mathematical model for the photo-acoustic process, we can qualitatively understand the mechanisms: (1) Thermal coupling based on the absorption of laser radiation, (2) heating and expansion occurring in the medium. (3) excitation of sound caused by sudden changes in medium volume.

Hidden objects can be located by echo location. This is a well-known idea in everyday life, as in the example of tapping a wall or floor to find studs or holes. This idea could also be applied to the process of evaluation of pavement quality, and buried mine location.

Traditionally, acoustic waves can be generated by direct physical stimulation, for example using an acoustic transducer. Laser-induced acoustic waves have more advantages in detecting objects:

- (1) This is a non-contact method of sound generation. This is the most important advantages for detection of dangerous object like landmines.
- (2) Coupling is easy and efficient because over 90% of optical radiation at 10.6um is absorbed in soil. Thus, the sound wave is generated directly in the ground.
- (3) The process is flexible. The width and power of the laser pulses can be controlled, the size of the laser spot can be focused and the scanning of laser shots can be easily implemented and changed by an optical scanner.

II. ACOUSTIC ECHO AND SIGNAL PROCESSING

The solution of acoustic wave transport in a medium can be described by applying elastic wave theory. In the most simple case, we consider the monochromatic plane wave in a liquid or in an isotropic elastic solid. Combining the acoustic wave equations and appropriate boundary conditions, we obtain the reflection coefficient,

$$R = \frac{Z_{II} - Z_I}{Z_{II} + Z_I}$$

where $Z_I = \rho_1 c_1 / \cos \theta_I$ and $Z_{II} = \rho_2 c_2 / \cos \theta_{II}$ are the acoustic impedances in two different media. ρ , c and θ are the density of the medium, velocity of the acoustic wave and propagation angle, respectively.

Table 1: Density and Velocity of sound in various media^[2].

Substances	Density g/cm ³	V _l m/s	V _s m/s
Aluminum, rolled	2.7	6420	3040
Copper, annealed	8.93	4760	2325
Glass, pyrex	2.32	5640	3280
Lucite	1.18	2680	1100
Polyethylene	0.90	1950	540
Polystyrene	1.06	2350	1120
Rubber, butyl	1.07	1830	
Rubber, gum	0.95	1550	

V_l: Velocity of plane longitudinal wave in bulk material

V_s: Velocity of plane transverse (shear) wave

The large acoustic impedance mismatch between soil/sand and land mine is the prerequisite condition of using acoustic echo detection. Table 1 shows the densities and velocities of sound in different media. In our experiment, we use dry sand as an acoustic medium, with the density of sand being about 2.6g/cm³. The velocity of sand varies according to the density and moisture content of the sand. In our samples, we measured the speed of sound in dry sand as about 280m/s, 20% less than the speed of sound in air. Compared with the speed of sound in metal, plastic or rubber, the mismatch of acoustic impedance is large enough for echo detection. Another important point is that the paths of reflection and refraction obey Snell' law:

$$\frac{\sin \theta_I}{c_1} = \frac{\sin \theta_{II}}{c_2}$$

Thus, we can calculate the relations between the position of the mine and the signal track of the mine. Figure 1 illustrates this concept. As we move the laser spot toward a target (a piece of aluminum), the arrival time of the reflected signal should follow a straight line with a shape given by the speed of sound in the medium.

Water is a very good medium for acoustic waves. The soil or sand in which a mine is usually buried dampens sound waves, therefore, the echo from the target is usually very weak in soil/sand. It is hard to find the target directly in this case. Also, from the signal processing point of view, the data acquisition method by scanning a laser spot and burying a detector in the soil makes interpretation difficult. The small signal from a buried target is often lost in changes of the larger direct signal which results from varying distance from source to detector.

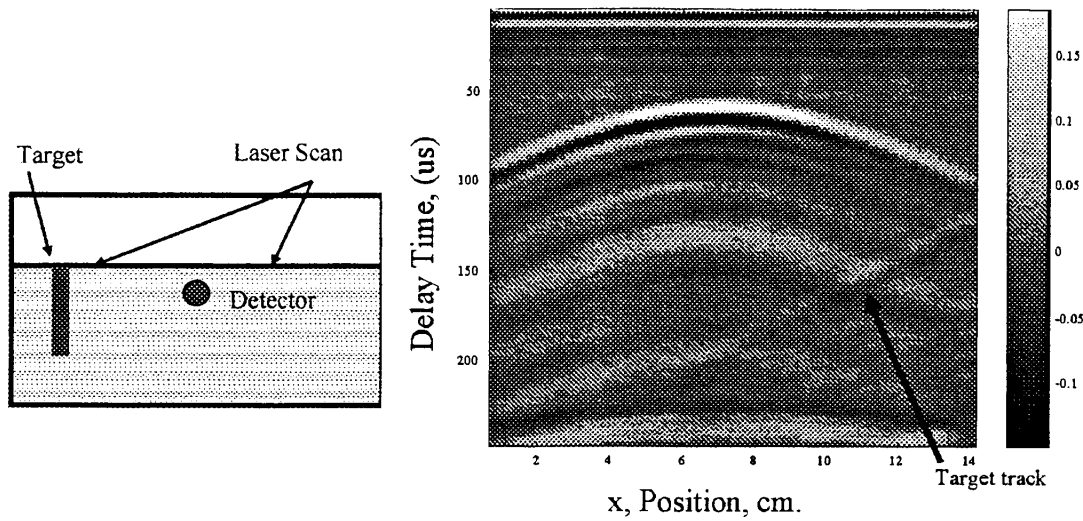

Figure 1. Acoustic echo in water

We considered another method for data acquisition that involves placing the detector over the surface of ground and making it relatively fixed respect to the laser spot, instead of burying the detector into the soil. This method lets us obtain a constant delay time, unless the surface is not perfectly flat.

Figure 3 shows some results acquired by using this method. In the cases where the mine is exposed to the surface of the ground, the laser pulse hits the surface of the mine directly, and the difference of acoustic excitation between the mine and the sand is easily detected. However, in the case of a buried mine, because of strong reflections at the boundary between sand and air, the sound echo from the buried mine is so weak that we can not find information about buried objects from the raw data directly. Thus, an appropriate method of digital signal processing is necessary.

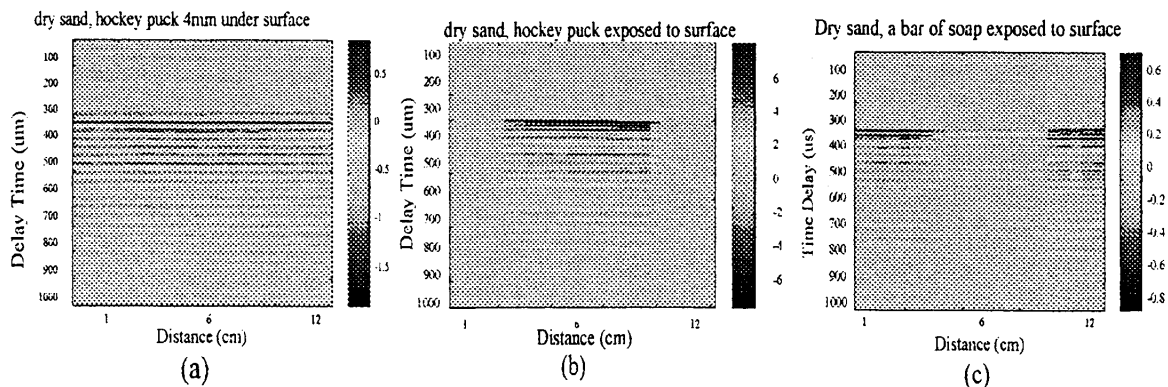

Figure 3. The sound echo. (a) Buried hockey puck 4mm under surface of sand. (b) A hockey puck exposed to the surface of sand. (c) A bar of soap exposed to the surface of sand.

Let us consider the procedure of acoustic echo detection again. After absorption and expansion, the spot of the laser pulse becomes a source of a pulsed sound wave. Echoes of the sound pulse arrive at the detector at different times after following different paths, as shown in Figure 4.

Figure 4. The signal analysis of reflection. S: The sound pulses from surface of ground, top surface of mine and bottom surface of mine. H: The impulse response of the detector. D: The resulting signal from detector.

The delay time contains information about the position of the ground surface and depth of the mine. The acoustic signal received by the detector is the convolution of the sound pulse and the impulse response of the acoustic detector. Because of the limited bandwidth of the detector and the attenuation of the echo signal, the reflection from the underground target is occluded by the strong signal from the surface of the ground. In order to pick up the sound echo from the buried mine, we can use an inverse processing technique in the frequency domain,

$$S = D / H$$

where D is the signal we got from the detector, H is the impulse response of the acoustic detector. Thus, $1/H$ is used as a filter function multiplied the received signal to obtain the original reflection distribution. At the points where the magnitude of H is near zero, the inverse process will produce a large amplification of noise. Thus, we use a slightly more complicated inverse method to limit the effects of noise:

$$Filter = \frac{H^*}{H \cdot H^* + \epsilon}$$

The new filter function avoids the problem of large amplification at small magnitude of H . The value of ε gives a general idea of the noise margin. The impulse response of the detector is usually a complex number in the frequency domain. We can use the real number $H \cdot H^*$, which is the intensity of the impulse response, and add it to ε . When the intensity of the impulse response is very large compared to ε , the filter function is nearly $1/H$, which is an inverse filter; when the intensity is small, the filter function is H^*/ε which represents a matched filter in the frequency domain.

From Figure 4 we can see that the filtering process is actually the inverse process from D (the detector signal) via H (impulse response of detector) to S (the sound echo) in the frequency domain. We call this inverse process deconvolution filtering.

III. EXPERIMENTAL RESULTS

A Laser Science LS150 pulsed CO_2 laser was used in our experiment to generate an acoustic pulse. The wavelength of the laser is 10.6 μm and the pulse width is about 100ns, with the energy per pulse being 150mJ. We buried a mine into a 30cm by 60cm sand box, with the depth of the sand about 10cm. We believe that the acoustic pulse should be very narrow, meaning it has wide bandwidth in frequency domain. Unfortunately, wide-band audio frequency transducer are not readily available to collect all of the information contained in the sound pulses. We have tried several detectors in our experiment, include two identical seismic transducers and two audio microphones with different frequency response. We used an HP-54615b Oscilloscope for data acquisition, and a DAQ multifunctional I/O board for system controlling (control of optical scanner, laser triggering and synchronization). All of the signal processing work has been done on a computer running Matlab.

We concentrated our research on non-metallic mines. We used some simulants that compare favorably to the constituents of a non-metallic land mine, include plastic box, racquet ball, soap and hockey puck. Figure 5 shows the pictures of the experimental setup and the simulants of mine.

(a)

(b)

Figure 5. (a) The experiment setup. (b) Simulants of mine

Figure 6 shows some results after the deconvolution filtering we discussed before. We used a seismic transducer as the acoustic detector which has 29kHz resonance frequency with narrow bandwidth of about 5kHz. We made a scan on the surface of sand with 25 pulses and a track of 12.5cm long, which crosses the buried mine. When the hockey puck was buried vertically in the sand box, after filtering, we obtained the image shown in panel (a) of Figure 6, which shows the circular shape of the puck. We also buried a hockey puck horizontally with the surface parallel to the surface of sand, then we obtained the result in panel (b) which shows the surface of the puck. If the puck is tilted to the surface, the reflection track is also tilted (panel c). The other picture is a bar of soap buried in sand box.

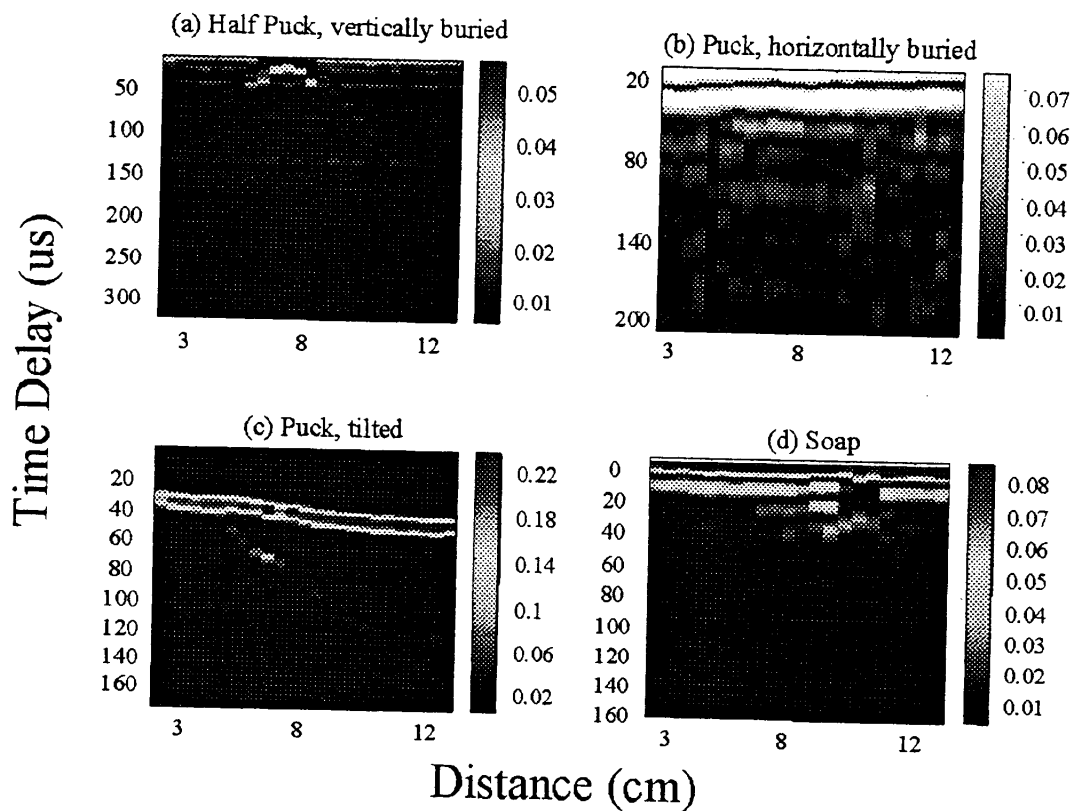

Figure 6. (a) Half hockey puck vertically buried in dry sand. (b) Hockey puck horizontally buried in sand with surface parallel to the surface of sand. (c) Hockey puck buried in sand with surface tilted compared with the surface of sand. (d) A bar of soap buried in sand.

Clearly, the results in Figure 6 provide the depth and shape information of underground objects. Furthermore, because the time delay of the sound echo is proportional to the depth, a surface scan of laser shots in 2 dimension, combined with the depth information, provides a 3-D picture of underground objects. Figure 7 shows the result of a surface scan for a half hockey puck. The detector is still the seismic transducer. We make slices, each with a different time delay, to show the strength of the reflection at that depth. We then combine these slices to produce a 2-D map as would be seen from above. Figure 7 shows several of these slices and the combined image.

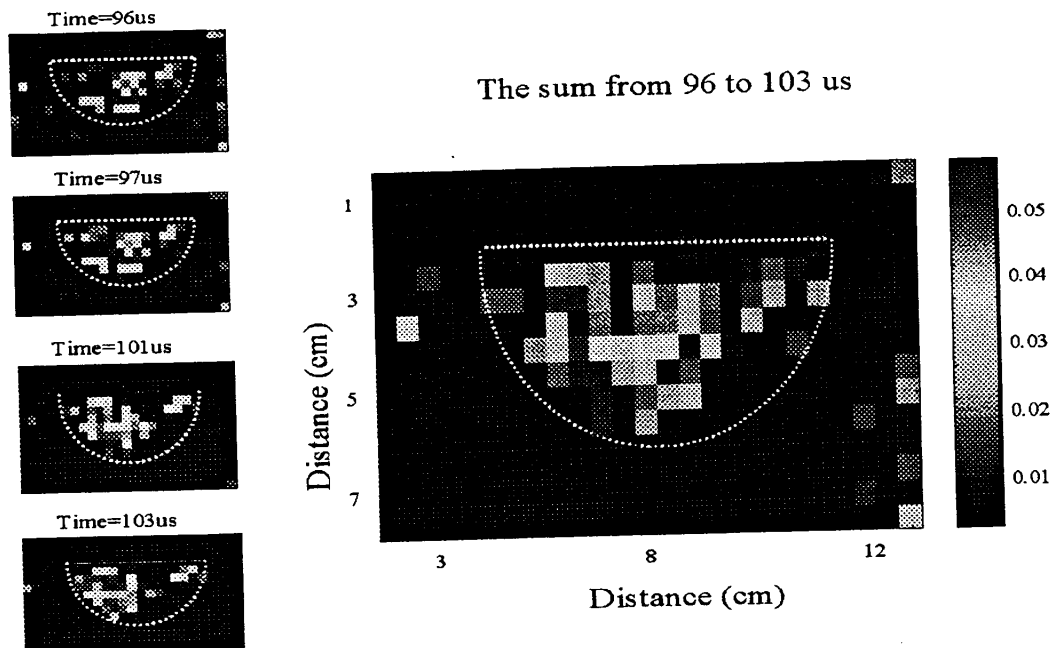

Figure 7. The 2-D scans for a buried half hockey puck: At different times, we can image different depth slices for underground imaging.

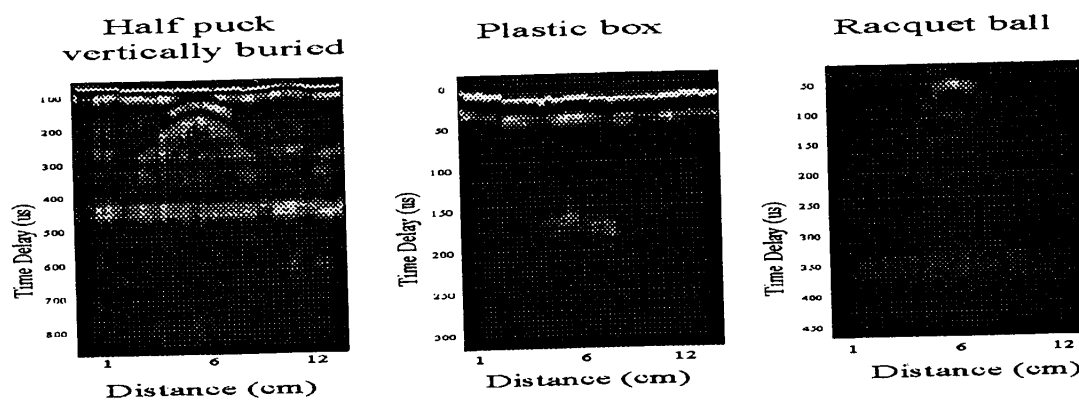

Figure 8. The experiment using an audio microphone. The simulants of mine are a vertically buried half hockey puck, an empty plastic box and a racquet ball respectively.

In the frequency domain, the acoustic detector only samples a part of the information contained in the sound pulse. Tests using different detectors are shown in Figure 8. We used an audio microphone which has wider bandwidth and lower cutoff frequency as acoustic detector. Different mine simulants including the half hockey puck, plastic box and racquet ball have been used in the experiment. The signal seems stronger than before because of the wider bandwidth. We also did a 2-d scan at the surface for a buried half hockey puck shown as Figure 9, and the result shows that the shape resolution is dimmer than it was with transducer. Thus we conclude that the resolution is degraded because the higher frequencies of sound (shorter wavelength) are not used.

Figure 9. The 2-D scans for a buried half hockey puck using the microphone as an acoustic detector: At different times, we can image different depth slices for the underground imaging.

IV. CONCLUSION

The experiments shown in this paper demonstrate that laser induced acoustic imaging is feasible for mine detection. As one of the prospective demining techniques, laser induced acoustic wave has many advantages, such as non-contact, easy control and detection of non-metallic mines.

The selection of data acquisition and signal processing method is also very important. We found that fixed detector over the surface of ground with constant relative position to the laser spot is a good acquisition method, and the deconvolution filter works well for picking up the information of underground objects.

The echo of the sound pulse has a very wide bandwidth in the frequency domain, but we only obtained a small part of the whole information because of the limitation of our acoustic detector. As shown in the experiment, the higher the center frequency, the better the shape resolution; the wider the bandwidth, the stronger the echo signal. Therefore, the ideal detector should have white frequency response.

The large acoustic mismatch between soil and buried mine promises success of acoustic imaging. By detecting the reflected sound pulse from the surface of mine, we can get clear shape information of underground objects, and thereby reduce false alarm rates which are typical of all mine detection techniques.

A mathematical model of the laser acoustic interaction should be a high priorities in the future work. We need to know more about the energy distribution of the acoustic wave. In order to collect more information from the sound echo, a better detector should be used in future experiment. We think that a laser Doppler vibrometer is a good choice, because it is also a non-contact detector with very high sensitivity and almost white frequency response. Also, it can image multiple locations and be scanned with the pulse laser. An operational system of acoustic imaging might be laser induced and laser detected. In addition, different types of soil should be taken into account. We will continue to try more media and do some experiments outdoor in the real ground as well.

Effects of Surface Roughness on Microwave Heating of Soil for Detection of Buried Landmines

Taner R. Oktar, Carey M. Rappaport, and Charles A. Dimarzio

Center for Electromagnetic Research
Northeastern University, Boston MA, 02115

ABSTRACT

Two common techniques proposed for detection of landmines are ground-penetrating radar (GPR) and infrared imagery. Because of the wide diversity of mines, the clutter which is encountered in minefields, and variation caused by the ground surface, the task of interpreting GPR signals is daunting. Likewise, variations in thermal properties of soil, solar heating, clutter, and surface irregularities lead to limited performance for IR imaging systems.

Throughout the past two years, our research has emphasized using the microwave energy to heat the ground with the goal of enhancing the infrared signatures. Wavelength, polarization, angle of incidence, properties of soil, chemical and physical structures of buried objects, and amount of roughness are the parameters affecting the extent of enhancement. We have previously shown a two-dimensional model for flat surfaces. In the present work we included a rough surface, to see the effects of the amount of roughness on both temperature distributions in the soil and temporal and spatial variations of surface temperature. We present results which show that the quality of the infrared surface images is dependent upon surface roughness.

Keywords: Landmines, microwave heating, infrared imaging.

1. INTRODUCTION

Detection of landmines has been a challenging research topic through decades for both military and humanitarian reasons. One of the techniques in solving the landmine detection problem is thermal infrared image processing, which was widely used for the detection of defects in materials, the detection of thermal leaks of power plants, and environmental remote sensing as well [Li, *et. al.*]. This thermal infrared imaging technique has also been investigated by DiMarzio *et. al.* [Sept. 1998] with an efficient modification yielding high performance. The suggested modification was to use a microwave power source enhancing the normal diurnal thermal cycle, since the thermal effects of buried objects were too weak due to the dominant absorption of solar irradiance very near the surface.

Microwave heating of soil has many advantages for the detection of landmines or shallow-buried waste [DiMarzio, *et. al.*, April 1998]. First, it contributes an additional discriminant caused by the contrast between the dielectric properties of soil and target along with thermal properties. Second, this kind of enhancement of diurnal solar cycle accelerates the process by reducing the time necessary for observable temperature changes on the surface of the ground under which an object is buried. Finally, controllability of microwave power source allows us to focus on doubtful areas, decreasing the false alarm rates. Furthermore, DiMarzio, *et. al.* [Sept. 1999] have investigated the angle of incidence of microwave source and dielectric properties of the object due to the fact that enhancement is affected by many parameters, such as, wavelength, polarization type of the waves, angle of incidence, properties of the soil, and physical and chemical structure of the buried object.

Those investigations were performed under the assumption of smooth, almost flat, surfaces. As the roughness of the surface to be explored increases, the signal indicating the presence of a buried object weakens and it gets harder to detect that object. In the experiments carried out at the Army's Gold Regions Research and Engineering Laboratory Hanover New Hampshire, the presence of any buried material couldn't be noticed. In figure-1, one can see the surface clutter, and the indistinctness due to the disorderliness. The roughness is the consequence of the disorderliness on the surface caused by the structure of the ground and the clutter such as vegetation. Here, we examine the effect of roughness on surface temperature increase by introducing new 2-dimensional absorption and thermal models.

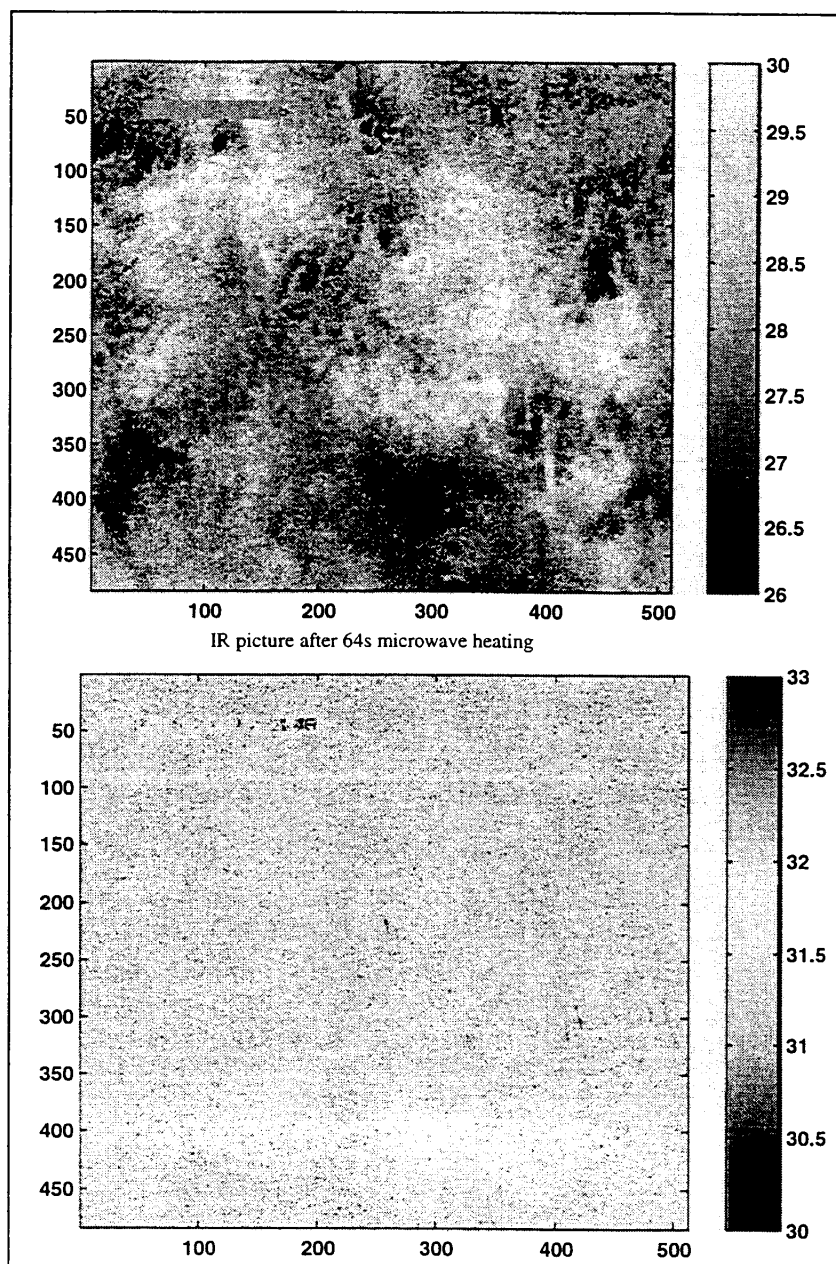

Figure 1. Surface clutter and detection difficulties due to this disorderliness.

2. TWO-DIMENSIONAL MODEL FOR ROUGH SURFACES

The new two-dimensional model for rough surfaces includes two main parts: An absorption model and a thermal model. These two models will be explained in detail in further paragraphs.

2.1. Absorption Model

The absorption model, based on the fundamentals of electromagnetic theory, uses the finite-difference, frequency-domain technique. In order to be able to avoid the reflections due to the computational limits, 8-layer PML boundaries surrounding the two-dimensional computational grid have been implemented into the model. These layers provide the electromagnetic grid to avoid reflections and have it propagate in an unbounded medium. Since roughness is introduced into the absorption model, the two-dimensional computational grid is composed of three different media: Air, soil, and target. A sample grid can be viewed in Figure-2. This model takes as inputs the horizontal and the vertical dimensions of the target to be buried under the soil and its location. Furthermore, the incident angle of excitation wave, the dielectric properties and the conductivity of each medium are described. The model forms the binary images of the rough surface and the target under the soil and calculates the absorbed power pattern in Watts/m³ resulting from both incident and scattered waves according to

$$P = \frac{1}{2} \bar{J} \cdot \bar{E} = \frac{1}{2} \sigma \bar{E} \cdot \bar{E} = \frac{1}{2} \sigma |\bar{E}|^2, \quad (1)$$

formulation. A sample absorbed power pattern has been demonstrated in Figure-3. The specifications of the material examined as target, ground, and air have been mentioned in Table-1.

It may be concluded that the surface just over the target would be cooler than elsewhere since the target heats up less than the ground surrounding it [DiMarzio, *et. al.*, Sept. 1998]. Nevertheless, due to the fact that electromagnetic part of the problem is much more complex, one must think over the other factors, such as the dielectric properties, location of the target, its size, *etc.* Several examples of the absorbed power at the surface for different depth have been examined. It has also been demonstrated that the power absorption pattern does not only depend on the chemical structure of the target, but also its physical characteristics and location [DiMarzio, *et. al.*, Sept. 1998].

Table 1. Specifications of the target, ground, and air.

Distance of target from the right edge of the computational grid.	8.85cm (≈3.48inches)
Depth of the target from the top of the computational grid.	3cm (≈1.18inches)
Size of the target	7.5cm×2.5cm (≈2.95inches×0.98inches)
Relative dielectric constant of the target	2.9
Relative permeability constant of the target	1
Conductivity of the target	1×10 ⁻³ S/m.
Relative dielectric constant of the ground	6.5
Relative permeability constant of the ground	1
Conductivity of the ground	7×10 ⁻² S/m.
Relative dielectric constant of the air	1
Relative permeability constant of the air	1
Conductivity of the air	≈0

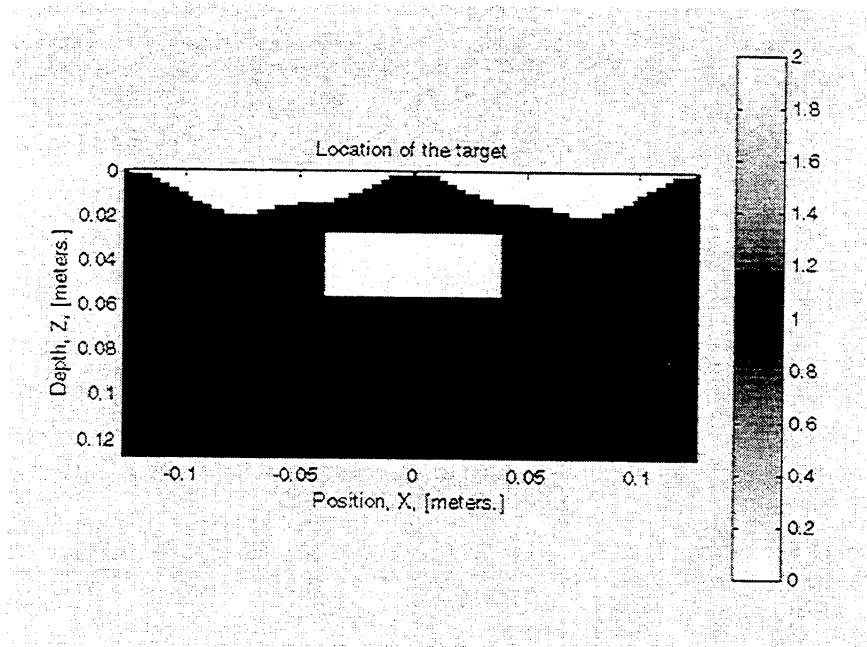

Figure 2. Sample grid for thermal model.

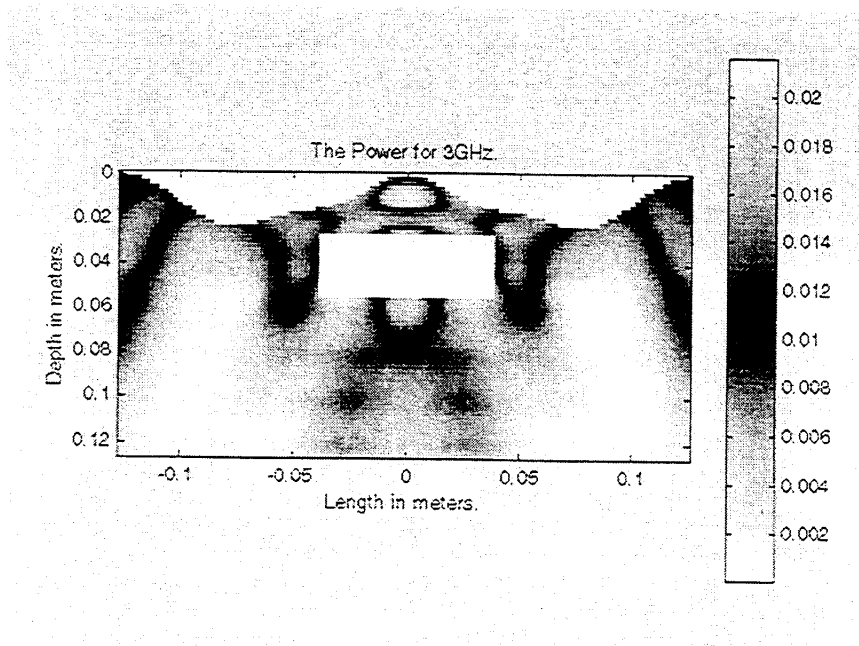

Figure 3. Absorbed power density pattern at 3GHz.

Here, how the shape of the rough surface affects the power absorption pattern has been examined. The surface, which is going to be investigated, could be either a periodic rough surface or a random rough surface. For the time being, periodic rough surfaces having sinusoidal harmonics with different ripple factors have been implemented. The function shaping the surface is given below:

$$f(x) = D - \delta \sin\left(\frac{\pi}{W}x\right) - \delta \sin^2\left(\frac{2\pi}{W}x\right) - \delta \sin^3\left(\frac{3\pi}{W}X\right), \quad (2)$$

where D , W , and δ determine the depth, the width of the grid, and the ripple factor respectively. Figure-4 shows the power absorption at the surface of a target with several different surface shapes.

Figure 4. Absorbed Powers at 3GHz. with different roughness amounts.

2.2. Thermal Model

A two-dimensional thermal diffusion model was implemented under the excitation of a microwave power source. Actually, the microwave absorbed power density obtained as a result of the absorption model is used as a power source. Like in the absorption model, the ground and the target buried under the ground are described by their geometric properties. The thermal diffusion equation to be solved in the identified two-dimensional computational grid is shown below:

$$T_{ij}^{n+1} = R(T_{i+1,j}^n + T_{i-1,j}^n + T_{i,j+1}^n + T_{i,j-1}^n) + (1 - 4R)T_{ij}^n, \quad (3)$$

where R is

$$R = D \frac{\Delta t}{(\Delta x)^2} \quad (4)$$

D is

$$D = \frac{k}{\rho c} \quad (5)$$

where k , ρ , and c are thermal conductivity, density, and specific heat of medium respectively. Δt and Δx represent the time and grid spacing. The temperature quantity T_{ij}^n in equation (3) is computed from information at points $(i+1, j)$, $(i-1, j)$, $(i, j+1)$, $(i, j-1)$, and (i, j) at time n shown in Figure-5.

Constant-temperature boundary conditions are applied at the grid boundaries and a convective boundary condition reference is used at the interface between air and ground. The microwave source is kept on for a while and then shut down. All temperature increases and decreases, belonging to each specific time, are calculated during the heating and cooling cycles. The time history diagram, the temperature function of transverse distance and time, is built up.

Figure 5. Computational grid for thermal model.

3. THE INVESTIGATION OF TIME HISTORY DIAGRAMS BELONGING TO ROUGH SURFACES WITH DIFFERENT RIPPLE FACTORS

As stated in section 2.2., rough surfaces with the target with the characteristics stated in Table-1 were implemented for the investigation. The investigation, which has been performed here, could be broken into two parts. In the first part, the amount of roughness, which was introduced into the surface shaping function mentioned in equation (2) by various ripple factors, 2, 3, 4, and 5 has been examined at only 3GHz. Furthermore, the effects of roughness on time history diagrams have been demonstrated in Figure-6. In the second group, the effects of frequency change have been investigated. The surface roughness applied here is unique; *i.e.* the study has been performed under the same rough surface. The ripple factor used in this simulation is 5. Frequencies are 0.5, 0.75, 1.0, 2.0, 2.5, and 3.0GHz. respectively. The results are presented in Figure-7. Both simulations were carried out under the assumption of zero angle incidences. The time history diagrams are also can be viewed from Figure-8 for frequency values of 0.5, 1, 2.5, and 3GHz.

4. CONCLUSIONS AND FUTURE WORKS

As can be seen from Figure-6, the time history diagrams look like very similar to each other. However, as inspected closer and in more detail, one can realize that the five distinct hot regions get narrow with increasing ripple factor δ . As a result of this, the gaps between these distinct hot regions can be distinguished more easily for the surfaces with higher roughness amounts than the surfaces that are relatively smooth.

From figure-7, one can draw several conclusions. It is useful to separate to have the images with two different groups: Low frequencies and high frequencies.

For low frequencies, one can easily observe that there is an obvious temperature rise in the middle of the location for the same surface shape, same soil and mine characteristics, and same mine location. As frequency increases, this temperature rise increases in the middle. On the contrary, the heating of the sides disappears. The temperature increases become concentrated in the middle portions.

For higher frequencies, the situation is a little bit different. As frequency increases, side-bands get more distinct. However, when the temperature rise in the middle is viewed, it is impossible to determine the presence of a mine. Overall, it is difficult to sort out temperature variations due to buried objects and those due to surface roughness. Temperature rise in the middle is sometimes high and sometimes low, due to the effects of electromagnetic interference of incident, transmitted, and scattered fields. In any case, the presence of the mine is evident.

We plan to investigate the frequency behaviors of these time history diagrams and to look at the changes in the heating pattern with frequency in the presence and absence of a mine. We believe this will yield new information, and reduce the effects of surface roughness.

Abstract

Humanitarian landmine detection and clearance is one of the most challenging, difficult and time-consuming tasks to be completed with existing technologies. Infrared (IR) Imagery has been used to find differences in heat transfer on the surface of the soil due to a buried object. In this paper, we will describe a method, *Dual Frequency Microwave Enhanced Infrared Thermography (MEIT)*. Heating with microwaves instead of natural sunlight leads to a number of advantages, such as more efficient heating to enhance the thermal signature, and the ability to sense electromagnetic as well as thermal properties of the buried object. However, like other IR techniques, it is limited by surface roughness. Thus, the two frequency technique is used to minimize the clutter introduced by the rough, irregular surface of the ground itself, and vegetation covering the ground. The dependence of scattered waves on frequency is weak enough to make this possible. A 2-D computational model of this method has been developed to simulate real-world landmine detection. Moreover, ROC (Receiver Operating Characteristic) curves are used to evaluate the performance of the system applying this method.

Keywords: Landmine detection, rough surface, infrared (IR) imagery, thermography, microwave enhanced, dual frequency, ROC curves.

I. INTRODUCTION

We have previously presented analytical and experimental results on Microwave-Enhanced Infrared Thermography. In [1] [2], we have shown that using microwave heating of the ground can produce strong enhancements of the infrared signature of the shallow-buried objects, while diurnal variation of the heating pattern, caused by natural sunlight, is much weaker. Moreover, we have described how different signatures impart electromagnetic and thermal information in [3].

In all the above work, analysis and results are based on an ideal uniform interface at air-ground boundary, say, a smooth surface. Furthermore, we have shown that the effects of surface roughness produce clutter, which masks the signals from buried objects in [4] [5]. As surface roughness increases, infrared signatures of buried objects become more unreadable and have an increasing probability of producing false alarms due to hot spots on the surface generated by local variation in surface orientation.

For detecting landmines and discriminating between landmines and other buried objects, this effect also increases the difficulty of the following image-processing procedure to extract information out of the obtained heating pattern.

In this paper, we present a modified MEIT technique, *Dual-Frequency MEIT*, which is developed based on previous work. In this new method, microwave sources with two different frequencies are used in two consecutive heating cycles on the ground. Then we obtain difference between two infrared signatures corresponding to the different frequencies, assuming that all the conditions of environment and of scatter have not been changed within the period between the two separated heating cycles.

In Section II & III, we will show that the signature of difference gives information about buried objects with reduced clutter, which mainly comes from rough surface and vegetation covering the surface. To validate the efficiency of this new method, at the end of this paper (Section IV), we have calculated ROC (Receiver Operating Characteristic) curves for both single frequency and dual-frequency technologies. The ROC curves indicate an overall improvement.

II. THE DUAL FREQUENCY TECHNIQUE V.S. THE SINGLE FREQUENCY TECHNIQUE

Surface roughness is the major factor limiting the MEIT technique in our recent research. As we discussed in [3], wavelength, polarization of the incident waves, as well as properties of the soil all have some influence on enhancement, while angle of incidence, physical structure and chemical composition of buried object are more important.

However, all the above discussion had assumed a flat, smooth surface. Based on some of our real world experiments, in comparison to those in the laboratory on a flat surface, we find that a rough surface contributes most to the distortion of infrared signature at the air-ground boundary, compared with all the other parameters. Thus, eliminating the clutter due to surface roughness becomes the first thing to be considered to ensure microwave enhancement.

We have noticed the fact that field irradiation under the surface depends most on Fresnel reflection and surface geometry and dielectric constants, and less on the wavelength of the incident wave. In our microwave model, computational simulation has also confirmed this idea.

Figure 2.1, Geometry of computational model, rough surface and the buried object

Figure 2.1 shows the geometry of the computational model we used in this paper, and Figure 2.2 explicitly shows that incident microwave power with different wavelengths produce, predictably, almost the same power distribution, as well as electromagnetic field distribution on the same rough surface. We explain this phenomenon as follows: no matter what wavelength is used for incident waves, absorbed power density at the surface mainly focuses at tips of the rough surface, because a unit volume of soil at tips has more effective area for absorption than that of other region.

Figure 2.2, Frequency independence of scattered wave, power density distribution at the surface under two different frequencies

Next, we consider how this simulation reduces the surface clutter. We know that using microwave heating instead of natural sunlight has many advantages, one of which is that we can take microwave wavelength as an adjustable parameter in the MEIT technique. By subtracting the two infrared signatures obtained under two different frequencies, one can finally achieve a signature of the buried objects, with clutter introduced by rough surface greatly reduced. Then we can more easily extract information about the buried objects under the ground from the thermal signature data. In the following section, we present some results obtained by a 2-D computational model based on the idea above.

III. COMPUTATIONAL RESULTS

Now it is time for us to use the 2-D numerical model developed according to the above analysis to simulate what happens during the period of a microwave heating cycle, which includes heat-up and cooling down periods. As described in our previous paper [1][2], the numerical model includes two main parts, the microwave model and the thermal model. The microwave model calculates total electromagnetic field including undisturbed incident plain wave plus scattered waves to get the power density distribution all over the under ground region. Then, the thermal model applies a thermal diffusion equation to calculate the temperature distribution variation on the surface as a function of time to form a THD (Time History Diagram) [5]. As presented in [3], initial signatures of microwave heating cycle show information about electromagnetic wave propagation in the vicinity of the object, and the purpose of the dual-frequency technique is mainly focused on improving the infrared signature contrast in this early heat-up cycle. Therefore, we only use the microwave model here to obtain the absorbed power density distribution. Some results obtained from the 2-D FDFD numerical microwave model simulations are shown below.

Figure 3.1 ($\sigma=0.00\text{mm}$)

Figure 3.2 ($\sigma=2.21\text{mm}$)

Figure 3.3 ($\sigma=4.42\text{mm}$)

Figure 3.4 ($\sigma=8.84\text{mm}$)

In figures 3.1 ~ 3.4, power density distributions on the top of the surface in our 2-D geometry, under different surface roughness, are shown in cases of frequency 0.915Ghz, frequency 1.115Ghz, and the corresponding dual-frequency, from top to the bottom respectively.

All the figures are obtained with the same shape of rough surface, and different extent of roughness for the same surface profile is represented by factor k ($0 < k < 1$). For example, when k is equal to zero, surface becomes flat, and when k is equal to one, the standard deviation of the surface height is 1.15cm in the above case.

From these figures, we find out that using the Dual Frequency technique efficiently reduces the clutter of rough surface comparing with power density distributions for the single frequency case. The rougher the surface becomes, the worse the signature contrast becomes for single frequency, while for the Dual Frequency case power density distribution remains almost the same. Thus, the Dual Frequency technique successfully extracts useful information of buried objects out of the clutter caused by surface roughness. Similar results are also obtained with other different rough surface profile.

One more thing we want to point out is, however, we cannot totally eliminate the distortion of heating pattern. Basically, there always exists some extent of dependence on wavelength for irradiation field pattern, which increase will increase difference between two frequencies. On the other hand, it is obvious that too close frequency difference yields a small signal as well as low clutter. So we have to choose the proper frequency pair to get as much enhancement as possible. The frequency pair we have used in this simulation has been optimized. To get optimized frequency pair, we have searched in a large range of the frequency domain to compare maximum signature difference between mine-free and mine case.

Furthermore, in the following section, we have also used another means, ROC curves, to validate the dual-frequency technique's efficiency at removing or minimizing clutter caused by surface's irregularities.

IV. ROC CURVES

To evaluate the performance of a certain detection system, ROC curves provide much help to understand overall detection statistics of the system and compare systems when a priori probability and cost function are not available.

For a single measurement, four results are possible: a correct detection, missed detection, correct negative, or false alarm. The distribution of three results depends on the distributions of signals where an object is present and where it is not. We assume that both distributions are Gaussian. In the present case, the widths of both distributions are determined by a combination of a fixed number and the standard deviation of the signal in the absence of a mine.

For an ideal detection system, these two distributions are sufficiently separated to ensure that true signals are always detected and that the probability of false alarms is zero. However probability distributions of real system always have some extent of overlap, shown as Figure 4.1 below. For any given threshold value of detection, the areas under each Gaussian curve to the right side of threshold are the probabilities of detection and false alarm, respectively.

To get ROC curves, we scan the threshold value from negative infinite to positive infinite, and calculate the corresponding probability for detection and false alarm, i.e., P_d and P_f . In fact, ROC curves are curves for P_d versus P_f parametrically depending on threshold value of system. Typical ROC curve looks like Figure 4.2. The more area under the curve is, the better overall performance of the detection system will be. The ideal system ROC curve is a straight line from

origin (0,0) to point (0,1), then to (1,1), and the straight line from origin (0,0) to point (1,1), as shown in figure 4.2, is as bad as random choice.

Figure 4.1 Preliminary of ROC Curves

Figure 4.2 Typical ROC curves

In our analysis, signal and clutter, mine and no mine present respectively, are both assumed to be Gaussian. We know that the Gaussian curves can be totally determined by two parameters, mean and standard deviation, where the latter is related to noise. When these two parameters are obtained from surface power density pattern, we can easily get ROC curves according to above definition. Our strategy to get ROC curves is that, first, we find the difference between maximum and minimum values of power density along rough surface in mine and no mine case, then use them as the means of Gaussian probability density distributions for true signal and false alarm, respectively. From our previous experiment data, the unpredictable behavior of the ground temperature variation, which is due to sunlight, is around a few Kelvins. So we take the minimum power density variation corresponding to 1 Kelvin as the standard deviation of Gaussian probability density distribution for both true and false alarm case. Then we add the standard deviation of the signal in the absence of a mine to indicate the clutter level.

We show ROC curves from simulation data as described above. As can be seen from Figures 4.3, with increasing surface roughness, ROC curves become worse and worse for the single frequency detection technique. The ROC curves for the dual-frequency technique become worse, though at a pace much slower than those of the single frequency technique.

However, as shown in Figure 4.3, when the surface roughness factor k is large enough, the dual-frequency technique begins to show its advantage over single frequency ones. From this time on, the single frequency technique tends to fail and the ROC curve suggests that the single frequency technique, in this case, is no better than a coin toss.

By using ROC curves, we validate that the dual-frequency detection technique has better performance when a target is under ground surface with irregularity.

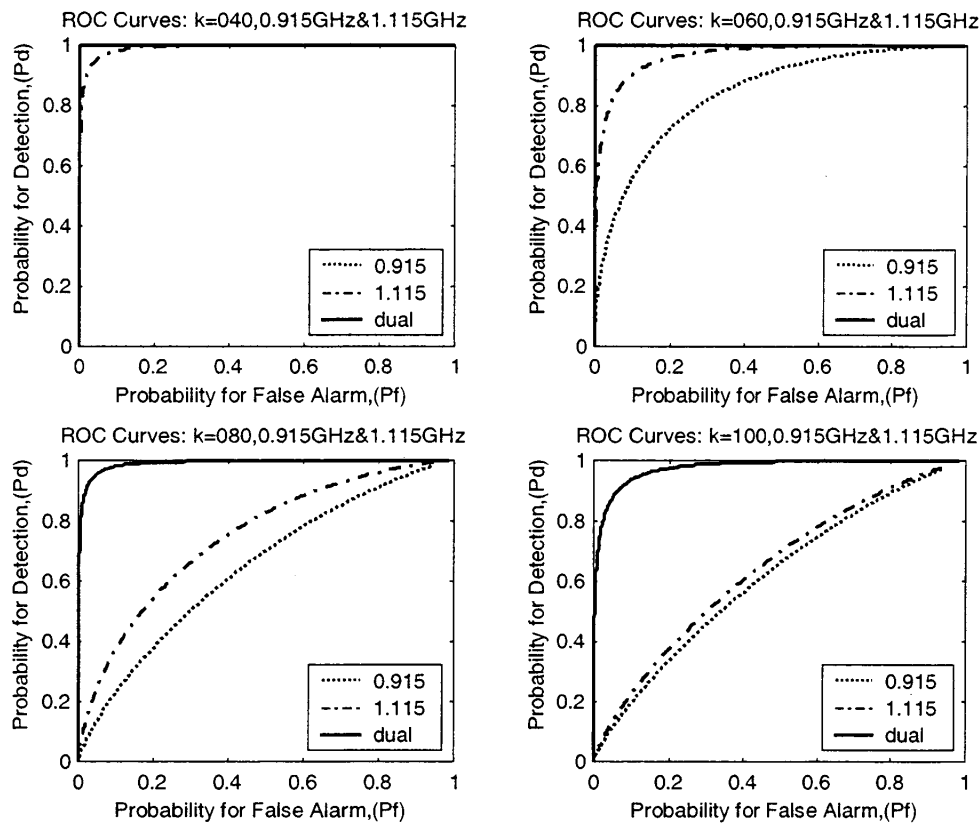

Figure 4.3 ROC curves for dual-frequency technique with increasing surface roughness factor k ($0 < k < 1$)

V. CONCLUSION AND FUTURE WORK

We have presented an improved MEIT technique for humanitarian landmine detection, *Dual-Frequency MEIT*. This technique mostly retains the advantages of original MEIT while it enhances us to observe an infrared signature of the shallow-buried object under rough surfaces. Then we have validated it by results obtained via numerical simulation and ROC curves. In the future work, we will account for two other essential factors, vegetation and variation in solar heating, both of which may mask the infrared signatures of the buried objects. By overcoming these difficulties, the MEIT technique will be a more valuable tool for detection of buried objects. Moreover, examining the thermal signature in later part of heating cycle will provide useful shape information about objects.

ABSTRACT

Acoustic sensing shows promise for the detection of buried landmines. One of us has previously demonstrated successful imaging of mine simulants buried at depths from the surface to 15 centimeters, using speakers and a laser vibrometer, which collects spectral data at low frequencies. The strength of the method is in the contrast between the porous soil and the nonporous mine, while the limitations are the strong attenuation of the probing acoustic wave and coupling of the sound directly into the vibrometer.

Another member of our group has shown that shallow-buried objects can be detected by acoustic pulses generated by a high-power pulsed laser and a microphone, producing signals which are processed in the time domain to observe echos from buried objects. The strengths of this method are the lack of direct acoustic coupling into the vibrometer and the resolution implicit in the high frequencies. The limitations are in the depth of penetration, the large size of the laser, and the low acoustic energy.

We have recently performed an experiment which combines the best features of both techniques. A new, portable, pulsed laser and the laser vibrometer were used at an outdoor test site to show that (1) sufficient laser energy can be coupled into the ground to produce signals larger than the ambient seismic noise, and (2) these signals are modified by buried objects. We will show some examples and consider the configuration for an operational system.

Key Words: Photoacoustic imaging. Landmine detection.

1. INTRODUCTION

It is widely recognized that successful humanitarian demining will require many sensors to achieve the combination of certain detection required to return land to civilian use and low false alarm rate to allow the removal process to proceed at an acceptable rate. One interesting approach is the use of acoustic sensing. One of the authors of this work has previously demonstrated successful imaging of mine simulants buried at depths from the surface to 15 centimeters, using commercially available speakers and a laser Doppler vibrometer. The speakers insonify a large area while the vibrometer produces an image by scanning the region of interest, collecting spectral data in a bandwidth from hundreds to thousands of Hertz, at each point. The strength of the method is in the contrast between the porous soil and the nonporous mine, while the limitations are the strong attenuation of the probing acoustic wave and coupling of the sound directly into the vibrometer.

Another member of our group has shown that shallow-buried objects can be detected by acoustic pulses generated by a high-power pulsed laser. In this case, the pulsed laser source is scanned across the target area and a microphone records signals, which are processed in the time domain. The signals show an acoustic pulse from the surface and the echo of the pulse from the buried object. Ten microseconds corresponds to a depth of about 1.5 centimeters. The strengths of this method are the lack of direct acoustic coupling into the vibrometer and the resolution implicit in the high frequencies. The limitations are in the depth of penetration, the large size of the laser, and the low acoustic energy.

We have recently performed an experiment which combines the best features of both techniques. A new, portable, pulsed laser and the laser vibrometer were used at an outdoor test site to show that (1) sufficient laser energy can be coupled into the ground to produce signals larger than the ambient seismic noise, and (2) these signals are modified by buried objects. We will show some examples and consider the configuration for an operational system.

Here we explore an all-optical implementation of an acoustic landmine detection system. We will present a brief overview of the advantages of an all-optical implementation, followed by a study of the mechanisms by which light generates sound, and a summary of our experiments.

2. USE OF LIGHT IN ACOUSTIC IMAGING

The all-optical implementation of acoustic imaging has two parts. In the first, a pulse of light generates sound in the ground, and in the second, a continuous wave (CW) laser vibrometer measures surface motion to measure the reflected sound from the object. Here we compare this approach to conventional all-acoustic techniques.

If sound is generated in the air, and transmitted into the soil, it is subject to severe losses caused by reflection at the soil-air interface. These losses are related to the variations in the speed of sound, and density, as well as the angle of incidence of the sound. Typical reflections can exceed 98%, with the result that an incident power level of 200 Watts in air can lead to peak pressures of as little as 200 Pascals in the soil. In contrast, if a pulse of laser light is absorbed in the ground, the resulting sound wave does not need to travel through the interface, and is thus not subject to loss. For a 150 millijoule laser pulse, our simulations indicate that a pressure of 10^5 Pascals can be generated. Thus, laser generation of sound is attractive because the sound can be generated directly in the soil without incurring the usual reflection loss.

On the detection end of the process, a similar or worse situation arises on reflection from the interface. Specifically, if the sound reflected from the buried object is scattered over a wide angle, large portions will be reflected much more strongly, and thus the transmission can be as low as 0.1%, to a microphone above the ground. The possibility of detecting such small signals in the presence of the larger ones produced by the source, or even in the presence of noise, is limited. On the other hand, surface motions related to buried objects are of the order of fractions of a micrometer, which are easily detected by laser vibrometry.

Thus, an all-optical implementation seems desirable because of the opportunity to maximize signal strength and, perhaps more importantly, because of the ability to avoid coupling of the receiver to the transmitter directly through the air.

The laser vibrometer has been used successfully in work reported elsewhere in this volume. The issues that remain to be discussed are the generation of the sound by the laser pulse and the propagation of the waves which are generated.

3. MECHANISMS OF SOUND GENERATION

We consider four different mechanisms for sound generation, and we find that at least two of them are likely candidates in different situations. In the first and most obvious, the soil is heated, and expands, thereby producing a compressional wave. This was our first assumption and is consistent with our first observations, reported previously [Li, *et. al.*, McKnight, *et. al.*, 1999], for which imaging has been demonstrated [Witten *et. al.*].

The second potential mechanism is radiation pressure, in which photon momentum is transferred to the soil. Numerical calculations have shown that the resulting impulse is much less than that produced by heating, and this option has been dismissed.

The third option is that the air between the sand particles is heated, resulting in a very different form of acoustic wave, specifically, the so-called Biot Slow Wave. This appears to be somewhat consistent with the results reported in this volume McKnight *et.*

al., 2000, when the laser beam is tightly focused. The other alternative is that the laser beam produces a plasma in the air, the expansion of which produces the acoustic pulse. As reported in by McKnight (2000), this is the more likely choice; We have observed "white" light emitted from the region of the laser spot in the case of a tightly focused beam, and upon spectroscopic analysis, this light has distinct lines associated with atmospheric gasses, as would a plasma. If the process were heating alone, the spectrum would be the smooth spectrum of black-body radiation.

We thus conclude that sound is generated by heating of the sand in the case of a broad laser beam (150 mJ in a 1-cm spot), and by plasma in the case of a tightly focused beam (150 or 18 mJ in a 1-mm spot). We have developed a model which predicts the performance of the broad beam, and are working to develop one for the focused beam. Although the sound of the plasma pulse is more easily audible to observers in the laboratory, it is not immediately clear that it produces a larger sound pulse in the ground, nor that this pulse propagates in such a way as to detect buried objects. Indeed some of our experiments suggest the opposite. We repeated the experiment discussed in Witten's paper mentioned above, but using a focused beam. Results were significantly worse, and it was not possible to observe the shape of objects. This result is not understood yet, and is the subject of further research.

4. EXPERIMENTS

To determine the feasibility of the all-optical approach, we conducted two days (28–29 July 1999) of experiments at the University of Mississippi mine lanes, using a portable pulsed CO₂ laser (Laser Science, Inc., Franklin, MA) with a pulse energy of 18 mJ, and a pulse length of about 100 nsec, as a source, and a scanning HeNe laser vibrometer (Polytec, PI, Auburn, MA) as a detector. The work was conducted in a small patch of ground over an anti-tank mine casing buried two inches deep. We focused the laser with a short focal length lens, so that a flash of visible light was seen when the pulse occurred.

The source laser was focused to nine positions, spaced about 25 mm apart, and the vibrometer collected data at six points near each source spot. If the spots overlapped closely, the vibrometer signal was contaminated by ejection of soil particles, and if it was too far away, the signals were not strong enough to detect with the particular configuration of the hardware used. A typical set of results is shown in Figure 1.

The two panels on the left show Fourier transforms of the displacement signals calculated by the vibrometer. The top shows two curves, one collected with the laser on, and the other, for reference, collected without the laser, and thus indicating the ambient motion of the ground. The lower panel shows the ratio of the signal to the background. This is the data set normally recorded by the vibrometer. On the right, we have inverse Fourier transformed this data to produce displacement, and then differentiated numerically to obtain velocity, both as functions of time. We note that in the spectral plots, there is

Figure 1 — Sample Results of All-Optical Acoustic Imaging.

a positive ratio at all frequencies, indicating that the ground surface motion resulting from the laser pulse exceeds the background acoustic activity, and does so by a substantial amount at most frequencies. In the time plots, the initial pulse is the most striking feature.

These plots illustrate the differences between the two types of acoustic imaging being performed by our individual groups. Using the speakers as sources, the most effective frequencies seem to be low, in the range of hundreds of Hertz, where the penetration of the ground is good. The successful mine detection work relies on spectral information in this range. The sound source is adjusted to produce mostly these low frequencies. In the laser-induced acoustic work, the energy is distributed across a much wider spectrum, as dictated by the interaction of the light and the soil. The high quality images reported by McKnight *et. al.* result from analysis of these signals in the time domain, and in particular, making use of frequencies as high as 30 kHz. However, it will be noted in the spectra that significant laser-induced acoustic energy exists at frequencies well below 2 kHz.

This discussion raises a number of interesting and complicated issues. Let us review the relevant times and frequencies. The pulse is typically a few microseconds in length, as shown on the top panel of Figure 2. This means that the spectrum has a width of something less than 1 MHz. For multiple pulses, this spectrum is multiplied by a comb function at the pulse repetition frequency, as shown in the lower panel. For a finite time sample, each comb tooth will be convolved with the Fourier transform of the time window. For the unfocused laser beam and higher frequencies, the footprint is large compared to the acoustic wavelengths, and the acoustic energy remains well collimated for some distance into the soil. Lower frequencies diverge faster, although they also travel longer distances in the soil. Although the laser-generated acoustic energy is spread over a wide bandwidth,

the narrow comb functions achievable with long dwell time may permit significant noise reduction by synchronous detection. Based on the work at the University of Mississippi reported elsewhere in this volume, these frequencies are particularly useful for detecting mines with a low false-alarm rate. The high frequencies can also be detected through synchronous detection, and based on McKnight, *et. al.* can provide exquisite imagery in three dimensions, for classification, particularly for smaller mines at shallow depths. Optimal use of the data will require further analytical and experimental effort.

5. CONCLUSIONS

We have shown that short pulses of laser light can produce easily measured acoustic signals in soil, which can be used for detection of buried objects. Many issues must be resolved to optimize this technique. In the most basic areas, the mechanism of sound generation is not well understood. Apparently different mechanisms exist for tightly and weakly focused spots. These evidently generate different types of waves in the soil, and the propagation of these waves is not yet understood. Next the information available at each range of frequencies must be investigated to determine the best use of the data. Finally, some choices for the laser pulse length, energy, and repetition frequency may have impact on improving the signal-to-noise ratio of the detected signal.

The ultimate result of this effort could be a non-contact acoustic sensor with the potential standoff distance limited only by the height of the vehicle on which it would be mounted. The optical source and receiver would eliminate problems of direct coupling of energy through the air, and the use of data over a wide frequency band could permit the detection of landmines of different sizes buried at various depths.

ABSTRACT

Mechanisms for the production of acoustic energy in soil by pulsed CO₂ laser excitation of the surface are reported. When the laser pulse is unfocused with a spot size about 1 cm in diameter, a single narrow acoustic pulse is observed with a spectral content near the detector limit of 100 kHz and a velocity of 255 m/s, close to the speed of sound in air. When the laser is focused to a spot size on the order of 1 mm diameter, the audible acoustic intensity is greatly increased and we observe a second broad acoustic feature. This feature has a much lower frequency (near 3 kHz) and velocity (75 m/s). We have tentatively identified the fast mode as a normal compressive mode and the slow mode as a Biot slow-wave. A study of visible light emission when the focused CO₂ laser beam strikes the sand surface indicates ionized nitrogen, oxygen, and silicon are present. This implies that the mechanism for sound production with the focused beam involves ionization by the optical electric field, expansion, and subsequent collapse of the air. The mechanism for sound production by the unfocused beam, which produces better imaging of underground objects, appears to be quite different.

Keywords: laser-induced, acoustic, landmine detection, Biot waves, porous media

1. INTRODUCTION

The use of high-frequency (~30kHz) acoustic waves produced by a pulsed CO₂ incident on the surface of dry sand for imaging of shallow buried objects such as anti-personnel landmines has been demonstrated in the laboratory^{1,2}. The mechanisms for the conversion of the optical pulses into sound, however, is poorly understood. Since the optimization of the process of optical to acoustic conversion in a porous media depends on understanding and modeling the physical processes, we have initiated an experimental investigation of the behavior of the acoustic modes created in soil under different laser pulse focusing conditions. For a broad, unfocused laser spot, modeling the soil as a uniform effective medium as in Figure 1a may be appropriate. If the laser is focused to a small spot comparable to the size of the sand grains as in Figure 1b, a more complex calculation may be necessary which takes into account the random position and orientation of the sand grains and the intervening air spaces. In addition, under focused beam conditions the optical field intensity can become very large, leading to different physical effects. We have observed

Figure 1 Conceptual models of optical-to-acoustic conversion in soil. a) An effective medium approximation may be adequate when the laser spot is much larger than the structure of the soil, b) The details of the interaction of the light with the discrete particles of the poro-elastic medium may be critical when the beam size is comparable to the particle size.

that focusing the laser beam to a spot size on the order of 1mm in diameter greatly increases the audible acoustic sound associated with the laser pulse and, in addition, can cause the production of a flash of visible light at the point where the infrared CO_2 pulse impinges on the sand. We have studied the time-dependence of the acoustic pulse at various depths and angles in the soil for both focused and unfocused laser pulses. For unfocused pulses we find a single acoustic mode with a velocity slightly less than the speed of sound in air with a directionality perpendicular to the soil surface. With a focused beam we detect two distinct acoustic features in the time trace: a sharp pulse with a velocity and spectral content similar to that achieved with the unfocused beam, and, in addition, a second broad pulse with a much lower frequency content which propagates at a slower velocity. We suggest that these two modes may be related to the two Biot modes allowed in poro-elastic media³.

2. EXPERIMENT

A photograph of the experimental setup is shown in Figure 2. The source laser is a LSI pulsed 10.6μ CO_2 TEA laser with a pulse length of 100ns, a pulse energy of 150mJ, and a repetition rate less than 20Hz. The laser is incident on a 1 m^2 surface of dry sand about 60 cm deep in which we would bury detectors or various types of subsurface targets. In the present studies of the optical-acoustic conversion mechanism, the acoustic signal was measured with a wide-band hydrophone (0-100kHz) which was buried at various depths and positions in the sand. This configuration contrasts with the experimental setup that we used to image underground objects. For imaging, our best results were obtained with a narrow-band (30kHz) tuned PZT detector which was suspended in the air above the position of the laser pulse on the surface of the sand.

The laser was used in two configuration: unfocused or with a focusing lense to reduce the spot size. The unfocused laser spot is an oval approximately $1.1 \times 0.7\text{ cm}$ in size. A germanium lens with a focal length of 25cm was used to focus the beam to a spot size less than 1mm in diameter, comparable to the size of the sand grains. 10.6μ light is very effectively absorbed in soil with a reflection less than 10% and skin depth of approximately 5μ . The sound produced by both the focused and the unfocused beams was audible across the room. With the focused beam the sound was considerably louder and there were flashes of visible light emitted and some movement of sand grains at the spot where the laser hit the surface.

The acoustic signal detected by the buried hydrophone for the focused and unfocused beams is shown in Figure 3 and Figure 4.

Figure 3 The time trace of the acoustic signal measured by a buried hydrophone as a result of a pulse from the unfocused laser on the sand surface.

Figure 4 The time trace of the acoustic signal measured by a buried hydrophone as a result of a pulse from the focused laser on the sand surface.

Figure 5 Experiment to measure the velocity in sand of the acoustic features in Figure 3 and 4.

The initial spike is electrical noise caused by the laser discharge. The acoustic pulse is dominated by a sharp peak with a width (about $10\mu\text{s}$) that is probably limited by the bandwidth of the 100kHz detector. For the focused beam only, there is a second, much broader feature with a peak-to-peak width of about $300\mu\text{s}$.

To determine the propagation speed of these two different acoustic features observed with a focused laser beam, we measured the change in the acoustic signal as a function of distance from the laser spot to the detector using the configuration in Figure 5. The time trace of the acoustic signal measured by a buried hydrophone as a result of a pulse from the focused laser at two different positions on the sand surface are shown on the left in Figure 6. Identifying the sharp feature by the initial spike, and the broad feature by the dip between the two broader peaks, in Figure 6 we plot the time delay after the laser fires of these two features as a function of distance from the laser spot to the detector. By taking the slope of these two curves, we find the velocities of the two features are dramatically different. The sharp feature propagates with a velocity around 255 m/s, while the broad feature propagates with a velocity of about 75 m/s.

The observation of acoustic modes with two different velocities in porous media is a well-known phenomena. In the theory of Biot, the solution for acoustic propagation in a random porous elastic media gives rise to two modes: a mode in which the frame and the fluid move in phase (compressional wave) and an addition mode in which the motion of the frame is out of phase with the motion of the fluid. Typically the in-phase mode has a velocity which is close to the velocity of sound in the fluid, while the out-of-phase mode, the "Biot slow wave" has a lower velocity. If we tentatively make an identification of the features we observe with the Biot modes, the sharp feature which travels at 255 m/s, close to the velocity of sound in air, could be the Biot in-phase mode, while it is natural to identify the broader feature, low-velocity feature with the Biot slow wave. Note that we only observe this second, slower wave under excitation with a focused laser beam.

To measure the angular dependence of the magnitude of the acoustic signal from the focused beam, we positioned hydrophones at different angles along an arch buried in the sand centered on the position of the laser spot, as shown in Figure 7. In Figure 8 and 9, we plot the peak amplitude of the sharp "fast-wave" signal and the

Figure 6 The arrival time vs. distance for the features indicated by the arrows in the inset. The propagation velocity in sand of the two features is determined as indicated from the slope of the lines.

Angular Distribution of Acoustic Intensity

broad “slow-wave” signal as a function of angle from the normal. The two modes show a dramatic difference in angular distribution, with the slow wave signal propagation peaked at angles perpendicular to the surface, while the fast-wave signal strength is peaked along the surface of the sand. The angular dependence of the fast-wave mode is hard to understand, since when the beam is unfocused we observe only a single mode with a shape and velocity similar to the fast-wave signal, but with an angular distribution sharply peaked at a direction normal to the surface, as shown in Figure 10.

The unfocused beam has a Rayleigh length d^2/λ on the order of 1 cm, so for distances into the sand on the order of 1 cm the unfocused beam looks like an extended source. The focused beam, on the other hand, has a Rayleigh length less than a millimeter and is a point source to a good approximation. Since the radius of the detector arch was about 10 cm, it is unlikely, however, the difference between the fast-mode angular dependence seen in Figure 9 and 10 can be accounted for by such physical optics effects. It is more likely that the different acoustic excitation physics between the broad laser beam and the focused beam, such as illustrated in Figure 1, may account for these differences. We will return to this question later.

Table I summarizes the differences between the two acoustic modes that are observed with the focused laser beam. We note that these differences may impact on the utility of the two modes for underground detection and imaging. The fast mode, having a

Comparison of Fast and Slow Acoustic Waves

	Fast Wave	Slow Wave
Unfocused Beam	Yes	No
Focused Beam	Yes	Yes
Speed	250 m/s	75 m/s
Frequency peak	100 kHz*	3 kHz
Directivity	Along Surface	Perpendicular to Surface
$\alpha(\omega)$	Unknown	Unknown

* Band-width of detector=100kHz ($1/\Delta t_{\text{detector}} = 10 \text{ MHz}$)

higher spectral frequency content may be more useful for high-resolution imaging where a small wavelength is desired. On the other hand, if we have correctly identified the slow wave as a Biot out-of-phase wave, it will see an exceptionally large contrast between the porous soil where the slow wave is allowed and any subsurface non-porous object where, since there is no longer any differentiation between frame and fluid, its propagation is forbidden. There may also be implications about detection strategies, since to the extent that the energy of the slow-wave is carried in the fluid, techniques that measure the motion of the solid surface, such as laser vibrometry, will be less effective than with an ordinary compressional wave. On the other hand, for the same reason the mismatch between the poro-elastic wave and the wave in the air may be less for the slow-wave than the fast wave, so that detection by means of a microphone above the soil may be more favorable for the slow wave.

It is noteworthy that our attempts so far at subsurface imaging with the focused beam have been less successful than our previous work with the unfocused beam. These imaging studies were carried out with an acoustic detector suspended in the air above the surface. It is not possible to say at present whether the lack of success was due to an inherent effect such as the longer wavelength of the slow wave, less efficient acoustic coupling to or from the soil and air, or some interference effects between the fast and slow acoustic waves, or more incidental effects such as noise from the movement of sand grains and drifting of the laser focus due to heating of the air and movement of the surface.

One clue about the mechanism for acoustic excitation is that a flash of visible light is observed which the CO₂ pulse hit the surface of the sand when the beam is focused, but not for the unfocused beam. Origins of this visible light that we considered were black-body incandescence of the sand surface, photoexcitation and luminescence of the sand material, and electric field ionization and recombination. The energy density of the focused beam is sufficient to heat the sand over 10⁶ °C if the effects of radiant emission and conduction are neglected, but this does not seem likely on the relatively long (0.1 μs) timescale of the pulse. Luminescence of SiO₂-based materials is usually very broad-band and can extend into the ultraviolet.

To gather more information about the light emitted when the focused CO₂ laser pulse strikes the sand surface, we measured the spectrum of the emitted light using a multispectral filter and a photomultiplier detector as in Figure 11. The measured spectrum is reproduced in Figure 12 and Figure 13. The emission peaks are negative, because the electron current of the photomultiplier

is converted to a negative voltage by a voltage-to-current amplifier. Electron photocurrent resulting from the detected light yields a negative voltage.

We have identified emission lines in the spectrum by comparison with the CRC Handbook of Physics and Chemistry. We note that large emission lines associated with ionized nitrogen, oxygen, and silicon are present in the spectrum which implies that the model for optical field ionization is the best model for the production of the light. The concentration of the electric field of the optical signal near the sharp points of the sand grains is the most likely mechanism for the breakdown and ionization of the air and sand.

Focused Beam Surface Interactions

The acoustic production for the focused beam can then be best explained by the collapse of the air following the rapid expansion associated with the ionization and plasma formation as shown in

Figure 14. The intense audible noise associated with the focused beam is analogous to the crack associated with an electrical arc or with thunder. One implication of this model is that the sound production for the focused beam is probably primarily as a compressional wave in the air above the soil. The reduced effectiveness of imaging with the focused beam may be a result of the poor coupling of this acoustic compressional wave in air into the soil.

Figure 14 Model for production of light and sound by focused laser beam impinging on soil surface.

The unusual angular dependence of the compressional fast wave for the focused beam seen in Figure 9 may represent the more effective transport of acoustic energy in the air along the surface of the sand than propagation in the sand. In effect, the sound produced by this ionization and collapse travels through the air to a point close to the high-angle, near-surface sensor and then propagates only a short distance into the soil to the detector. Since the velocity of the fast wave is very near the speed of sound in air, it is very difficult to distinguish this propagation channel from propagation through the soil. The slow wave may not have the same channel available to it because a Biot wave will not propagate in a single component fluid such as the air.

3. CONCLUSIONS

The production of acoustic energy in soil by a pulsed CO₂ laser has been studied. When the laser beam is focused to a spot size comparable to the soil grains, a much louder acoustic sound is observed and two different acoustic modes are detected in the soil. One mode, which we identify with a normal compressional acoustic wave has a velocity (255 m/s) close to the speed of sound in air, and a bandwidth of at least 100kHz. The second mode, which we have tentatively identified as a Biot slow-wave phenomena, has a velocity of only 75 m/s and a spectral peak near 3 kHz. By analyzing the visible light emitted by the focused laser beam, we conclude that for the focused laser pulse the acoustic energy is produced by ionization of the air and soil components, with a rapid expansion and subsequent collapse of the air column. Preliminary investigations have indicated that imaging of subsurface objects with the focused beam laser is not as successful as with a broader unfocused beam. This may be a result of the poor coupling of sound produced in air into the soil. Studies to measure the attenuation and dispersion of the acoustic signals produced by the focused and unfocused laser beams are underway.

PROFILING THE PERFECTLY MATCHED LAYER TO IMPROVE LARGE ANGLE PERFORMANCE

B127.6

Northeastern University
Boston, MA 02115

Absorbing Boundary Conditions (ABCs) are used in Finite Difference Time Domain (FDTD) scattering problems in order to prevent reflections off the lattice edges. The introduction of the Perfectly Matched Layer (PML), (Berenger, *J. Comp. Phys.*, Oct. 94), revolutionized ABCs. In continuous time and space, the PML completely absorbs waves, independent of frequency and angle of incidence and can attenuate these waves at an arbitrary rate. Despite the obvious utility of the PML, its numerical implementation is problematic. The amount of attenuation experienced by waves incident on a PML drops off sharply as the angle of incidence, θ , increases. Despite considerable effort in interpreting, adapting and improving it, little success has been achieved in modifying the PML in such a way as to achieve consistent performance over a wide range of angles, until now. Presented are the constitutive values of conductivity σ that will allow the PML to achieve a total reflection of -100 dB (0.001%) through angles beyond 60°. Also presented is the background and methodology required to determine these values.

In order to understand the problems in discretizing the PML, consider that it has been established that the decay rate of the PML in continuous time and space is $\alpha = \sigma \eta \cos \theta$. When discretized, the total two way loss for the an N-layer PML is $L = \text{Exp}(-2 \sum_{n=0}^{N-1} \sigma_i \eta \cos \theta \Delta)$, assuming perfectly conducting termination. The value of σ at a spatial point within the PML is σ_i , Δ is the spatial increment and i is the spatial index. Because the decay rate per PML layer, defined by $S_i = \sigma_i \eta \Delta$ is a source of discretization error, the values of S_i must be chosen carefully (Rappaport, *IEEE Trans. Magn.*, May 96) and clearly any S_i may not be arbitrarily large. The minimization of computational overhead requires that N be as small as possible. However, since L is inversely proportional to $\cos \theta$, if N and the values of σ_i are too small, L may become unacceptably large. Berenger found that varying the conductivity parabolically $\sigma_i = \sigma_f (i/N)^2$, where σ_f is a constant, optimized absorption. Still, Berenger's published results indicate that reflections from the discretized PML increase rapidly as θ increases.

To find a set of σ_i that will allow the PML to achieve consistent results over a wide range of angles requires one assumption and two observations. Consider an 8 layer PML, this allows for profiling of 16 half-layers, since at every spatial point, there is a σ_i associated with both \vec{E} and \vec{H} fields.

Based on Berenger's results, it is assumed that there exists a profile of the form $\sigma_j = \sigma_f (j/16)^p$, $j = 1, 2, \dots, 16$ ($i = [j/2]$) where σ_f and p must be found to optimize performance. The first observation is that reflections off the PML at small angles are dominated by discretization error. Finding the best set of σ_j 's for small angles is simply balancing the discretization error against L . An increase in σ_f will increase the discretization error and decrease L . The value of p effects the change in one value of σ_j to the next. If this "contrast" is large, reflections from adjacent spatial points are increased. The overall effect of changes in p are difficult to predict. The second observation is that reflections from the PML at large angles are dominated by L . It will be shown that discretization error goes down with an increase in θ . The key then, is to have σ_f large enough to provide a suitable attenuation at large angles and to adjust p to minimize both the discretization error and L at low angles.

One-dimensional FDTD simulations (Winton, Rappaport, *97 ACES Symp. Dig.*, to be published) are used for an automated search for σ_f and p . The gaussian pulse width and FDTD parameters are those used by Berenger to facilitate comparison. Reflections were analyzed for angles from normal to 60°. When an appropriate set of parameters was found, several angles were tested with the 1-D simulations and verified with 2-D simulations.

The results above clearly indicate that significant improvement over the parabolic profile has been achieved for angles between 0° and 75°. In some cases this improvement is as much as 40 dB.

DETECTING ANTIPERSONNEL MINES WITH A HANDHELD PARABOLIC REFLECTOR TRANSMITTER / MULTISTATIC RECEIVER IMPULSE GPR

Abstract

A novel handheld time-domain array GPR antipersonnel mine detection system using an offset paraboloidal reflector antenna is described. The reflector collimates rays from an ultra-wideband transmitting feed, directing the microwave impulse forward, in front of the antenna structure. As such, much of the ground reflected wave is directed further forward, away from the operator, the reflector, and the receiving antennas, and thereby reducing the major source of clutter. The wave transmitted into the ground that interacts with the target, generating significant backscatter returning toward the receiving antennas. These receiving antennas are configured in a 2 by 2 array to provide spatial focusing in both the along- and cross-track directions.

This system has been built and tested at both Lawrence Livermore National Laboratory, and GeoCenters, Inc. In both cases, custom-built wideband antenna elements generate narrow pulse shapes, which allow for resolving small non-metallic targets buried at shallow depths. The LLNL's Micro-Power Impulse Radar (MIR) operates in the 1.5 to 5 GHz range a very narrow pulse shape. The Geo-Centers wideband TEMR antenna elements have higher power, though lower frequency range (850 to 1700 MHz), and generate less residual ringing in the time signal.

Preliminary measured data from both systems indicate that the surface clutter is indeed reduced relative to the target signal, and that small non-metallic anti-personnel mines can be reliably detected at burial depths as shallow as 1 inch in both dry sand and dry vegetative clay loam soil.

Introduction

The Northeastern University Multidisciplinary University Research Initiative (MURI) demining effort, sponsored by the Army Research Office, has been investigating novel sensing systems and processing algorithms to detect small, shallow buried, low metal content antipersonnel mines. Finding buried plastic mines with conventional electromagnetic induction metal detectors is problematic, due to the relatively low amount of metal (just in the firing pin) relative to surrounding metallic clutter [1]. Ground penetrating radar (GPR) has been shown to be effective in detecting shape anomalies characteristic of buried mines [2]. However, identifying buried target signals amid rough ground clutter is particularly difficult for small mines buried close to the ground surface. To address this problem, it is essential that the GPR sensor minimize the strongest scattering contribution: the ground surface reflection.

A new GPR system designed at Northeastern University, and fabricated at both Lawrence Livermore National Labs (LLNL) and Geo-Centers, Inc. reduces this ground clutter by illuminating the sample ground surface with a forward propagating, quasi-planar wave, and receiving the scattered signals with a two-dimensional multistatic array. Since the scattering by a small target is relatively isotropic, while scattering by the ground is primarily specular, a planar transmitted signal is well suited for shallow GPR detection. Plane wave illumination has another advantage beside clutter reduction compared to point source excitations: for a given target burial depth, the wave incident on a target from a plane wave source will always scatter the same way. For a point source, the incident wave on a given target will be illuminated from the side for one transmitter position and directly above for another. This constant exposure angle for the planar wave makes processing the returned signals more straightforward.

In both the LLNL and Geo-Centers systems, the excitation signal is sufficiently short in time duration to resolve small targets and discriminate the ground surface from a shallow buried target. The multistatic array concept provides for additional clutter rejection and time-domain focusing [3]. This focusing is accomplished by measuring, comparing, and summing the backscattered signals at each receiver in the narrow time window between the times when the residual ground reflected wave passes the receiver and before this wave re-reflects from the reflector components.

The finite-difference time-domain (FDTD) [4] method has been used to electromagnetically model the novel GPR configuration. We implemented the 2-D FDTD code to simulate the generation of the non-uniform plane wave, the scattering by the modeled dispersive soil ground surface, the scattering by the target, and the retransmission back into the air, confirming the clutter minimizing characteristics of this mine detector.

Parabolic Reflector Transmitter GPR

The quasi-planar transmitted wave is generated using an offset paraboloidal reflector antenna. The resulting wave is incident at 45 deg. to normal, and is fairly uniform over the portion of ground being investigated. Because the transmitted wave diverges very little from reflector to the ground, most of the power incident from the illuminating feed is transferred to the ground. Much of the ground reflected wave is directed further

forward, away from the operator, the reflector, and the receiving antennas, reducing clutter. In addition, the wave transmitted into the ground is incident on the target in the same manner for any antenna position: always as a plane wave with constant soil path length and incident angle. Since the scattering from an electrically small buried target is primarily isotropic, there will be a significant backscattered signal, propagating oppositely to the surface clutter signal, returning toward the receiving antennas.

Figure 1 shows the geometry of the parabolic reflector and the way it directs rays from the transmitting feed to the ground. Diverging rays leaving the transmitter reflect from the paraboloidal surface, emerging as parallel rays, in such manner as to keep the path length from the feed to an inclined wavefront constant. The inclined wavefront is perpendicular to -- and propagates along -- the axis of revolution of the parent paraboloid, which includes the parabola focus and vertex. Also, the reflector produces a beam of microwave energy with an abrupt drop in power outside the ray tube bounded by the perimeter of the reflector. As long as the distance from reflector to ground S is comparable to the projected reflector diameter D , the rays representing the transmitted wave will be parallel, and the wave will be planar. The governing equation for the nearfield of the reflector is: $S \ll 2 D^2 / \lambda$, so when the reflector is positioned close to the ground, the radiated wave is in the nearfield, and concepts of antenna gain and radiation pattern are irrelevant.

An offset section of the paraboloid is selected to avoid blockage of rays by the feed structure. In contrast to offset reflectors used in communications applications, this offset section is particularly deep, extending from the vertex past the focal point by twice the focal length, giving an F/D ratio of the parent paraboloid of about 0.15. The best offset section extends from 45 deg. to about 115 deg. from the symmetry axis, which ensures that the front and rear edges are at the same height above ground. For a parabolic focal length of 20 cm, the projected aperture diameter of the reflector is about 47 cm, which nominally illuminates an elliptical spot of ground with axes 47 and 67 cm. For a reflector positioned 33.5 cm above the ground, the center of this elliptical region is immediately below the front edge of the reflector, and all of the collimated rays from the reflector would reflect from a flat ground just missing the front of the reflector.

Figure 1. Geometry of the offset parabolic reflector

The receivers are positioned under the reflector, but behind the point on the ground at the center of the illuminated spot. The 4 receivers are arranged in a rectangular 2 by 2 array, with the forward pair separated by about 40 cm, and the backward pair by the same distance, 20 cm behind the forward pair. Since the receivers are displaced from the centerline, they do not appreciably block any of the wave from the reflector to the ground.

For FDTD modeling the dispersive soil, several modeling methods have been proposed to avoid convolution in the time domain [6,7]. Our method makes use of the Z-transformation. We approximate the frequency dependent conductivity using the (2-2) Pade' approximant

$$s(Z) = \frac{b_0 + b_1 \cdot Z^{-1} + b_2 \cdot Z^{-2}}{1 + a_1 \cdot Z^{-1}} \quad (1)$$

and assume a constant average dielectric constant. With the a_1 , b_0 , b_1 , b_2 parameters in (1) chosen to match the experimental data, such as Puerto Rican clay loam [8] with density 1.4 g/cc and moisture 10%, we have $a_1 = -0.88$, $b_0 = 0.9162$, $b_1 = -1.6766$, $b_2 = 0.7611$, and $\epsilon = 4.2$. The perfectly matched layer (PML) absorbing boundary condition is used in the FDTD model to terminate the computational grid [9,10]. Computational models of the parabolic reflector system indicate that the wave reflected by the offset parabola does indeed remain planar over the illuminated region of ground, and that the scattering by rough soil surface is primarily specular. In addition, the mine scattered signal appears to be circular, showing that the electrically small target scatters almost isotropically.

Lawrence Livermore National Laboratory System and Results

The Lawrence Livermore National Laboratory (LLNL) Micro-Power Impulse Radar (MIR) was used as the transmitter source for one of fabricated systems [5]. This radar source generates an impulse with pulse width of about 300 ps and frequency range from about 1.5 to 5 GHz (see Figure 2), and has the particular advantage of being small and extremely low cost: both important features for mine detectors used in developing countries. This source was assembled with a custom-built metallic offset paraboloidal reflector. Figure 3 shows the full mine detector prototype; Figure 4 shows the device performing measurements at the test site at LLNL. In this test, a non-metallic antipersonnel mine simulant was buried in dry sand 1 in. below a very rough surface. This is a particularly challenging detection problem, because the dielectric constants of the plastic body TNT filled mine and the surrounding soil are very close. In addition, the random rough surface height variation is of the order of the height of the mine, and its burial depth. Thus, the anomaly detection is frustrated by low signal to clutter both in terms of size and contrast.

The result of processing the measured signals is shown in Figure 5, with bright areas signifying anomalies. Although there is still appreciable clutter from the rough ground, the target is still visible in the center of the image. The extent of the rough ground variation precludes clutter suppression using purely signal processing means. However,

by ensuring that the ground scattered signal specularly reflects away from the receivers, the target signal can be discriminated from the clutter.

Figure 2 LLNL MIR pulse shape

Figure 5 Detection results for the LLNL MIR system for rough sand with AP mine buried 1 in.

Geo-Centers System and Results

Another mine detection system based on the offset parabolic reflector transmitter was fabricated by GeoCenters, Inc. The reflector consists of metallized fiberglass, and the antenna elements are proprietary Transverse Electromagnetic Rhombus (TEMR), fed by a 1 ns impulse shown in Figure 6.

The system is shown in Figure 7 as it is configured for measuring signals on the Northeastern University test track. The targets in this test were seven non-metallic antipersonnel mine simulants buried 1 in. in moist loam, with naturally occurring vegetation. While this soil surface was not as rough as in the LLNL test, there is significant realistic clutter from long grass. The seven targets were spaced roughly 60 in. apart.

Figure 8 shows the detection results by combining the registered signals from the four receivers each with the moving average background signal removed. It is apparent that six of the seven targets are detected (note the proximity to the indicated true positions), and only one false alarm is generated.

Figure 8 Detection results for the Geo-Centers TEMR system for vegetated moist loam with AP mine buried 1 in.

Conclusions

A novel GPR mine detection system that reduces ground surface clutter has been developed and tested. The detector uses an offset parabolic reflector to generate a forward propagating plane wave to illuminate the ground and a 2-dimensional multistatic array to focus and enhance the received backscattered signal. Numerical simulations support the concept of specular ground reflection with more isotropic target scattering.

Measured signals using both the LLNL MIR and the Geo-Centers TEMR radars for rough dry sand and vegetated moist loam indicate that small non-metallic targets can be detected and discriminated from the cluttered background, even when shallow buried to a depth of 1 in.

ABSTRACT

Microwave heating of soil offers the potential to enhance infrared signatures of buried objects such as landmines. In uniform soil, with no vegetation and a flat surface, images can be obtained showing the shape of the objects, to aid in their identification. Combined with other subsurface imaging modalities, this promises a reduced false alarm rate, leading to more effective demining operations. However, in the presence of rough ground, non-uniform soil, vegetation, and solar heating, the signatures become much more complicated. In this work, we examine some of these issues, based on outdoor experiments and a two-dimensional model.

Key Words: Microwave heating, infrared imaging, landmine detection.

1. INTRODUCTION

We have previously reported analytical and experimental results showing that microwave heating of the ground can produce enhancements of the infrared signature of buried objects [DiMarzio, et. al., Sept. 1998], and we have described two time periods in which different signatures impart information about the electromagnetic properties and thermal properties, respectively [DiMarzio, et. al., 1999]. In those works, analysis was performed assuming a flat ground surface, and experiments were conducted in controlled laboratory settings, with dry sand or soil in the absence of vegetation. Here we report on preliminary measurements in an outdoor environment and a model which accounts for surface roughness.

Previous laboratory work had been hampered by the requirement to enclose the test area in a screen box to prevent exposure of the IR camera and the personnel to microwave

energy. In the outdoor experiments, we used an elliptical reflector antenna to direct the energy to the test area. We observed that this antenna was very successful in keeping the energy concentrated on the target, with the result that a short distance away, microwave power density was at a safe level. This permitted us to operate the IR camera during heating.

However, we also determined that spatial and temporal variations in heating by solar energy exceeded the temperature fluctuations we were trying to observe to detect buried objects. Furthermore, the surface signatures were severely contaminated by the presence of surface irregularities and vegetation. These issues led us to modify the model reported in the previous work to accommodate surface roughness. Future work with the model will also accommodate solar heating and vegetation.

2. EXPERIMENTS

The outdoor experiments were performed at the Army's Cold Regions Research and Engineering Laboratory (CRREL), in Hanover, NH, on 29-30 June 1999. Two cameras were in use; a modified Mitsubishi IR focal-plane array (320X240 pixels), and a Boeing microbolometer. A key element of the project was the use of an elliptical reflector for the microwave energy. In previous research, the microwave source, a 2.45-GHz. magnetron from an industrial microwave oven, attached to a homemade copper feed horn, was enclosed in a copper-screen shield which prevented microwave energy from leaking into the surroundings. Infrared images taken through the screen were not satisfactory, and it was necessary to stop heating and open the enclosure in order to take pictures. The upper left portion Figure 1 shows the test site with the reflector and feed horn mounted on a gantry crane. The feed horn is at one focus of the ellipsoid, 0.5 meters from the vertex, while the other focus, 4.5 meters from the vertex, is placed approximately at the ground surface. Because the ellipsoid is large (1.5 meters across), the radiation pattern from the feed horn is contained within the reflector, the power at the edges of the reflector is almost zero, and sidelobes are insignificant. The center right portion of the figure shows the two infrared cameras mounted on tripods. Survey measurements taken continuously during the heating experiments revealed an exposure level at and beyond the rail seen at the base of the tripods of less than the detection limit of our power meter, a fraction of a milliwatt per square centimeter. During experiments, personnel were kept outside this rail although measurements of power were still below the safety standard at locations considerably closer to the heated area.

Three mine simulants, shown in the right-hand side of Figure 1, were buried just below the surface near the focus of the ellipsoid. Because the antenna performed better than expected, we only heated the area containing one of the simulants. The grass in the area where the mines were buried was very dense, as shown in the left panel of the figure.

Figure 1 — Outdoor Test Site at Cold Regions Research and Engineering Laboratory, with Equipment in Place for Microwave-Enhanced Infrared Thermography.

3875-15

Solar heating of about 1000 Watts per square meter is often mentioned as sufficient for infrared detection of buried objects such as landmines. Typically, one waits until the diurnal heating or cooling reaches a maximum, and then examines an infrared image of the scene. In addition, the presence of clouds can dramatically alter the temporal distribution of solar heating. Figure 3 shows an example, taken from the two days of our test. On the first day, solar irradiance was only about half the normal level, and, although there were some short-term fluctuations associated with clouds, and there were some showers during the day, the overall heating was less than would occur on a sunny day. The temperature

Figure 2 — Area Where Mine Simulants Were Buried (Left), and the Simulants (Right).

3875-16

of the ground was relatively stable at the time of our experiment, as shown by the top curve of Figure 4, which indicates the surface temperature as a function of time. In both figures, the time axis is hours from midnight local time (0400Z) on 29 June, extending through two days, until the end of 30 June. Figure 5 shows an infrared image from the first experiment. The mine location clearly shows a level of heating greater than that of the surrounding environment, but there are a number of clutter signals in the surrounding area with temperatures equally high. Furthermore, the mine signature is not particularly well defined, probably because of the clutter caused by the vegetation. This can affect the microwave heating directly because of the absorption of the microwave energy, and indirectly, by modifying the water content of the soil by varying the exposure to sunlight. More importantly, it can affect the temperature reported by the infrared camera. In some cases, the camera will see through gaps in the vegetation, while in other pixels it will see leaves of grass. Some pixels may include some of each. Clearly further work in processing is required.

The second test occurred at a time of intense increase in solar irradiance in the visible, as morning clouds began to clear. Note the increasing surface temperature following the slight flattening during the cloudy period. Note that the high rate of increase in temperature is seen at depths of greater than 10 centimeters. This presents the greatest challenge for observing microwave-enhanced infrared signatures, because the ground temperature is changing rapidly, and the rate of change is also changing rapidly. Thermocouple readings on the ground showed unpredictable behavior over several Kelvins, depending on

Figure 3 — Time History of Solar Irradiance in 2π Steradians, at the Test Site.

3875-18

probe placement, shading by grass, and changes in sunlight and soil composition. In general these changes were larger than those we expected to observe from microwave heating. Figure 6 shows an image taken during this second experiment. Although there is a suggestion of increased heating in the area near the mine, it is evident that there are much higher temperatures in other regions. Any attempt to make measurements based on microwave heating will be require extensive processing to remove the effects of such clutter. It should be pointed out that these problems arise for both passive solar and microwave-assisted heating scenarios.

Figure 4 — Time History of Surface and Underground Temperatures.

2. MODEL DEVELOPMENT

In the previous work, we reported a model for microwave heating of landmines buried in soil, based on a finite-difference, frequency-domain solution of the wave equation and a finite-difference solution of the thermal diffusion equation. In light of the results reported in the above section, we see the need to expand our model to address rough surfaces, vegetation, and solar energy. The first step is the inclusion of a rough surface. Figure 7 shows a result for thermal diffusion in the presence of a landmine (TNT) under a rough surface in Puerto Rican clay loam, for a microwave heating at 2.45 GHz. Because the mine is less conductive than the surrounding soil at this frequency, it heats less. At this point, the microwave model has not been implemented, so the flat-surface model is used, with data set to zero in the air above the actual rough surface. Thus the electromagnetic distribution of energy is not correct but, given that distribution, the thermal behavior is

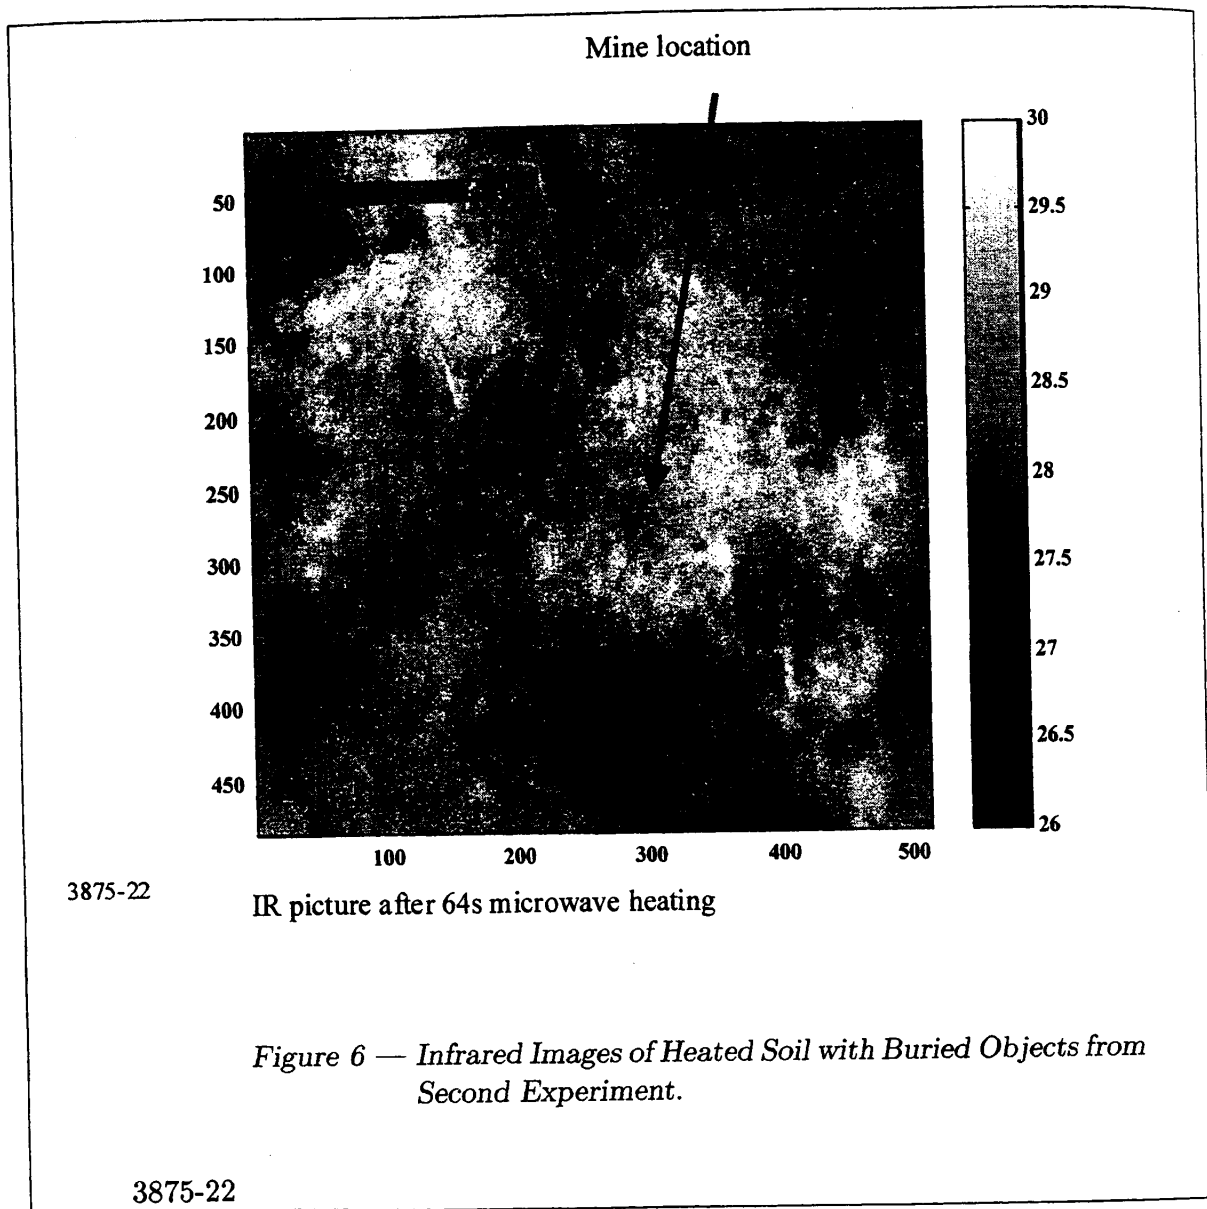

2. MODEL DEVELOPMENT

In the previous work, we reported a model for microwave heating of landmines buried in soil, based on a finite-difference, frequency-domain solution of the wave equation and a finite-difference solution of the thermal diffusion equation. In light of the results reported in the above section, we see the need to expand our model to address rough surfaces, vegetation, and solar energy. The first step is the inclusion of a rough surface. Figure 7 shows a result for thermal diffusion in the presence of a landmine (TNT) under a rough surface in Puerto Rican clay loam, for a microwave heating at 2.45 GHz. Because the mine is less conductive than the surrounding soil at this frequency, it heats less. At this point, the microwave model has not been implemented, so the flat-surface model is used, with data set to zero in the air above the actual rough surface. Thus the electromagnetic distribution of energy is not correct but, given that distribution, the thermal behavior is

correct. It is evident that the thermal diffusion process is influenced by the rough surface, but that the mine signature is still visible at the surface as it was in the case of a smooth surface. The two panels on the left show color plots of temperature for the cross-section during heating, while those on the right show the same plots during cooling. In the lower left plot, the mine has begun to heat through conduction from the surrounding hotter soil. As the mine heats up, a hot spot is observed in the local high point in the surface above the mine. Later this hot spot disappears through conduction and convection, and the shape of the mine is evident in a cool spot, although the mine continues to increase in temperature.

4. CONCLUSIONS AND FUTURE PLANS

We have shown that microwave heating of soil can be used to enhance infrared signatures of buried objects. Both solar and microwave-enhanced signatures are influenced by surface irregularities, vegetation, and variations in solar heating. At times of high solar heating, the microwave enhancement can be masked by clutter. Vegetation masks the transfer of energy in and out of the soil. Nevertheless, bare spots can be observed through the vegetation, and imaging algorithms may be developed to capitalize on these bare spots. The model will be completed to account for vegetation and solar heating. Experiments

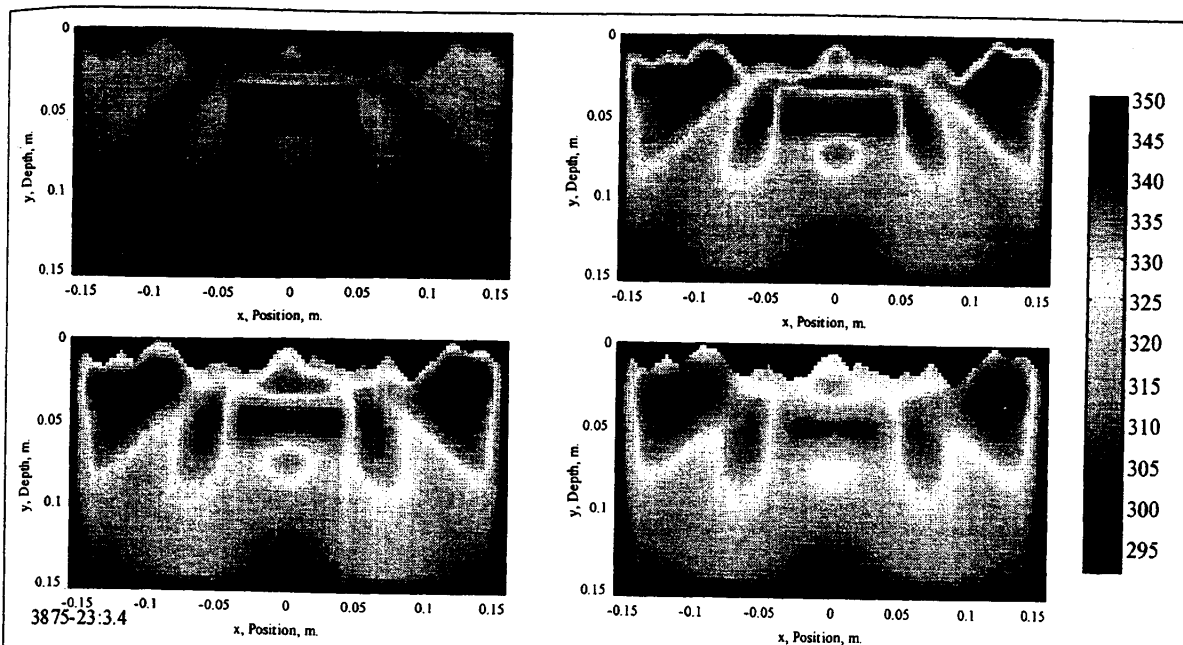

Figure 7 — Preliminary Results from Model for Microwave Heating of Ground with a Rough Surface.

3875-23

and analysis will begin to address whether the use of different wavelengths and fusion with other sensing modalities can provide help in reducing the effects of clutter. If these issues can be addressed, microwave-enhanced infrared thermography can provide a valuable tool for detection of buried objects.

5. ACKNOWLEDGMENT

We wish to thank Dr. Gary Koh of the U.S. Army Cold Regions Research and Engineering Laboratory, in Hanover, New Hampshire, for the use of his test site, supporting instrumentation, and for his help during the test program. We also thank Arnold Dean of GeoCenters for providing the elliptical reflector. This work was sponsored by the OSD MURI Program under Army Research Office Grant number DAAG55-97-1-0013.

ABSTRACT

Detection of buried objects presents a formidable challenge which requires many different approaches. Infrared imaging has proven its versatility in a number of applications. Recent advances in technology have opened the door for spectroscopic imaging systems which can produce images of reflectivity or emissivity as a function of two spatial dimensions and wavelength. These imagers have been largely unexploited for detection of buried and surface-laid landmines.

Several promising opportunities exist for this application in different parts of the infrared spectrum. Variations in soil moisture content, vegetation condition, and soil composition may well be related to the presence of shallow-buried objects. In addition, polarimetric signatures appear useful in detecting man-made objects on the surface and may even help in detecting buried objects.

This paper will explore both the feasibility of using infrared spectral imagery in the 1-to-2.5 and 8-to-12 micrometer infrared bands to detect surface-laid and buried objects.

1. INTRODUCTION

The detection of landmines is widely recognized as an extremely difficult challenge, requiring multiple sensing strategies with different operating scenarios, sensor modalities, and algorithms. In this work, we explore the use of hyperspectral imaging in two bands of the infrared spectrum. We consider the short-wavelength infrared band from 1 to 2.5 micrometers, in which water and soil contamination are detectable using scattered sunlight, and the long-wavelength IR band from 8 to 12 micrometers, in which material properties and surface characteristics can be determined from emissions from the surface. In the latter case, we also consider polarimetric measurements.

Recent advances in technology allow nearly simultaneous imaging and spectral characterization in what is called hyperspectral imaging. A dispersive element is placed in front of a camera and multiple images are collected. In one configuration, the dispersive element acts as a filter, allowing the camera to capture an image at only one wavelength. Successive pictures are collected at different wavelengths. In another, the optical system causes the camera to image a single line in space, for example, in the horizontal direction on the camera, while the dispersive element distributes the contributions from different wavelengths across the camera in the vertical direction. If the camera is scanned or mounted on a vehicle, successive pictures build a two-dimensional image in a "pushbroom" mode. In either case, a three-dimensional array of data is obtained, in which the coordinates correspond to two spatial dimensions and wavelength. Conventional spectroscopy can be performed on each spatial pixel, or more sophisticated processing can be performed on the full three-dimensional array. Furthermore, data can be collected in polarimetric channels to extract further information from the scene.

In preparation for using hyperspectral imaging in the detection of landmines and similar objects, we explore the spectra of relevant materials to determine what signatures may be expected in conditions related to demining. Here we report on some studies in two wavelength bands.

2. SHORT-WAVELENGTH-IR MEASUREMENTS

In the short-wavelength infrared band, self-emission is low, and the spectrum of an object is determined by reflected sunlight. The reflection spectrum can be used to determine composition of a material. Frequently soil composition varies strongly with location. Disturbance of the soil in laying a buried mine will result in deeper soil being brought to the surface and the spectral difference between the disturbed region and the surroundings will remain for a long time. Given the many natural variations which can be detected in soil spectra, this technique is not sufficient to locate landmines by itself, but is likely to be useful in conjunction with others, particular to address the issue of false

A laboratory spectrometer was modified to hold soil samples in a reflective mode. Soil samples were placed in the holder and measured from 1.1 to 2.5 micrometers. Figure 1 shows two soil spectra with different water content. Soil 1 is a loam with 10%

Figure 1 — Soil Spectra with Varying Water Content.

clay, 50% sand and 40% silt, while Soil 2 has 10% clay, 65% sand and 25% silt. There are significant differences in the content of several elements as well. The difference in absorption around 1.9 micrometers is a measure of the water content. In soil 1, several other water absorption lines become apparent. Soil 1 has an overall higher reflection. The overall reflectivity is probably not a useful parameter in detecting burial of objects, as wide ranges of variation are to be expected, and in operational scenarios, these results would be affected by lighting conditions. What may prove useful is the comparison of adjacent regions. Thus, hyperspectral imaging will permit simultaneous detection of the spatial variations in overall reflectivity and spectral features.

The emerging technology of acousto-optical tunable filters may permit the development of hand-held hyperspectral cameras to detect soil moisture, spatial changes in soil composition, and perhaps changes in the condition of vegetation, which can indicate the presence of objects below the surface. Used in conjunction with other, more established demining detectors, this technology could help to reduce the false-alarm rate and thus improve the speed of the overall demining process.

3. LONG-WAVELENGTH-IR MEASUREMENTS

In the long-wavelength infrared band, the contribution of scattered sunlight is low and the spectrum of an object is determined by its temperature and emissivity. Infrared thermography can detect changes in these parameters and, combined with polarimetry, can detect different surface characteristics. The emissivity of a surface depends on its composition, shape, and orientation. In the case of soil, transmission does not occur, so conservation of energy dictates that the sum of reflectivity and absorption equal unity.

Figure 2 — *Fresnel Reflection from a Lossy Medium.*

Furthermore, the laws of thermodynamics require that the absorptivity equal the emissivity. Thus, emissivity is related to reflectivity by

$$\epsilon_x(\lambda, \theta) = A_x(\lambda, \theta) = 1 - R_x(\lambda, \theta),$$

where ϵ is the emissivity, A is the absorptivity, R is the reflectivity, and all are functions of the wavelength λ , the angle of observation θ , and the state of polarization, x . As an example, Figure 2 shows the Fresnel reflectivity of a surface having an index of refraction equal to $1.5 + 1.25i$. At the grazing angles typical of forward-looking mine detection, a significant difference exists between the two polarizations. This plot is for a smooth surface typical of a man-made object. For rough surfaces, the results become more complicated, involving details of the surface texture.

Spectral measurements were made using a FTIR spectrometer with a wire-grid polarizer before the lens against realistic target scenes on the test range shown in Figure 3.

Polarimetric difference images showed greatest contrast at polarization angles of zero and 60 degrees. Figure 4 shows results for a plastic frisbee on a sand background. The left panel shows the two spectra and the right panel shows their difference. The difference is particularly significant in view of the fact that the plastic only subtends 7 percent of the field of view. Interestingly, the polarimetric signature depends strongly on wavelength, and a polarimetric sensor could see a positive, negative, or zero signal, depending on the wavelength band.

Table 1 summarizes the polarimetric data. When the polarimetric signatures are converted to degree of linear polarization (DOLP), and corrected for the fraction of the field of view that is filled by the target, it is evident that strong polarimetric signatures exist for several targets.

Table 1
Key Polarimetric Results

	Sandy Asphalt	Tan CARC	Frisbee	Green CARC
DOLP (Tgt and Bkg)	0.02	0.02	0.01	0.02
Fractional FOV	?	0.24	0.07	0.15
Angle Normal to LOS	83	59	75	69
DOLP (Tgt Only)	?	0.08	0.14	0.13

ARS-68-03 14

Figure 3 — Outdoor Test Range.

Polarimetric differences for a tan CARC (chemical-agent resistant coating) target are shown in Figure 5. In this case, the CARC target is placed against sandy asphalt, which has a net polarimetric signature, integrated over the spectrum, as indicated by the degree of linear polarization shown in Table 1, similar to that of the CARC. However, the spectral signatures are noticeably different, as are the spectral polarimetric signatures, suggesting that both polarimetry and spectral data are important.

The possibility also exists for detecting soil disturbances associated with mine burial in a spectral band. Figure 6 shows spectra obtained in the laboratory for a "chunk" of soil removed from near the test range and for the same soil after being pulverized. The chunk was placed on an IRTAN window in the laboratory spectrometer, and is not considered representative of soil which will be encountered *in situ*. Nevertheless these results suggest that soil characteristics are dependent upon recent activity. These results

Figure 4 — Polarimetric Spectra for Plastic Frisbee.

are consistent with recent data in the literature [Johnson et. al.], which suggest that the increased reflectivity in the 8 to 10 micrometer region of the spectrum is caused by an increase in the number of small particles which are created when the soil is disturbed, but are later removed through erosion by wind and water. Polarimetric signatures of these samples were not investigated, but such a study is proposed for the future.

In conclusion, polarimetric signatures in the band from 8 to 14 micrometers are useful in detecting surface objects. Hyperspectral images are also useful and appear to be complementary. Combined polarimetric, hyperspectral FIR imaging may yield additional information about landmines scattered on the surface. Preliminary measurements suggest that this technique can be used to detect subsurface landmines as well, indirectly by measuring soil disturbances.

Future plans include, in the short term, additional measurements and polarimetric images using an uncooled microbolometer camera and a wire-grid polarizer. In the long term, filters will be added to produce hyperspectral, polarimetric images. More careful studies of different types of surfaces and soils will continue, using the existing FTIR instrument.

ABSTRACT

A short pulse of laser light can act as a source of acoustic energy for acoustic imaging. Although there are a number of mechanisms by which the light pulse may generate sound, all require a pulse of high peak power density and short duration. In this work, we address examples where the material is highly absorbing at the laser wavelength, and the sound is generated near the surface. In these cases, there exist two different mechanisms which can convert the light to sound. The first is heating followed by expansion, and the second is generation of a plasma in the air above the surface. In the first case, sound generation occurs in the medium of interest and the energy efficiency can be very high, in the sense that no reflection losses occur. We present two applications from our own research.

1. INTRODUCTION

Acoustic imaging is useful in many different applications, ranging from the everyday example of a carpenter locating a stud by tapping the wall, to advanced ultrasound imaging of the body. A common requirement in all applications is the coupling of energy from a sound source into the material of interest. A pulsed laser offers several advantages as a

source of acoustic energy. First, it is remote. The laser can be a long way from the material to be tested [Li, et al.]. If the acoustic detection is accomplished with a laser vibrometer, then the complete acoustic imaging task can be performed from a long distance away [DiMarzio, et al.], for example, on hostile targets. Because of the good resolution possible with lasers, it is possible to make remote measurements with good transverse resolution, limited only by the size of the optics. Second, it is well calibrated. Many lasers are capable of delivering repeatable pulses. Third, it may be very efficiently coupled. Depending on the exact mechanism of interaction, sound may be generated in the medium itself, eliminating the losses associated with reflection at the surface. This will be discussed in more detail later. Fourth, optical properties (eg. spectroscopic) may be sampled acoustically, providing novel information.

Generation of sound by light is covered by several different names corresponding to different physical phenomena. We will begin with a cursory review some of the better known examples, before turning to the applications of interest in this paper. In an early application [Oraevsky], described as the photo-acoustic effect, light impinges on a sample of gas. If the wavelength of the light is tuned so that the gas is absorbing, a sound is produced, and detected by a sensitive microphone. The shape and duration of the acoustic pulse is determined by the interaction of the light and the medium. The strength of the acoustic signal, plotted as a function of the laser wavelength, yields the absorption spectrum of the gas.

In opto-acoustic imaging, light is incident on biological tissue. The tissue is weakly absorbing so that absorption occurs along the path of the light. In this case, an acoustic signal is generated which propagates to the detectors. The shape of the acoustic pulse is determined by the travel time from each point along the laser beam to the detectors and the absorption profile of the tissue at the laser wavelength. The primary absorber of light in tissue is hemoglobin, which has a highly structured optical absorption spectrum, which changes when oxygen is bound to it. As a result opto-acoustic imaging can detect blood vessels, discriminating between veins and arteries [Oraevsky, et al.].

In contrast to these examples, in the applications to be discussed in the present paper, the optical absorption is strong, and most of the light is absorbed within a few optical wavelengths of the surface of the medium. Possible mechanisms of interaction are optical radiation pressure, various forms of heating and expansion, and plasma generation.

2. DETECTION OF SHALLOW-BURIED LANDMINES

Pulses of light have been used experimentally to detect buried objects such as landmines [Li et. al.]. Figure 1 shows an example of an acoustic pulse generated in sand by a 100 nanosecond, 150 millijoule pulse of light from a carbon-dioxide laser. The receiver is a B & K model 8103 hydrophone with a bandwidth of 100 kHz, buried a few centimeters below the surface. As the sand is strongly absorbing at the 10.6-micrometer wavelength of

the laser, most of the light is absorbed, rather than reflected. The absorption depth is of the order of the wavelength, so most of the light is absorbed in the first few micrometers of soil. This light heats the sand faster than thermal diffusion can cool it, with the result that the sand expands at the point where the laser is incident, and produces an acoustic pulse. In most acoustic imaging systems [Sabatier and Xiang; Scott et al.; Donskoy and Ekimov], the sound is generated in the air above the soil, and most of it is reflected because of the impedance mismatch at the interface. In the case of laser-induced sound, at least in this configuration, with 150 mJ of energy in a 1-cm diameter, the light is absorbed in the sand, the acoustic pulse is generated there, and a substantial fraction of the laser energy is converted to sound in the sand. Although the laser pulse is only 100 nanoseconds, the resulting sound pulse width is a few microseconds, because of the thermal properties of the sand.

The times and energy densities discussed above are consistent with other qualitative observations we have made over the years [unpublished]. For example, one of us used this effect to locate a carbon-dioxide laser beam in order to align a laser radar, having 20 millijoules of energy in a pulse length of 2 microseconds and pulse-repetition frequency of 140 Hertz. The 140-Hz tone was readily apparent to the ear when the beam impinged on a variety of surfaces, even though the beam diameter was almost 30 centimeters. In contrast, a recent attempt at generating sound in sand with a laser pulse length in the tens of microseconds failed. In the latter case, although the pulse energy was sufficient, the longer pulse meant that power was delivered so slowly that thermal diffusion cooled the sand during the pulse, leading to a lower peak temperature and less expansion of the sand. Calculations have shown that radiation pressure of light produces a lower acoustic pulse than the heating effect under our conditions. As the pulse length becomes longer, of course, the heating effect becomes smaller, while the effect of radiation pressure remains substantially the same.

Figure 2 shows the result of scanning a laser beam over the surface of the sand in two dimensions, and processing the signals to determine the time of reflection from a pair of buried hockey puck halves. The color shows the strength of the strongest reflected signal. Because the ground location was known approximately, the ground signal was removed, and the strongest remaining signal was used. In addition to the signal strength, this technique also provides depth information, which is useful in imaging as well. The receiver was a barium titanate transducer with a center frequency of 29 kHz and a bandwidth of about 5 kHz, located above the surface. Other receivers such as the 100-kHz hydrophone mentioned earlier, and an inexpensive microphone were also used, but this transducer produced the best results. The narrow bandwidth removed low-frequency noise, provided high sensitivity and reduced noise. The frequency was sufficiently high to provide good depth information and transverse resolution, but not so high as to be absorbed before reaching the buried object. The sand box was moved while the laser and microphone remained in the same locations. The halves are oriented so that their flat surfaces are toward the surface of the sand, and are placed about 1 cm apart, and about 1 centimeter deep. This

depth is particularly important for the demining application, because ground-penetrating radars have difficulty discriminating shallow buried objects from surface returns. Note that the shape and space between the pucks are easily resolved. The pulse is composed of frequencies up to tens of kilohertz, so the wavelengths are on the order of a few centimeters and longer. Thus, this is an example of near-field imaging.

Increasing the power density raises the peak temperature and results in an increase in performance, but this increase has its limits. We have performed experiments with different laser spot sizes, and found that as the spot size is reduced, other effects begin to become important. One of these appears to be the generation of a plasma in the air above the sand. This is evident by the appearance of visible light being emitted from the contact point, in spite of the incident light having a wavelength well into the infrared. To an observer of the experiment, the resulting sound is impressive. A 18-mJ pulse produces a "pop" easily detected a few feet away and a 150-mJ pulse produces an explosive sound which attracts the attention of anyone in the laboratory. However, as impressive as this may be, the detection of buried objects has not been as successful. In this case, the sound is generated in the air above the sand. As seen in Figure 1, this produces a very different acoustic pulse with lower frequencies, and a slower sound speed. This wave is less absorbed

in the sand, but it must first pass through the air-sand interface where the loss to reflection is high. Furthermore, the plasma itself absorbs the light, and the plasma itself thus moves up away from the sand during the light pulse. Thus it appears that the best approach for detection of buried objects may be to use a pulse shorter than a few microseconds, with energy density just below that sufficient to initiate the plasma. This conclusion is offered somewhat tentatively, because the use of lower frequencies shows great promise for mine detection in view of their greater penetration. Because this application is based on near-field imaging, the resolution is not determined by the wavelength, and the normal benefits of smaller wavelengths are not relevant. Research is currently under way to determine the best compromise between the ability to transfer energy to the medium and the frequency distribution of that energy. To date, most of the detection has been done by detecting the acoustic signal directly, but in the future, a laser vibrometer will make the technique completely remote, and perhaps more sensitive.

3. NON-DESTRUCTIVE TESTING OF PAPER

The second application of Laser Induced Acoustic (LIA) sensing is in the field of Non-Destructive Testing (NDT). When employed for NDT, LIA used to generate an acoustic pulse, either through a process of localized thermal expansion, an ablation shock wave or both. The generated acoustic pulse then either propagates through the test medium or on the surface. Surface detection is performed through interferometric techniques or Doppler shift detection via a coherent laser sensor.

Detection of the acoustic wave reveals information about the test medium in several potential ways. Interruption or reflection of the acoustic wave can pinpoint cracks or localized faults - such methods have been employed to interrogate the quality of aircraft skins or other critical components. Detection of the magnitude and time delay at a point removed from the initiation point of the acoustic wave can reveal information related to the material properties, such as density, stiffness and other mechanical properties.

Recent work performed at the Lawrence Berkeley Laboratory with the support of the U.S. Department of Energy, in collaboration with one of us, at Laser Science, Inc., has used the latter technique to measure the quality of paper, non-destructively and *in-situ*. This differs from the mine-detection application in several ways. It is a single-point measurement, and imaging is not required. The resulting acoustic wave is inherently two-dimensional, being contained within the paper. The first parameter to be measured is the speed of the wave and depth of penetration is not an issue, so high frequencies are of primary importance.

The key elements of paper quality include overall strength (tensile and compressive) fiber orientation and fiber strength. Classical methods to check these quality control parameters include cutting samples from the large paper rolls after the manufacturing process is completed and the large "webs" are shut off. The paper is then inspected and the manufacturing process modified to correct any errors and improve the quality of the paper. This is a time-consuming operation that costs money while wasting significant amounts of material and energy. Contact methods employing ultrasonics have been developed and employed that used transducers to generate and sense acoustic waves to monitor paper quality: However, the pressures needed to interface the transducers to the paper roll are only adequate for the heavier grades of paper and damage the lighter grades.

The non-destructive, and in this case totally non-contact, technique employing LIA uses a YAG or TEA CO₂ laser to generate a sub-microsecond laser pulse that is focused onto the paper that is streaming between the paper rollers in the web at 30 meters per second. As the pulse duration is quite short relative to the speed of the moving paper, the acoustic pulse that is generated is essentially a point source. In conjunction with the firing of the pulsed laser, a laser-based interferometer "stares" at a probe point on the paper which is at a fixed location (several millimeters) offset from the point where the acoustic pulse is generated. Because the paper is moving, the probe point (where the

acoustic pulse is detected) must actually travel at a speed equal to that of the moving paper to maintain the fixed offset between acoustic point source and probe point. This is accomplished through the use of a rotating mirror and optical encoder, which essentially freezes the paper motion relative to the probe point and synchronizes the pulsed laser.

The key parameter measured in this technique is the time delay between pulsed laser firing (start of acoustic pulse) and detection of the pulse at the probe point. Knowing then the fixed offset distance provides the acoustic velocity of the wave in the paper, which is then related to elastic properties of the medium. Empirical relationships have already been established to relate elasticity to properties of strength.

4. CONCLUSIONS

Laser-induced acoustic pulses can be used for a variety of applications in many different types of media. The mechanisms of interaction are many, and vary with the characteristics of the media, the wavelength of the laser light, the pulse length, total energy, and spot size. Different mechanisms generate different acoustic pulses which can be tailored to the application. Two examples have been considered in which the medium is highly absorbing. In both cases, the propagation time of the acoustic wave is of importance. In the landmine case, near-field imaging is possible because the objects of interest are a few wavelengths from the surface. In the second example, the goal is to measure the speed of sound in a thin medium. In both cases, the laser offers significant advantages over other acoustic imaging techniques because of its remote measurement capability with good transverse resolution, its repeatability, and its efficiency.

Imaging Dielectric and Conductivity from GPR Measurements

Alan J. Witten

School of Geology and Geophysics, University of Oklahoma,
810 Energy Center, Norman, OK 73019-0628

ABSTRACT

It has been shown that, for non-conductive backgrounds and non-conductive spatial heterogeneities, two- and three-dimensional images of spatial variations in wave speed can be reconstructed from broadband ground penetrating radar (GPR) measurements. In diffraction tomography, the reconstructed image is the so-called object function which, for non-conducting heterogeneities, is one minus the square of the real refractive index. In cases where spatial variations in electrical conductivity exist, the object function is complex with real part related to relative changes in the real refractive index and the imaginary part representing the spatial variations in conductivity. Thus, by considering the complex object function, it is possible to reconstruct images of both wave speed and conductivity. The procedure presented here is used to reconstruct images of wave speed and conductivity for several buried targets.

Keywords: diffraction tomography, ground penetrating radar, wave speed, electrical conductivity

1. INTRODUCTION

Tomographic imaging has been applied in geophysics to wave-based data to reconstruct images of geologic structure and isolated buried objects. There are various imaging procedures ranging from straight ray algorithms to non-linear inversions. The particular type of imaging algorithm considered here is diffraction tomography¹. Geophysical diffraction tomography (GDT) was first considered for a multi-bistatic transmission mode measurement geometry using a single frequency and the synthesis of multiple direction of insonifying plane waves². This work has been extended to a multi-monostatic measurement geometry where wave sources and receivers are assumed to be co-located and moved in unison along a line or over a plane^{3,4}. Such a measurement geometry is typical of GPR measurements and, for this geometry, broadband information is used.

Traditionally, GDT has been used to reconstruct images of the spatial variations in wave speed. In many applications, the problem is one of target discrimination and, as such, there may exist many buried targets of similar size, shape, and wave speed while only a relatively small number of these targets are of interest. For example, land mines are relatively small and may appear as many other near-surface naturally-occurring or man-made objects. If the object of a geophysical investigation is to locate all possible land mines for subsequent remediation, the cost associated with the removal of all false positives could be prohibitive. An even worse situation is one where land mines exist in a host soil where the wave speed of the land mine is nearly that of the soil. In such cases, land mines may not be detected. It is clear that there is a need to develop better techniques for the discrimination of buried targets and one possible approach to this problem is to reconstruct images of wave speed and electrical conductivity of buried objects. By considering two physical properties, there is more information for target discrimination and less likelihood of a target being "invisible".

For transmission mode radio wave measurements, it is possible to reconstruct wave speed and electrical conductivity using straight ray algorithms. In these methods, perturbations in travel time are associated with spatial variations in wave speed while amplitude variations are associated with attenuation induced by spatial variations in electrical conductivity. Apart from the known limits of straight ray algorithms, there is an addition problem

associated with the separation of wave speed and attenuation from travel time and amplitude. The Green's function for wave propagation is complex so that there is a blending of real (propagation) and imaginary (attenuation) resulting in the travel time being corrupted by attenuation and vice versa. While diffraction tomography has its own limitations, it does not assume any explicit separation of travel time and amplitude and, subject to a weak scattering approximation, rigorously treats the blending of real and imaginary parts^{5,6}. By considering the imaging reconstruction to be complex, a method is established here whereby separate images of wave speed and electrical conductivity can be obtained.

2. MULTI-MONOSTATIC BROADBAND IMAGING

The GDT algorithm has previously been published where only spatial variations in wave speed were considered^{3,4}. Since the separate imaging of wave speed and conductivity is based on this algorithm, it is summarized here. Since the examples given later are based on one-dimensional measurements over a line on the ground surface, only the two-dimensional imaging algorithm is presented. This algorithm can easily be generalized to three dimensions for data acquired over a plane.

The reconstruction of wave speed from broadband multi-monostatic measurements is based on the inversion of the frequency domain wave equation subject to the Born approximation⁷ given by

$$u_s(\mathbf{r}) = k_0^2 \int d\mathbf{r}' G(|\mathbf{r} - \mathbf{r}'|) u_0(\mathbf{r}') O(\mathbf{r}'), \quad (1)$$

where u_s is the temporally Fourier transformed time-domain scattered field, G is the Green's function for the scalar Helmholtz equation, u_0 is the incident wave, for a non-conducting background and spatial heterogeneities, $k_0 = \omega \sqrt{\mu_0 \epsilon_0}$ is the background wavenumber for frequency ω , magnetic permeability μ_0 , and dielectric constant ϵ_0 , $O(\mathbf{x}) = 1 - (c_0^2/c^2(\mathbf{x}))$ is the object function that defines the spatial variations in wave speed $c(\mathbf{x}) = 1/\sqrt{\mu_0 \epsilon(\mathbf{x})}$ associated with spatial variations in dielectric $\epsilon(\mathbf{x})$ in terms of the background wave speed $c_0 = 1/\sqrt{\mu_0 \epsilon_0}$. It has been assumed in Eq. (1) that the incident field u_0 arriving at the receiver has been removed from the data either by appropriate time gating or filtering so that this component of the data is absent in u_s .

For a co-located point source and receiver, the incident field u_0 is given by $G(|\mathbf{r} - \mathbf{r}'|)$ so that Eq. (1) becomes

$$u_s(\mathbf{r}) = k_0^2 \int d\mathbf{r}' G^2(|\mathbf{r} - \mathbf{r}'|) O(\mathbf{r}'). \quad (2)$$

Assuming that the measurements are made at positions ℓ on a line in an x, z coordinate system $\mathbf{r} = (\ell, 0)$ where z is measured vertically upward, the plane wave expansion for the Green's function G can be used⁸, the data spatially Fourier transformed with respect to measurement location ℓ

$$\tilde{u}_s(\kappa) = \int d\ell e^{-i\kappa\ell} u_s(\ell, 0),$$

and a resulting integral approximated by stationary phase to give

$$\tilde{u}_s(\kappa) = \frac{ik_0 e^{i\pi/4}}{4\sqrt{2\pi} \sqrt{4k_0^2 - \kappa^2}} \tilde{O}(\kappa, \sqrt{4k_0^2 - \kappa^2}), \quad (3)$$

where

$$\tilde{O}(\kappa, \sqrt{4k_0^2 - \kappa^2}) = \int d\mathbf{x} e^{-i(\kappa x + \sqrt{4k_0^2 - \kappa^2} z)} \frac{O(\mathbf{x})}{\sqrt{|z|}}$$

and it is clear that Eq. (3) relates the one-dimensional spatial Fourier transform of the data to the two-dimensional spatial Fourier transform of the object function divided by the square root of the depth. This equation can be used to represent the Fourier transform of $O_1 = O/\sqrt{|z|}$ in terms of the data as

$$\tilde{O}_1(\mathbf{K}) = -\frac{i}{k} 4\sqrt{2\pi} \sqrt{4k_0^2 - \kappa^2} e^{-i\pi/4} \tilde{u}_s(\kappa), \quad (4)$$

where $\mathbf{K} = (\kappa, \sqrt{4k_0^2 - \kappa^2})$.

Images of object function and hence wave speed can be reconstructed by inverting the two-dimensional spatial Fourier transform given by Eq. (4). Typically, data is acquired over uniform spacings in ℓ and the spatial and temporal Fourier transforms of u_s result in \tilde{u}_s being known at uniform intervals in ω (or alternatively k_0) and κ . To avoid \mathbf{K} -space interpolations necessary to implement the inverse Fourier transform, this inverse transform is expressed as integrals over κ and k_0 to give

$$O(\mathbf{x}) = \mathcal{L}[\tilde{u}_s], \quad (5)$$

where

$$\mathcal{L}[\] = -\frac{4i\sqrt{2}}{\pi\sqrt{\pi}}\sqrt{|z|}e^{-i\pi/4} \int dk_0 \int \frac{d\kappa}{\sqrt{4k_0^2 - \kappa^2}} e^{i(\kappa x + \sqrt{4k_0^2 - \kappa^2} z)} [\], \quad (6)$$

and O is taken to be real. Figure 1 shows the \mathbf{K} -space coverage over which \tilde{O}_1 is known. From this coverage, expectations of the images resulting from the application of Eqs. (5) and (6) can be deduced. First note that there

Figure 1: Illustration of the \mathbf{K} -space coverage of the multi-monostatic imaging algorithm where $\mathbf{K} = (K_x, K_z)$.

is no coverage at the origin. This implies that there is no spatial DC information present and the reconstructions will represent only the boundaries associated with changes in wave speed. This is common to linearized reflection mode imaging. Another artifact associated with the lack of \mathbf{K} -space coverage at the origin is the reconstruction of O will necessarily have a zero mean. Experience with this algorithm has established that, for features that are large compared to a wavelength, a zero mean is produced by filling the otherwise hollow interior of a feature with an opposite contrast. For targets that are small compared to a wavelength, a zero mean is produced by a ring around the feature having an opposite contrast. Concentric rings around the image of objects will occur as a result of bandwidth limitations. Although the coverage shown in Fig. 1 indicated information at $K_z = 0$ this can only be achieved when measurements extend out to $\ell = \pm\infty$. Since can never be the case, the lateral boundaries of features can never be reconstructed.

3. IMAGING OF WAVE SPEED AND ELECTRICAL CONDUCTIVITY

It can be shown that the procedure outlined in Sect. 2 can be directly used to separately image wave speed and electrical conductivity. In the more general case of a non-conducting background and a heterogeneity that has both

a difference in wave speed and electrical conductivity with respect to the background, the object function can be expressed as

$$O(\mathbf{x}) = 1 - \frac{k^2(\mathbf{x})}{k_0^2} = 1 - \frac{\mu_0 \epsilon(\mathbf{x}) \omega^2 + i \mu_0 \sigma(\mathbf{x}) \omega}{\mu_0 \epsilon_0 \omega^2}, \quad (7)$$

where $\epsilon(\mathbf{x})$ and $\sigma(\mathbf{x})$ are spatial variations in dielectric and electrical conductivity, respectively. It is clear from this representation that the object function is complex where $O = O_R + iO_I$ and

$$O_R(\mathbf{x}) = 1 - \frac{\epsilon(\mathbf{x})}{\epsilon_0} = 1 - \frac{c_0^2}{c^2(\mathbf{x})}, \quad (8)$$

and

$$O_I(\mathbf{x}) = \frac{\sigma(\mathbf{x})}{\epsilon_0 \omega}. \quad (9)$$

Similarly, the two-dimensional spatial Fourier transform of the object function is complex where, from Eqs. (8) and (9),

$$\tilde{O}_R(\mathbf{K}) = 1 - \frac{\tilde{\epsilon}(\mathbf{K})}{\epsilon_0}, \quad (10)$$

$$\tilde{O}_I(\mathbf{K}) = \frac{\tilde{\sigma}(\mathbf{K})}{\epsilon_0 \omega}, \quad (11)$$

and $\tilde{O} = \tilde{O}_R + i\tilde{O}_I$.

From Eq. (4), the real part of \tilde{O}_1 is

$$\tilde{O}_{1R}(\mathbf{K}) = \Re \left\{ -\frac{i}{k} 4\sqrt{2\pi} \sqrt{4k_0^2 - \kappa^2} e^{-i\pi/4} \tilde{u}_s(\kappa) \right\}$$

so that the image of wave speed variations is simply the real part of $O(\mathbf{x})$ given by Eqs. (5) and (6). Since the two-dimensional Fourier transform of the spatial variations in electrical conductivity relative to the background dielectric ϵ_0 is $\sigma(\mathbf{K})/\epsilon_0 = \omega \tilde{O}_I(\mathbf{K})$, the two-dimensional spatial Fourier transform of this relative conductivity divided by the depth is given by

$$\omega \tilde{O}_{1I}(\mathbf{K}) = -\omega \Im \left\{ \frac{i}{k} 4\sqrt{2\pi} \sqrt{4k_0^2 - \kappa^2} e^{-i\pi/4} \tilde{u}_s(\kappa) \right\}.$$

It is now clear that spatial variations in wave speed can be reconstructed using

$$1 - \frac{c_0^2}{c^2(\mathbf{x})} = \Re \{ \mathcal{L}[\tilde{u}_s] \}, \quad (12)$$

and spatial variations in relative electrical conductivity can be reconstructed using

$$\frac{\sigma(\mathbf{x})}{\epsilon_0} = \Im \{ \mathcal{L}[\omega \tilde{u}_s] \}, \quad (13)$$

where \mathcal{L} is defined in Eq. (6).

This procedure is only valid when the background is non-conducting. In cases where there is a background conductivity (σ_0), the background wavenumber $k_0 = \sqrt{\mu_0 \epsilon_0 \omega^2 + i \mu_0 \sigma_0 \omega}$ is complex and the integral transform given in Eq. (3) is not a Fourier transform. Although more complicated and less computationally efficient, separate imaging of spatial variations in wave speed and conductivity can still be accomplished.

4. RESULTS

The reconstruction algorithms for wave speed and electrical conductivity given by Eqs. (12) and (13) have been applied to broadband GPR data acquired at two sites. The first is a test site where 400 MHz center-frequency antennas were used over a variety of known shallowly buried objects of similar size and shape but composed of different

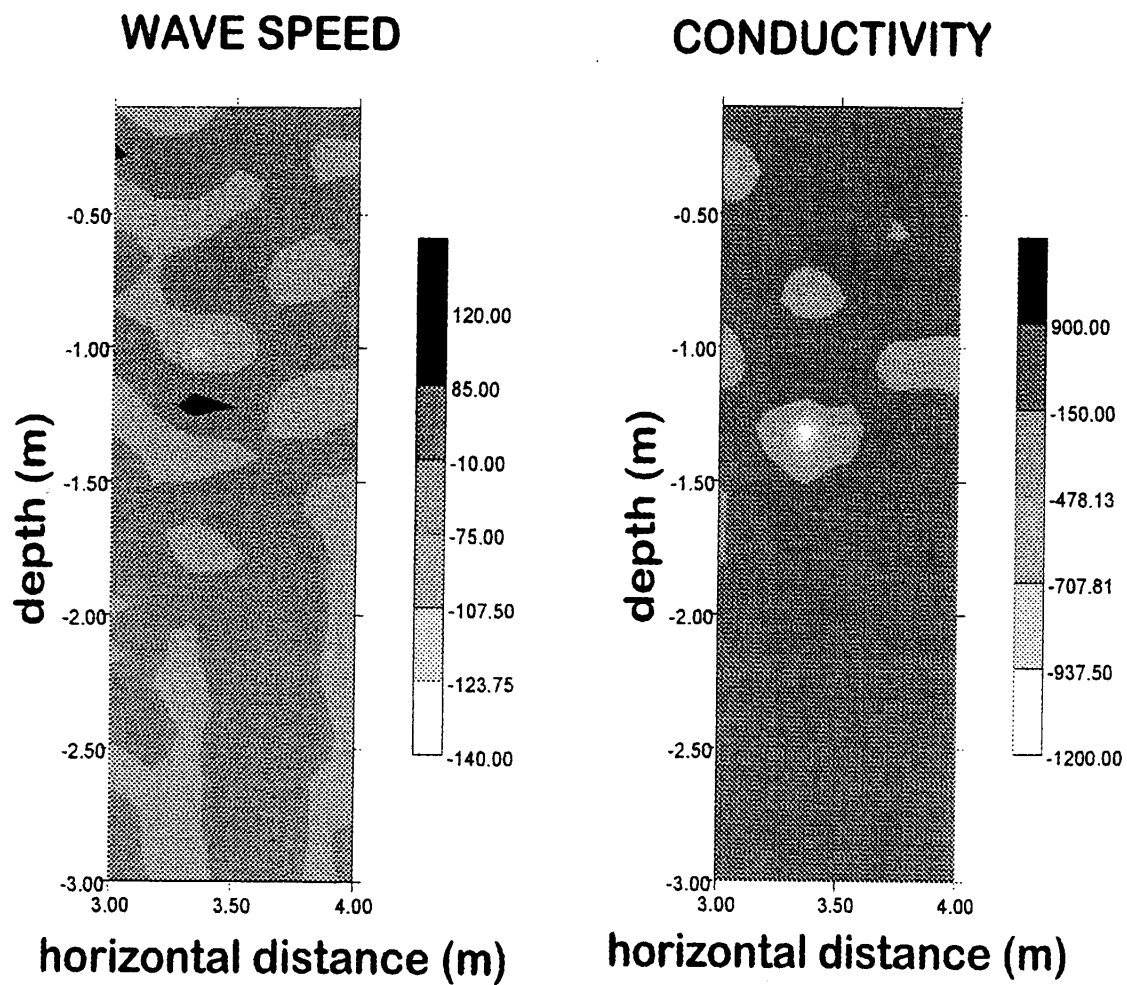

Figure 2: Gray scale image of wave speed and electrical conductivity for a polystyrene disk. Darker shades of gray are associated with larger values of wave speed and conductivity.

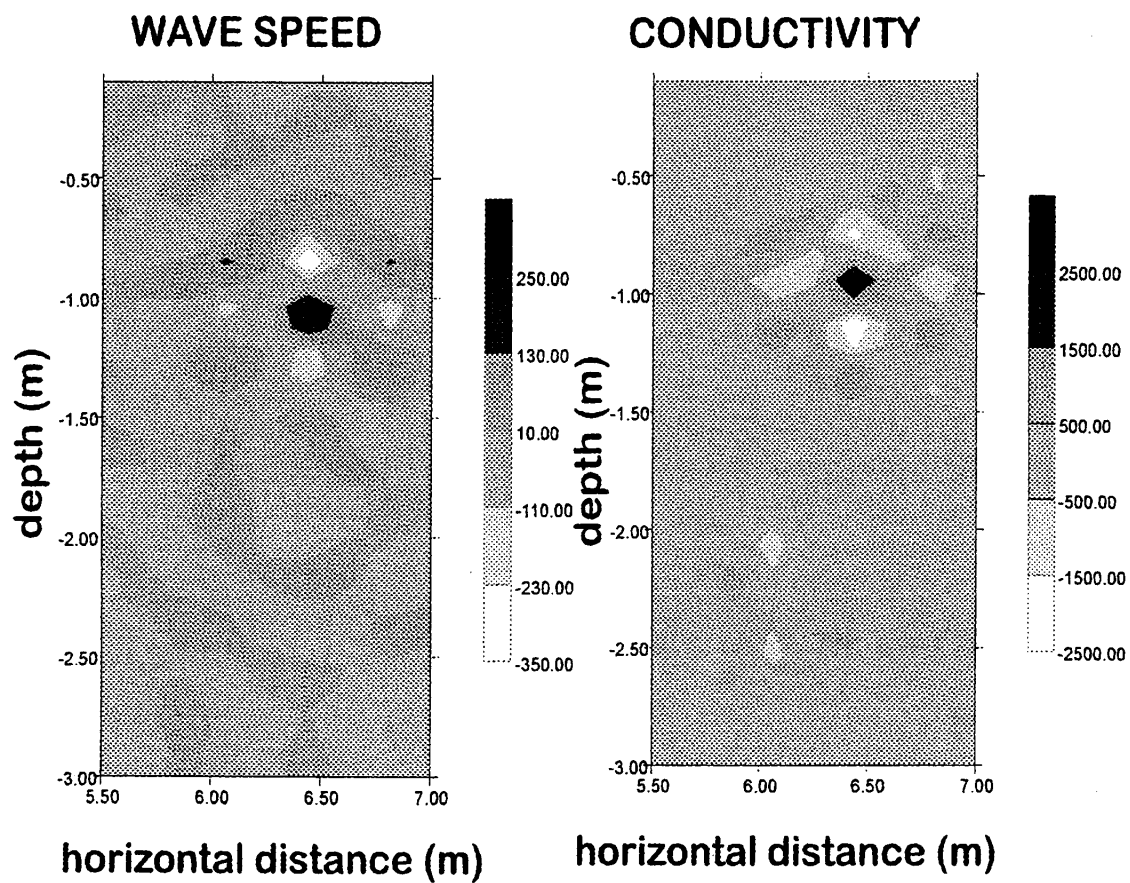

Figure 3: Gray scale image of wave speed and electrical conductivity for a concrete tube. Darker shades of gray are associated with larger values of wave speed and conductivity.

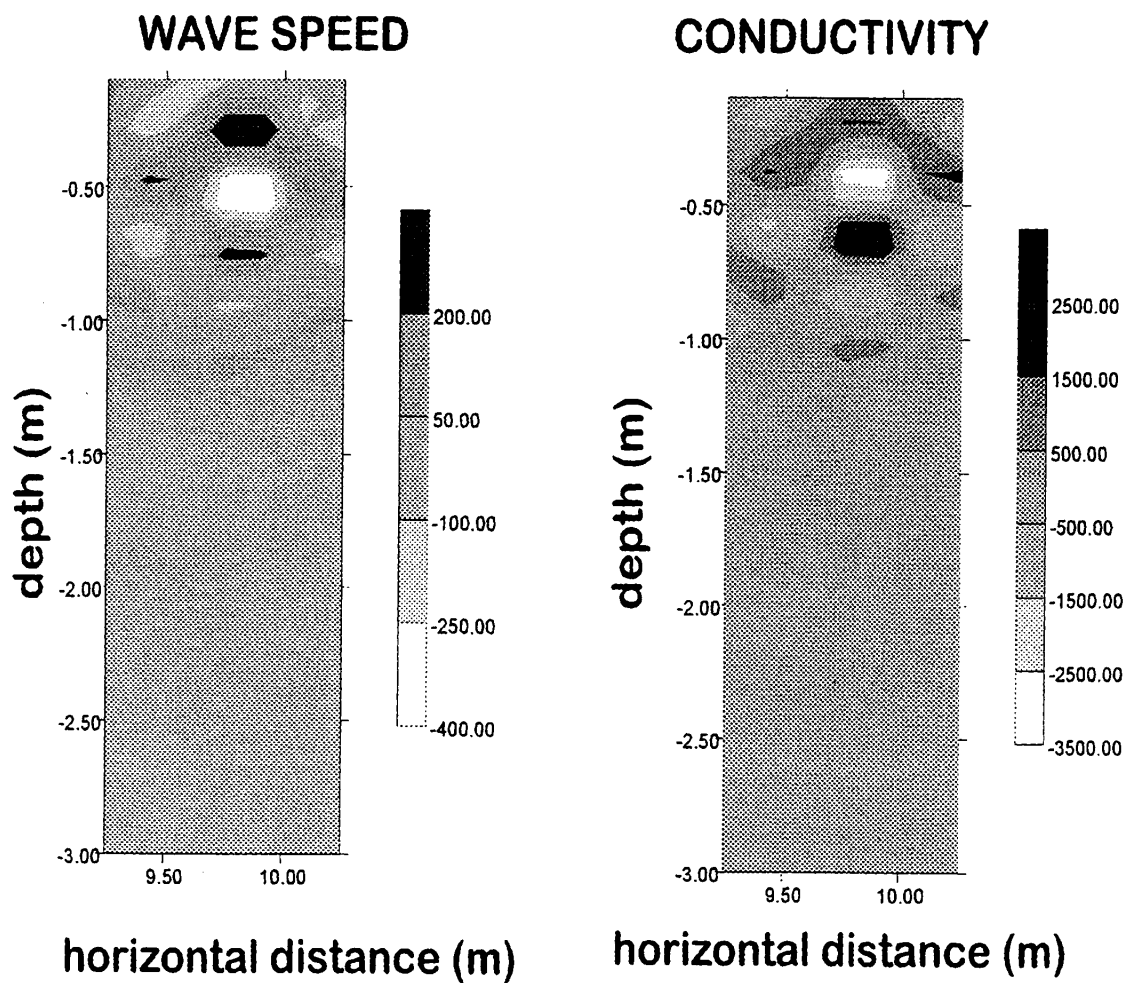

Figure 4: Gray scale image of wave speed and electrical conductivity for a iron tube. Darker shades of gray are associated with larger values of wave speed and conductivity.

materials. The second site contains a shallowly buried land mine of unknown type, size, and depth. At the land mine site, 1000 MHz center-frequency antennas were used.

Figures 2, 3, and 4 display reconstructed values of wave speed and conductivity as gray scales for three different targets at the test site. The images of the polystyrene disk (Fig. 2) and the iron tube (Fig. 4) yield the anticipated results that the polystyrene disk exhibits a high relative wave speed and low conductivity and the iron tube exhibits low relative wave speed and high conductivity. For the concrete tube, both the relative wave speed and conductivity are high. The sizes of three targets are small relative to wavelength and, as a result, the boundaries of the features blur together making them appear solid rather than hollow as would be expected since there is no spatial DC information. The ringing evident in some images is a result of both the zero-mran requirement and bandwidth limitations.

Figure 4 presents gray scale images of wave speed and electrical conductivity, similar to those given in Figs. 2, 3, and 4; for the data acquired at the land mine site. In this figure, the presence and location of the mine is obvious.

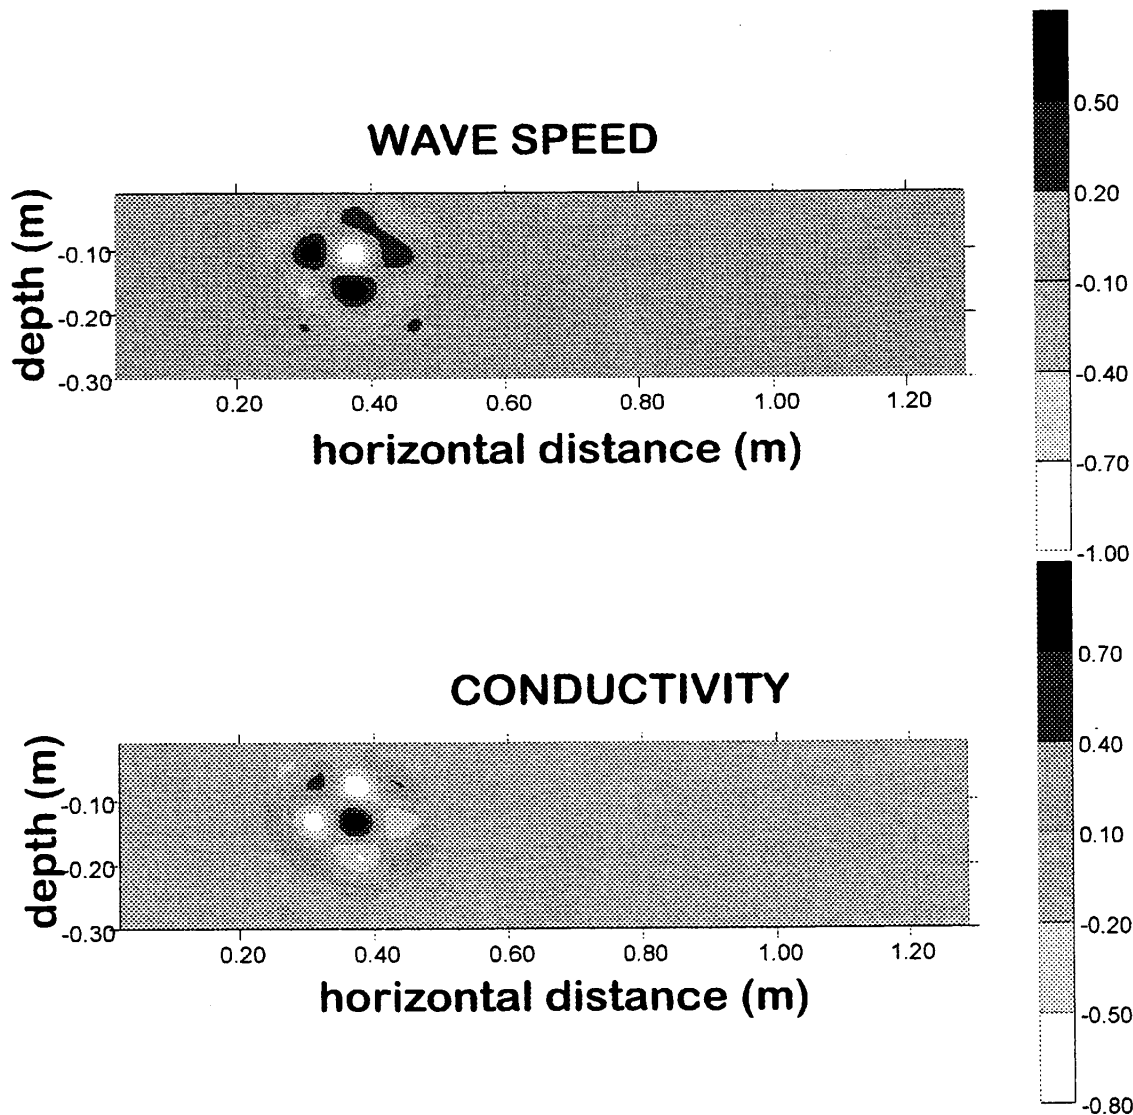

Figure 5: Gray scale image of wave speed and electrical conductivity for a buried land mine. Darker shades of gray are associated with larger values of wave speed and conductivity.

Because these images reveal that this feature has a wave speed greater than the background and an electrical conductivity less than the background, it is suspected that this is plastic mine. An interesting feature in these images is the low wave speed and high electrical conductivity in the center. This could be an image artifact associated with zero-mean object function requirement (Sect. 2) or it could be real. If the center of the image actually has a reverse contrast, then a zero-mean may approximately be realized without any image artifacts. If this central feature is real, it could be the metallic firing pin components of the mine.

5. CONCLUSIONS

A method has been developed, within the formalism of diffraction tomography and for a multi-monostatic measurement geometry, whereby spatial variations in wave speed (dielectric) and electrical conductivity can be reconstructed from broadband GPR measurements. When applied to known buried objects, the results proved consistent with the material composition of these objects.

Although the procedure described here is for multi-monostatic measurements and for a non-conducting background in two dimensions, it can readily be generalized to three dimensions and for a conducting background. Furthermore, it can also be extended to multi-bistatic transmission and reflection geometries.

Statistical modeling of rough surface scattering for ground-penetrating radar applications

George A. Tsihrintzis, Carey M. Rappaport, Scott C. Winton, and Peter M. Johansen

Center for Electromagnetics Research

Department of Electrical and Computer Engineering

Northeastern University

Boston, MA 02115, USA.

ABSTRACT

Rough surface clutter is a significant source of interference in non-specular ground penetrating radar (GPR) applications that needs to be suppressed to maintain high performance in the signal processing. Our research is in the directions of (i) development and testing of flexible parametric models for the statistical distribution of clutter that rely on the theories of alpha-stable random processes, (ii) establishment of bounds on the performance of signal processing algorithms, and (iii) design and analysis of robust, non-Gaussian signal processing algorithms based on the statistical clutter models. Synthetic data simulated with FDTD techniques are extensively used.

Keywords: Rough surface scattering, ground penetrating radar, FDTD modeling.

1. INTRODUCTION

A buried mine sensing modality with great opportunity for detailed physics-based modeling is Ground Penetrating Radar (GPR). To maximize the potential of mine detection with GPR, the radar must be wideband, to use as much of the frequency-dependent scattering information as possible. Within this area, developing accurate computational and statistical models of the mine/soil/air environment is of paramount importance. These models can be used to determine if and under what conditions a particular mine-like target can be observed and what are optimal detection procedures and help design new sensors to best collect the data needed for the detection algorithms. Particularly important are stochastic rough surface studies with FDTD simulation, since surface clutter is the major source of interference obscuring the signal from the mine (signal of interest).

The exact wave equations result in a nonlinear model for the wave-surface interaction, one that is analytically difficult to invert. Therefore, approximations are usually made to the exact nonlinear model, which are valid and

sufficient only under restricting conditions. Most common approximations arise (i) either from perturbations to corresponding solvable "smooth" surface problems [5, 3, 2] or (ii) from the Kirchhoff approximation [1]. Perturbation solutions apply in the limiting case when the deviations of the rough surface from a smooth one are small with possibly large slopes relative to the wavelength. On the other hand, the Kirchhoff approximation is applicable if the irregularities of the surface have large radii of curvature relative to the wavelength. Both methods break down when incidence and/or observation angles approach grazing and none applies when the surface is rough on length scales comparable to the wavelength. Recently, field-phase perturbation techniques were reported [6] which reduced to the usual (field) perturbation techniques or the Kirchhoff approximation in the low and high frequency limits, respectively, but were also valid in intermediate frequencies.

In this paper, we present a framework for designing algorithms for detection of radar returns from buried mines in the presence of rough surface clutter. The rough surface height function is modeled as a realization from a Gaussian process and the electric field clutter statistics are related to the surface statistics via first order perturbation analysis. It is shown that the effect of clutter is minimized if the receiver is placed in the backscatter region of the mine. More specifically, the paper is organized as follows: Section 2 reviews first-order field perturbation analysis of electromagnetic scattering from a rough surface and relates field statistics to rough surface statistics. Section 3 is concerned with mine target backscatter simulation in both the frequency and time domains and preliminary conclusions on the "optimum" receiver location. Finally, Section 4 summarizes the paper and points to related future research.

2. ELECTROMAGNETIC ROUGH SURFACE SCATTERING

A. Electric Field Equations

We are concerned with the reflection of plane electromagnetic waves from a surface $z = h(x, y)$, which is almost, but not quite flat as illustrated in Fig. 1. As in [3], we are going to assume that the surface is a realization from a periodic random process with period L , thus

$$z = h(x, y) = \sum_{m,n=-\infty}^{\infty} S_{m,n} \exp[-i \frac{2\pi}{L}(mx + ny)]. \quad (2-1)$$

The upper medium ($z > h(x, y)$) is non-dispersive with dielectric constant $\epsilon_0 = 8.854 \times 10^{-12}$ farad/meter, permeability $\mu_0 = 1.257 \times 10^{-6}$ henry/meter, and conductivity $\sigma_0 = 0$, while the lower medium ($z < h(x, y)$) is dispersive with frequency-dependent relative dielectric constant ϵ_r , permeability μ_0 , and frequency-dependent conductivity σ .

A horizontally polarized monochromatic electromagnetic plane wave with electric field

$$E_x^i = 0, \quad E_y^i(x, y, z) = \exp[-ik_0(\sin \theta x - \cos \theta z)], \quad E_z^i = 0 \quad (2-2)$$

is incident on the two media interface, where $k_0 = \omega \sqrt{\mu_0 \epsilon_0}$ is the wavenumber at the frequency ω of the wave and θ is the angle between the direction of propagation of the incident wave and the positive z axis assumed such that $\sin \theta = \frac{2\pi \nu}{k_0 L}$ for some integer ν .¹ In the absence of interface roughness, the interaction of the incident wave and the

¹It is assumed that the time-dependent wave is $E^i(x, y, z) \exp(i\omega t)$.

interface would result in a *specularly* reflected wave with electric field

$$E_x^r = 0, \quad E_y^r(x, y, z) = R \exp[-ik_0(\sin \theta x + \cos \theta z)], \quad E_z^r = 0 \quad (2-3)$$

for $z > h(x, y)$, where the specular reflection coefficient R is given by

$$R = \frac{1 - \rho}{1 + \rho}, \quad \rho = \frac{\sqrt{\epsilon_r + \sigma/(i\omega\epsilon_0) - \sin^2 \theta}}{\cos \theta} \quad (2-4)$$

Similarly, the specular wave propagating in the lower medium has electric field

$$E_x^t = 0, \quad E_y^t(x, y, z) = T \exp[-ik_0(\sin \theta x + a\sqrt{\epsilon_r + \sigma/(i\omega\epsilon_0) - \sin^2 \theta} z)], \quad E_z^t = 0, \quad (2-5)$$

for $z < h(x, y)$, where the transmission coefficient T is given by

$$T = \frac{2}{1 + \rho} \quad (2-6)$$

with ρ as in Eq.(2-4). Thus, no depolarization occurs in the absence of interface roughness.

When the two media interface is rough, however, Eqs.(2-3) through (2-6) are no longer valid and both non-specular reflection and transmission and depolarization of the incident wave occur. The resulting exact scattered wave is non-trivial to compute and, in general, one needs to resort to numerical techniques. However, under the assumption of "low" frequency ω , "small" relative dielectric constant ϵ_r and conductivity σ , and "small" maximum interface height function (maximum of $|h(x, y)|$), perturbation corrections to Eqs.(2-3) and (2-5) become valid first-order approximations. The resulting expression for the y -component of the electric field is [3]

$$E_y = \begin{cases} E_y^r + \sum_{m,n=-\infty}^{\infty} A_{m,n} \exp[-i\frac{2\pi}{L}(mx + ny) - ia(m, n)z], & \text{for } z > h(x, y) \\ E_y^t + \sum_{m,n=-\infty}^{\infty} B_{m,n} \exp[-i\frac{2\pi}{L}(mx + ny) + ib(m, n)z], & \text{for } z < h(x, y) \end{cases} \quad (2-7)$$

with similar expressions for the x - and z -components E_x and E_z of the electric field. In Eq.(2-7), we have defined

$$ia(m, n) = \sqrt{-k_0^2 + \frac{4\pi^2}{L^2}(m^2 + n^2)} \quad (2-8)$$

$$ib(m, n) = \sqrt{-k_0^2(\epsilon_r + \frac{\sigma}{i\omega\epsilon_0}) + \frac{4\pi^2}{L^2}(m^2 + n^2)}, \quad (2-9)$$

where $a(m, n)$ is either positive real or negative imaginary and the same would be true for $b(m, n)$ if the lower medium were non-conducting. To first order, the coefficients $A_{m,n}$ and $B_{m,n}$ are given by [3]

$$A_{m,n} = B_{m,n} = \frac{2iUS_{m-n,n}}{d(m, n)} \left[\frac{4\pi^2 n^2}{L^2 D_{m,n}} - 1 \right], \quad (2-10)$$

where

$$U = \frac{k_0^2 T}{2} (\epsilon_r - 1 + \frac{\sigma}{i\omega\epsilon_0}) \quad (2-11)$$

and

$$D_{m,n} = \frac{4\pi^2}{L^2}(m^2 + n^2) - b(m, n)c(m, n) \quad (2-12)$$

with

$$c(m, n) = \sqrt{k_0^2 \left(\epsilon_r + \frac{\sigma}{i\omega\epsilon_0} \right) - \frac{4\pi^2}{L^2} (m^2 + n^2)} \quad (2-13)$$

and

$$d(m, n) = b(m, n) + c(m, n). \quad (2-14)$$

We see that besides the specularly reflected and transmitted components, the electric field also contains a non-specular reflection and transmission due to the interface roughness. Additionally, depolarization occurs as the electric field vector also has x - and z -components.

B. Relation of Surface Statistics to Clutter Statistics

Consider now the surface height function as a realization from a periodic Gaussian random process of a certain covariance function. Since the Fourier series coefficients $S_{m,n}$ are given via a linear transformation of the surface height function, they constitute a Gaussian vector of a certain covariance matrix \underline{R} . Similarly, since the electric field clutter in Eq.(2-7) is a linear functional of the Fourier series coefficients $S_{m,n}$, the clutter will constitute a Gaussian process of some covariance function. Relating the covariance function of the electric field clutter to that of the Fourier series coefficients, we get:

$$\begin{aligned} \langle E_y(x, y, z) E_y^*(x', y', z') \rangle &= 4|U|^2 \sum_{m,n=-\infty}^{\infty} \frac{\sigma_{m,n}^2}{|d(m, n)|^2} \left[\frac{4\pi^2 n^2}{L^2 D_{m,n}} - 1 \right] \left[\frac{4\pi^2 n^2}{L^2 D_{m,n}^*} - 1 \right] \\ &\quad \exp \left[-i \frac{2\pi}{L} (m(x - x') + n(y - y')) - i(b(m, n)z - b^*(m, n)z') \right], \end{aligned} \quad (2-15)$$

where

$$\sigma_{m,n}^2 = \langle |S(m - n, n)|^2 \rangle. \quad (2-16)$$

3. MINE TARGET BACKSCATTER SIMULATION FROM ROUGH DISPERSIVE GROUND

A. Frequency Domain Simulation

Consider again the configuration in Fig. 1, in which a cylindrical object (mine) is buried in soil with its center located at $(0, 0, z_m)$ ($z_m < 0$) and interrogated by a monochromatic plane wave. We define the (frequency-dependent) object function

$$O(x, y, z; \omega) = \begin{cases} \Delta k^2 \equiv \omega^2 \mu \epsilon_0 (\Delta \epsilon_r - \frac{\Delta \sigma}{i\omega\epsilon_0}), & \text{if } |z - z_m| \leq \delta z \text{ and } \sqrt{x^2 + y^2} \leq \Delta \rho \\ 0, & \text{else,} \end{cases} \quad (3-1)$$

where $\Delta \epsilon_r$ and $\Delta \sigma$ are the differences in dielectric constant and conductivity, respectively, between the object and the soil.

Under the assumption that the interface between air and soil is perfectly flat, the signal due to the mine is given to first-order by

$$E_y^m(x, y, z) = \iint dK_x dK_y e^{i(K_x x + K_y y)} B(K_x, K_y, K_{0x}, K_{0y}, \omega) e^{im_1(K_x, K_y)z} I(K_x, K_y), \quad (3-2)$$

where

$$I(K_x, K_y) = \pi \Delta k^2 \Delta z \Delta \rho \operatorname{sinc} \left[\frac{\Delta z}{2} (m_2(K_x, K_y) + m_2(K_{0x}, K_{0y})) \right] \frac{J_1 \left[\frac{\Delta \rho}{2} \sqrt{(K_x - K_{0x})^2 + (K_y - K_{0y})^2} \right]}{(K_x - K_{0x})^2 + (K_y - K_{0y})^2} \cdot e^{-i[m_2(K_x, K_y) + m_2(K_{0x}, K_{0y})z_m]} \quad (3-3)$$

and

$$B(K_x, K_y, K_{0x}, K_{0y}) = -i \frac{\mu \omega [(K_y^2 + m_1 m_2)(K_{0y}^2 + m_1^0 m_2^0) + K_x i K_{0x} (K_y K_{0y} - m_1 m_1^0)]}{16 \pi^4 (m_1 + m_2)(K_x^2 + K_y^2 + m_1 m_2)(m_1^0 + m_2^0)(K_{0x}^2 + K_{0y}^2 + m_1^0 m_2^0)} \quad (3-4)$$

In Eqs.(3-2), (3-3), (3-4), we have defined

$$K_{0x} = k_0 \sin \theta \quad (3-5)$$

$$K_{0y} = 0 \quad (3-6)$$

$$m_1(K_x, K_y) = -\sqrt{k_0^2 - K_x^2 - K_y^2} \quad (3-7)$$

$$m_2(K_x, K_y) = \sqrt{k_0^2 \left(\epsilon_r - i \frac{\sigma}{\omega \epsilon_r} \right) - K_x^2 - K_y^2} \quad (3-8)$$

$$m_1^0 = m_1(K_{0x}, K_{0y}) \quad (3-9)$$

$$m_2^0 = m_2(K_{0x}, K_{0y}). \quad (3-10)$$

We simulated the field in Eq.(3-2) with frequency $\omega = 1$ GHz, angle of incidence $\theta = \frac{\pi}{3}$, relative dielectric constant of lower medium $\epsilon_r = 4$, relative dielectric constant of mine $\epsilon_{mine} = 3.8$ (or $\Delta \epsilon_r = -0.2$), conductivity of lower medium $\sigma = 0.001$, and conductivity of mine $\sigma_{mine} = 0$ (or $\Delta \sigma = -0.001$). The mine was buried 5 cm in the soil ($z_m = -0.05$) had a radius of 2 cm ($\Delta \rho = 0.02$) and a height of 2 cm ($\Delta z = 0.02$). The top plot in Fig. 2 is a contour plot of the magnitude (intensity) $|E_y|$ of the electric field in Eq.(3-2) on the plane $z = 0.2$, i.e., 20 cm above the air/soil interface. The bottom plot in Fig. 2 is a plot of the values of the electric field intensity $|E_y|$ along the x -axis at $z = 0.02$. From Fig. 2, it is clear that, for the given simulation parameters, the mine's scattered field propagates mostly in the backward direction. This is in contrast with the observation that reflections from the air/soil interface are mostly in the forward direction. Thus, the ratio of the mine signal over the clutter is maximized in the backscatter direction and that is the appropriate receiver location for maximum detection performance.

B. Time Domain Simulation

The frequency domain analysis presented above is based on first order approximations to the interaction of electromagnetic waves with the mine/air/soil environment. A more reliable analysis needs to be based on the exact interaction between the electromagnetic waves and the mine/air/soil environment, as such can be provided by numerical techniques. Additionally, the analysis needs to be done in the time domain, to reveal the time separation between signals. In our work, we have been combining dispersive soil FDTD modeling with new research in statistical rough surface modeling to give a realistic prediction of the scattering from ground with and without a mine target. Our results show clearly that even with the very low dielectric contrast of a non-metallic mine buried in sand, the backscattered signal from the mine can be readily observed and interpreted. The important aspects of the sensing is that the excitation pulse be short and inclined to the ground surface.

Our test case consists of a small circular antipersonnel mine; 4 cm in diameter, with no metal components—only TNT—embedded in either 10% moist clay loam (which is quite dispersive) or dry sand (which has a lower dielectric constant than TNT). The ground surface is chosen to be quite rough, with height statistically varying with position as much as ± 15 cm over a 1 m path. The mine target is buried close to the surface (making it notoriously difficult to sense with radar), within 5 cm. Two conditions enable a radar to detect a mine in this challenging case: 1) the radar pulse must be short enough to allow scattering from the ground surface to separate in time from the scattering from the buried mine, and 2) the incident pulse must be inclined relative to the surface normal, so that the specular reflection propagates away from the source. By positioning a receiver near the surface, slightly behind the suspected mine position, and observing the backscattered signal at the time when a signal leaving the suspected mine would arrive at the receiver, a received signal above a nominal clutter threshold would unambiguously indicate the presence of a mine. For our simulations, a 2 GHz modulated gaussian pulse, incident at 30 deg. from normal, with a single receiver 20 cm above the ground surface is sufficient to highlight the presence of an entirely plastic mine.

Observing the total field as a function of position with the mine present (Figs. 3 and 4) and the field due to just the ground without the mine (Figs. 5 and 6) shows the difference (the mine's backscattered field) (Figs. 7 and 8) quite clearly in the backscattered direction. While most of the wave reflected from the ground surface propagates mostly forward, the field scattered from the mine propagates in all directions, and this backward propagation can be distinguished even in the presence of the incident and specularly reflected fields. That is, by positioning detectors behind the target, illuminating the ground with an inclined wave, and time gating the received signal to correspond to the arrival time from a target buried at a given distance, the measured signal (exceeding a tunable threshold) will be due solely to the buried object. A receiver positioned as in Fig. 3 (or 4), would measure the signals given in Figs. 4 and 6 with and without the mine present, respectively.

Our work continues with the study of polarization effects (specifically TM polarization with Brewster angle incidence), the clutter effects of buried rocks and moisture variations, incident pulse tailoring for specific targets, and sensor placement for optimal detection.

4. SUMMARY AND FUTURE WORK

In this paper, we attempt to combine dispersive soil FDTD modeling with new research in statistical rough surface modeling to give a realistic prediction of the scattering from ground with and without a mine target and to allow the application of optimum hypothesis testing theory to solve the problem of detection of radar returns from buried mines in the presence of rough surface clutter. For the rough surface, we proposed a statistical model that relies on the theories of sub-Gaussian random processes [4] and is a generalization of the Gaussian model that allows for impulsiveness.

We reviewed first order field perturbation electromagnetic scattering from rough surfaces and related the electric field clutter statistics to the statistics of the rough surface. We showed that within first order theory, a cylindrical mine scatters a plane wave mostly in the backward direction, as opposed to ground reflections which are mainly in the

forward direction. We verified this result with numerical (FDTD) electromagnetic wave propagation and scattering analysis.

Our work continues with the study of polarization effects (specifically TM polarization with Brewster angle incidence), the clutter effects of buried rocks and moisture variations, incident pulse tailoring for specific targets, and sensor placement for optimal detection. Future work will also be in the directions of validation of the sub-Gaussian model on real data and design and performance documentation of algorithms for detection of buried mines for a large variety of realistic models for the signals returned by the mine.

ABSTRACT

A laboratory-scale acoustic experiment is described where a buried target, a hockey puck cut in half, is shallowly buried in a sand box. To avoid the need for source and receiver coupling to the host sand, an acoustic wave is generated in the subsurface by a pulsed laser suspended above the air-sand interface. Similarly, an airborne microphone is suspended above this interface and moved in unison with the laser. After some pre-processing of the data, reflections from the target, although weak, could clearly be identified. While the existence and location of the target can be determined by inspection of the data, its unique shape can not. Since target discrimination is important in mine detection, a three-dimensional imaging algorithm was applied to the acquired acoustic data. This algorithm yielded a reconstructed image where the shape of the target was resolved.

Keywords: laser-acoustics, diffraction tomography, maximum likelihood estimation, mine-like targets

1. INTRODUCTION

A fundamental limitation in the use of acoustic methods for problems such as mine detection is associated with acoustic coupling to the ground. The need for mechanical contact between both sources and receivers makes the deployment of sensors slow and, hence, impractical for applications such as mine detection that require rapid data acquisition. The use of laser-induced compressional waves can eliminate the need for source-soil coupling and, with the laser source, acoustic energy from shallowly buried objects can potentially be recovered with a near-surface airborne microphone. Such measurements eliminate the need for any sensor coupling to the ground surface.

In this paper, laser acoustic measurements are described. In a laboratory setting over a simple, shallowly-buried mine-like target in a multi-monostatic measurement geometry a laser source and an adjacent microphone are moved in unison over a plane above the ground surface.

Subsequently, a three-dimensional imaging algorithm is applied to these measurements, with the hope of both recovering buried targets from within signal noise and, furthermore, distinguish mine-like targets from other targets that might be encountered in the shallow subsurface.

2. THE THREE-DIMENSIONAL IMAGING ALGORITHM

The three-dimensional imaging algorithm used here is an extension of a two-dimensional multi-monostatic filtered backpropagation algorithm developed by Molyneux and Witten¹. Here it is assumed that a co-located acoustic source and receiver are moved in unison along the horizontal plane $z = 0$. The measured acoustic wave field $\bar{u}(\mathbf{r}, t)$ is the total field measured at point \mathbf{r} on the measurement plane at time t . This total field can be represented by the superposition of the incident field \bar{u}_0 , the field that would be measured in the a homogeneous medium, and a perturbed field \bar{u}' associated with any scatterers that are present.

The imaging algorithm is implemented in the frequency domain so that temporal Fourier transformed wave fields

$u(\mathbf{r}, k_0)$, $u_0(\mathbf{r}, k_0)$, and $u'(\mathbf{r}, k_0)$ are introduced and defined as

$$f(\mathbf{r}, k_0) = \int dt \bar{f}(\mathbf{r}, t) e^{i c_0 k_0 t},$$

where \bar{f} and f represent the total, incident, or perturbed wave fields and their temporal Fourier transform. The background wavenumber k_0 is defined to be ω/c_0 where ω is the frequency and c_0 is the assumed real wave speed in the propagating medium in the absence of any scatterers. For any scatterers located in the half-space $z < 0$ and invoking the Born approximation, the perturbed wave field can be represented as

$$u'(\mathbf{r}, k_0) = -i \frac{k_0^2}{4\pi} \int d\mathbf{x}' O(\mathbf{x}') u_0(\mathbf{x}') \int \frac{d\mathbb{Q}}{\sqrt{k_0^2 - \alpha^2}} e^{-i(\mathbb{Q} + \sqrt{k_0^2 - \alpha^2} \hat{\mathbf{z}}) \cdot (\mathbf{x}' - \mathbf{r})}, \quad (1)$$

where $\mathbf{x}' = (x', y', z')$, the integral over $\mathbb{Q} = (\alpha_x, \alpha_y, 0)$ is the Weyl expansion for scalar Green's function², $\hat{\mathbf{z}}$ is the unit vector in the vertical (upward) direction, and

$$O(\mathbf{x}) = 1 - \frac{k^2(\mathbf{x})}{k_0^2} \quad (2)$$

is the object function and $k(\mathbf{x})$ is the spatial variations in wavenumber that can be complex. For a point acoustic source located at \mathbf{r} , the incident field at \mathbf{x}' is

$$u_0(\mathbf{x}') = i \int \frac{d\mathbf{r}}{\sqrt{k_0^2 - \beta^2}} e^{i(-\sqrt{k_0^2 - \beta^2} \hat{\mathbf{z}}) \cdot (\mathbf{x}' - \mathbf{r})}. \quad (3)$$

Taking k_0 to be real, the real part of the object function

$$O_R(\mathbf{x}) = 1 - \frac{c_0^2}{c^2(\mathbf{x})} \quad (4)$$

where $c(\mathbf{x})$ is the spatial variations in wave speed, is one minus the square of the real refractive index. The imaginary part of the object function, O_I is the spatial variations in attenuation per unit length. Given a known background wave speed c_0 , the spatial variations in wave speed $c(\mathbf{x})$ and the attenuation per unit length that characterize scatterers can be recovered from the object function via Eqs. (2) and (4). Thus, an inversion of Eq. (1) subject to Eq. (3) whereby the object function is expressed as a function of the temporally Fourier transformed data u' can be an imaging algorithm.

A first step in the inversion of Eq. (1) is to seek a deconvolution by Fourier transforming the acquired data, u' with respect to measurement location \mathbf{r} . Defining

$$\tilde{u}'(\mathbf{l}, k_0) = \int d\mathbf{r} u'(\mathbf{r}, k_0) e^{-i\mathbf{l} \cdot \mathbf{r}},$$

substituting Eq. (3) into Eq. (1), the spatially Fourier transformed data becomes

$$\tilde{u}'(\mu, k_0) = \frac{k_0^2}{2} \int d\mathbf{x}' O(\mathbf{x}') e^{-i\mathbf{l} \cdot \mathbf{r}'} I \quad (5)$$

where

$$I = \int \frac{d\mathbb{Q}}{\sqrt{k_0^2 - \alpha^2} \sqrt{k_0^2 - (\alpha - \mu)^2}} e^{-i(\sqrt{k_0^2 - \alpha^2} + \sqrt{k_0^2 - (\alpha - \mu)^2}) z'}, \quad (6)$$

and $\mathbf{r}' = (x', y', 0)$.

The fact that the integral I remains in Eq. (5) is an indication that the spatial Fourier transform was not completely successful in the required deconvolution. The reason for this is that the measurement geometry is multi-monostatic where, by taking source and receiver to be coincident, eliminated one independent vector, either the source location

or the receiver location, that can be used for deconvolution. Had the measurement geometry been multi-bistatic where the source and receiver are positioned independently, two spatial Fourier transforms (one for the source position and one for the receiver position) could have been employed to completely deconvolve Eq. (1). For this reason, it is now necessary to deal with the integral given by Eq. (6). No exact, closed-form solution to this integral has been found; however, it has been shown¹ that for the support of O in the far-field of the measurement point, $k_0 z \gg 1$, the integral can be accurately approximated by stationary phase to give

$$\tilde{u}'(\mathbf{r}', k_0) = i \frac{k_0}{8\pi} \tilde{O}_1(\mathbf{K}), \quad (7)$$

where

$$\tilde{O}_1(\mathbf{K}) = \int d\mathbf{x}' \frac{O(\mathbf{x}')}{|z|} e^{-i\mathbf{K} \cdot \mathbf{x}'} \quad (8)$$

and

$$\mathbf{K} = (\mathbf{r}', \sqrt{4k_0^2 - \mu^2}) = (\mu_x, \mu_y, \sqrt{4k_0^2 - \mu^2}). \quad (9)$$

Equation (7) provides the needed relationship between the object function and the acquired data that can be inverted analytically. Before implementing this inversion, it is useful to recall that a far-field approximation was necessary to achieve the form given by Eq. (7). Consequently, this approximation has the potential to limit the applicability of any imaging algorithm based on Eq. (7) to scatterers that are much deeper than one wavelength. Numerical analyses performed by Molyneux and Witten¹ have established that, within the Born approximation, the invoked far-field approximation is more restrictive in the forward sense, Eq. (7), than in the inverse sense. In fact, there is no loss of image fidelity for scatterers in the near-field when compared with scatterers in the far-field.

The final form of the imaging algorithm can easily be established by expressing \tilde{O}_1 as a function of \tilde{u}' and inverting the indicated three-dimensional Fourier transform to give

$$O(\mathbf{x}) = -i \frac{4|z|}{\pi^2 c_0} \int d\omega \int d\mathbf{r}' \frac{\tilde{u}'(\mathbf{r}', k_0)}{\sqrt{4k_0^2 - |\mathbf{r}'|^2}} e^{i\mathbf{K} \cdot \mathbf{x}}. \quad (10)$$

In this equation, the integral over the vertical component of the wavenumber, K_z has been cast as an integration over the signal bandwidth. In order to obtain some expectation of the results that can be achieved from image reconstruction based on Eq. (10), it is necessary to characterize the \mathbf{K} -space coverage. It is clear from Eq. (9) that, for a particular frequency ω or its associated background wavenumber k_0 , this coverage will be an upper hemispherical surface of radius $2k_0$ centered at $K_z = k_0$. Exploiting bandwidth adds concentric hemispherical surfaces; however, there is no \mathbf{K} -space coverage at the origin. With no knowledge of \tilde{O}_1 at $\mathbf{K} = 0$, there can be no spatial DC information about the scatterers. Thus, for heterogeneities that are relatively large, images will be hollow. For smaller objects, their boundaries will blur together providing an image that is only apparently solid. This absence of spatial DC information is typical of reflection-mode signal processing subject to the Born approximation where only transitions between objects of differing properties can be recovered.

3. MAXIMUM LIKELIHOOD ESTIMATION

The use of an imaging algorithm, such as the one described above, requires some form of visual inspection of the reconstructed image to establish that any feature appearing in the image has the size and shape characteristic of a target of interest. This inspection step can be eliminated by considering a related signal processing algorithm that essentially produces an image related to likelihood of occurrence of a specified target. The approach considered here is referred to as maximum likelihood estimation³.

By defining the acquired data as $u'(\mathbf{r}, \omega)$ and a data template $U(\mathbf{r}, \omega; \mathbf{x}_0)$ to be either simulated or measured data for a target of interest located at \mathbf{x}_0 , it is clear that a good indication that this target of interest is present and located at \mathbf{x}_0 is that the error

$$E(\mathbf{x}_0) = \sum_{\omega} \int d\mathbf{r} [u'(\mathbf{r}, \omega) - U(\mathbf{r}, \omega; \mathbf{x}_0)]^2 \quad (11)$$

is below some small value characterized by the signal noise. It is recognized that Eq. (11) is simply the mean square difference, over all data, between the data and the data template. While this equation can be applied directly to identify targets of interest from measurements, its use will require either measured or simulated data templates for all targets of interest at many possible target locations.

The number of data templates can be reduced to a single data template for a given target type by first using Parseval's theorem to express the sum over all data given by Eq. (11) as the similar sum of the spatial Fourier transforms of the data and the data template

$$E(\mathbf{x}_0) = \sum_{\omega} \int d^1 \left[\tilde{u}'(\omega, k_0) - \tilde{U}(\omega, k_0; \mathbf{x}_0) \right]^2. \quad (12)$$

The relationship between the spatial Fourier transforms of the data and the object function derived for imaging can be used to analytically move the target. From Eq. (7), the data template can be expressed as

$$\tilde{U}(\omega, k_0; \mathbf{x}_0) = i \frac{k_0}{8\pi} \tilde{O}_1(\mathbf{K}; \mathbf{x}_0).$$

If it is now assumed that a data template is available for a target located at \mathbf{x}_{ref} , this data templated can be represented by

$$\tilde{U}_{ref}(\omega, k_0) = \tilde{U}(\omega, k_0; \mathbf{x}_{ref}) = i \frac{k_0}{8\pi} \tilde{O}_1(\mathbf{K}; \mathbf{x}_{ref}).$$

From the shift rule for integral transforms,

$$\tilde{O}_1(\mathbf{K}; \mathbf{x}_0) = \tilde{O}_1(\mathbf{K}; \mathbf{x}_{ref}) e^{-i\mathbf{K} \cdot (\mathbf{x}_0 - \mathbf{x}_{ref})},$$

or

$$\tilde{U}(\omega, k_0; \mathbf{x}_0) = \tilde{U}_{ref}(\omega, k_0) e^{-i\mathbf{K} \cdot (\mathbf{x}_0 - \mathbf{x}_{ref})}. \quad (13)$$

Equation (13) is the desired result in that it allows the synthesis of a data template at an arbitrary location \mathbf{x}_0 from a measured or simulated data template at any known location \mathbf{x}_{ref} . When Eq. (13) is used in Eq. (12), the error E can be computed by a combination of numerical integrations that are independent of target location and a spatial Fourier transform with respect to potential target locations.

4. THE LASER-ACOUSTIC EXPERIMENT

An experiment was conducted to acquire acoustic wave reflection data from a shallowly buried object in a sand box. The target was a 7.5 cm diameter hockey puck that was sliced in half radially and buried 1 cm deep in the sand box. To create acoustic waves in the sand, a pulsed laser was suspended above the surface of the sand. An impulsive acoustic wave was created by the interaction of the laser pulse with the air-sand interface⁴. The acoustic receiver was a transducer suspended 5 cm above the laser spot. The laser-transducer pair were moved in unison above the surface of the sand. Figure 1 illustrates this measurement geometry.

Data were acquired by moving the source-receiver pair along a series of parallel "scan" lines. Each scan line was 7 cm long and the transducer output voltage as function of time was measured at 15 points along each scan line. Twenty five scan lines were acquired over a length of 12 cm. (Fig. 2). This provided a uniform, horizontal (x, y) coverage at 0.5 cm intervals. At each measurement location, 1000 voltage measurements were acquired at 0.5 microsecond intervals. Data acquisition began (time zero) at a constant time after the time of the laser pulse.

Figure 3 is a plot of the output voltage versus time for one of the spatial measurement locations. The acoustic data are characterized by strong "ringing" presumably associated with a resonant mode of the transducer. This ringing made the identification of features in the time series associated with reflections quite difficult. For this reason, each time series was pre-processed with a filter to suppress the artifacts of resonance. This filter has the form

$$\tilde{u}'(t) = \int d\omega h(\omega) s(\omega) e^{-i\omega t}, \quad (14)$$

Figure 1: Illustration of the measurement geometry in a vertical cross-section.

Figure 2: Illustration of the spatial measurement configuration.

Figure 3: An example of the acoustic transducer output voltage as a function of time for one measurement location.

where

$$h(\omega) = \frac{s_{ref}^*(\omega)}{s_{ref}s_{ref}^* + \epsilon}, \quad (15)$$

s is the temporally Fourier transformed time series for any of the spatial measurement points in a particular scan line, s_{ref} is the temporally Fourier transformed time series for the first spatial measurement point in that scan line, the $*$ denotes complex conjugation, and ϵ is a constant included to eliminate any singularities in the filter h .

The filter described by Eqs. (14) and (15) has the added benefit of effectively moving the receiver location to surface of the sand. Figures 4(a) and (b) display the time series for every spatial measurement location along scan lines 1 and 12, respectively. In these figures, output voltage is displayed as gray levels with darker shades of gray associated with higher output voltages. Referring to Fig. 2, scan line 1 does not pass over the puck and, as such, there should be no evidence of a reflection from this feature. However, scan line 12 passes over the hockey puck at approximately its widest part so that a reflection from the sand-hockey puck interface should appear in the data. These data, as presented in Fig. 4, are consistent with these expectations. The pre-processed time series can also be presented as a time slice where output voltage at a fixed time is presented as a function of measurement position (x) along each scan line for all scan lines (y). Figure 5 is a gray scale presentation of the temporal data time-sliced at 53.5 microseconds. The horizontal surface of the hockey puck is clearly identified in this figure and its shape is reasonably well resolved.

5. IMAGING RESULTS

The three-dimensional imaging algorithm, Eq. (10), was applied to the pre-processed laser-acoustic data. Apart from the specification of the measurement geometry, the only user inputs to this algorithm are associated with the specification of the background wavenumber k_0 so that a background acoustic wave speed c_0 and a bandwidth must be specified. Most of the power in the acoustic signal was confined to a frequency band between about 10 and 60 kHz; however, there was limited spectral power out to about 250 kHz. Since a broader bandwidth produces better images, a bandwidth between 10 and 250 kHz was used for the reconstructions presented here. The background

Figure 4: Transducer output voltage as function of time for (a) scan line 1 and (b) scan line 12. The horizontal axis is measurement position (x) along the scan line and the vertical axis is time in microseconds. The output voltage is displayed as gray scales having values defined by the palette on the right.

Figure 5: Gray scale presentation of output voltage time-sliced at 53.5 microseconds.

wavespeed used was 700 m/s, a value typical of poorly cemented sandstone.

Figures 6, 7, and 8 show vertical cross-sectional slices through the three-dimensional image below scan lines 1, 8, and 12, respectively. Each figure shows both real and imaginary parts of the reconstruction of the object function $O = O_R + iO_I$ where, as noted earlier, O_R can be considered to be spatial variations in relative reflectivity and O_I can be taken to be spatial variations in attenuation per unit length. These images reproduce some expected features. First, there is no evidence of the hockey puck in the vertical cross-section below scan line 1 (Fig. 6). The hockey puck does appear in the images of both O_R and O_I below scan lines 8 (Fig. 7) and 12 (Fig. 8) with the puck appearing wider below scan line 12 than scan line 8. Additionally, the puck appears with a positive contrast in O_R indicating that the wave speed of the puck is greater than the host sand. The O_I contrast of the puck is negative suggesting that the puck is less attenuating than the sand.

Figure 6: Reconstructed image of (a) O_R and (b) O_I through a vertical cross-section below scan line 1 displayed as gray scales.

Figure 7: Reconstructed image of (a) O_R and (b) O_I through a vertical cross-section below scan line 8 displayed as gray scales.

One surprising result is that the O_I reconstruction is more robust than the O_R reconstruction. This fact can be seen by comparison of Figs. 7 and 8. The same plotting contrast was used for O_I ; however, different plotting contrasts were required to make the puck apparent in the O_R images in both vertical cross-sections. This fact becomes more evident when viewing a horizontal slice through the three-dimensional image at a depth of 1.8 cm (Fig. 9). Here the hockey puck can easily be distinguished in the O_I reconstruction but not in the O_R reconstruction.

Figure 8: Reconstructed image of (a) O_R and (b) O_I through a vertical cross-section below scan line 12 displayed as gray scales.

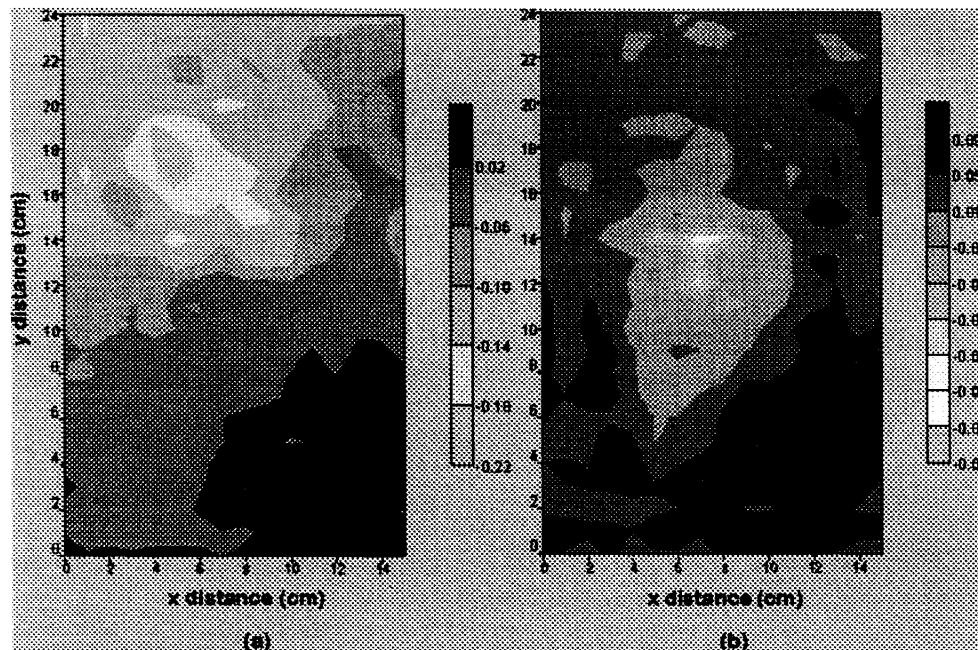

Figure 9: Gray scale image of the three-dimensional image of (a) O_R and (b) O_I horizontally sliced at a depth of 1.8 cm.

6. CONCLUSIONS

One of the objectives of this study was the evaluation of the efficacy of acoustic measurements of scattering from subsurface objects when the sensors are not in intimate contact with ground surface. In geophysical acoustic measurements, the need for mechanical coupling between both source and receiver with the ground surface is the rate limiting factor in data acquisition. For the demining problem, not only does this coupling issue slow the speed of data acquisition to point where it becomes impractical, it also presents a risk of inadvertent mine detonation.

It has been established here, at least for the ideal conditions of a shallow object in near-homogeneous background and

a planar interface, that reflections from this target can clearly be identified. As evident in Figs. 4 and 5, after some slight pre-processing the presence and location of the target can clearly be identified. Even under ideal conditions; however, the ground is quite heterogeneous where numerous man-made and naturally occurring objects may be found. For this reason, there is an ancillary discrimination problem where a detected buried object must be identified as being mine-like with some reasonable level of confidence. There are a number of attributes that can be considered for target discrimination. Here, the rather unique shape of the half hockey puck target was used and the objective of signal processing was to reconstruct this shape using a three-dimensional multi-monostatic reflection-mode imaging algorithm.

The quantity imaged is the object function which is complex having a real part that is associated with relative spatial variations in wave speed and an imaginary part that is associated with relative spatial variations in attenuation per unit length. The reconstructed three-dimensional image was displayed as two-dimensional cross-sections representing slices of this three-dimensional image that are horizontal and vertical. While both the real and imaginary parts of the object function produced images of vertical cross-sections where the target was clearly identifiable (Figs. 6a, 7a, and 8a), the wave speed contrast (the real part of the object function) varied with horizontal y -direction (Fig. 2). Consequently, the target could not be distinguished in the horizontally-sliced image based on the wave speed reconstruction (Fig. 9a). This was not the case for the reconstruction of attenuation per unit unit length. For this variable, the contrast was consistent from vertical cross-section to vertical cross-section so that the target location and shape could be clearly identified in the horizontally-sliced image (Fig. 9b).

While the imaging results obtained here suggest that attenuation per unit length is the more robust image, it is important to recall that the target appears as a relative low in this variable. This fact, in turn, suggests that there is some background attenuation. If this is indeed the case, the background wavenumber k_0 taken to be real in the imaging algorithm must, more properly, be taken to be complex. For a complex background wavenumber, the integral transform defined by Eq. (8) is no longer a spatial Fourier transform so that a different inversion procedure must be implemented such as the algebraic one given by Witten et. al.⁵. In principle, it is possible to apply such an algorithm here; however, in practice it is necessary to have some estimate of the imaginary part of k_0 . In light of this information, it useful to reconsider what was actually imaged. There are two important implications associated with a complex k_0 . First, it must be recognized that there is a depth-dependent attenuation and, as a result, a depth-dependent gain must be introduced into the imaging algorithm. This is not a significant factor here since the target was shallow and the absence of this gain factor only serves to slightly reduce the contrast of the reconstructed image. More important is the fact that a complex background wavenumber produced a blending of the real and imaginary parts of the object function that is not accounted for in the imaging algorithm. Thus, the quantities reconstructed are truly not the real and imaginary of the object function but some blending of the two. The interpretation of the real part and imaginary parts of the object function as being an indication of relative wave speed and relative attenuation, respectively, is now suspect; however, together these two imaged quantities reproduced the shape of the target providing the desired discrimination.

The computational problems associated with imaging when k_0 is complex can avoided when using maximum likelihood estimation. In such cases, the imaging algorithm, Eqs. (7) thru (10), requires an inversion of an integral transform with a complex wavenumber; however, the maximum likelihood estimator, Eqs. (12) and (13), is a forward transform and can be implemented with simple and computationally-efficient numerical procedures. A further benefit of maximum likelihood estimation not previously discussed is that the vertical component of the wave vector \mathbf{K} , $K_z = \sqrt{4k_0^2 - \mu^2}$ is complex, not only when k_0 is complex, but also when $|\mu| > 2k_0$. This fact implies that there is little benefit to imaging using a fine spatial sampling since this sampling maps into large values of μ that must be discarded. Since the maximum likelihood estimator does not require an inverse integral transform, both complex k_0 and $|\mu| > 2k_0$ can be incorporated without any computational complications. When $|\mu| > 2k_0$, evanescent waves exist. These waves propagate horizontally and decay exponentially in the vertical direction. When targets are in the near-field, there can be significant energy in evanescent modes and, by exploiting this information, target discrimination can be enhanced⁶.

Abstract. Diffraction tomography (DT) is a quantitative technique for high-resolution subsurface imaging. In general, DT algorithms are used for subsurface imaging with propagating waves. In this study an imaging algorithm is developed and tested for use with broadband electromagnetic induction for a so-called 'multimonostatic' measurement geometry; a primary and secondary coil are coincident and move in unison over a uniformly spaced grid, on or above the ground surface. The algorithm is formulated in three dimensions and tested on simulated data for inhomogeneities that are both two and three dimensional. The algorithm is also applied, in two dimensions, to data acquired over a pair of parallel tunnels. One important finding is that good images can be reconstructed when the frequency band is limited to the case where all skin depths are greater than the depth of inhomogeneities.

1. Introduction

Since the early 1980s (Devaney 1982), work has been proceeding on the development of a class of high-resolution imaging algorithms that has become known as diffraction tomography (DT). The earliest concepts for geophysical diffraction tomography (GDT) (Devaney 1984) were for transmission-mode measurements—either offset vertical seismic profiling or cross-borehole—where tomographic images are reconstructed for a fixed frequency of illuminating wave.

In a parallel development, Won (1980) showed that broadband electromagnetic induction (EMI) could be used to perform vertical soundings of the Earth. By moving a coil pair along or above the ground surface and acquiring data over a broad range of frequencies at each coil location, a defocused image will result from displaying the secondary coil output as a function of skin depth and horizontal coil position. To illustrate this, consider an isolated conductive anomaly at some depth d in a homogeneous background and a coil pair fixed on the ground surface directly above the inhomogeneity. Increasing the skin depth δ (decreasing the driving frequency) from some small value to successively larger values, such that δ remains less than d , will not produce any significant change in the measured secondary field. This is because: (1) the background conductivity is constant; and (2) both the primary and secondary field decay exponentially with the skin depth so that the conducting anomaly is exposed to a very weak primary field that, in turn, produces a weak secondary field that undergoes substantial decay between the anomaly and the ground

surface. The secondary field strength is some weighted average of the vertical variations in conductivity over the skin depth. Consequently, as δ is increased to the point where it is comparable to d , the inhomogeneity produces a perturbation in the secondary field. As δ increases beyond d , the vertical extent of the anomaly occupies a decreasing fraction of the skin depth and the secondary field becomes progressively weaker. Since the field from a dipole coil diminishes by geometric spreading at a rate inversely proportional to the distance cubed, moving the coil pair laterally away from the inhomogeneity and repeating the sounding yields an attenuated and, since the field propagates as well as decays with distance, perhaps, phase-shifted replicate of the sounding taken directly over the inhomogeneity. Thus, the display of broadband EMI data as a function of measurement position and skin depth essentially produces a blurred image of the anomaly that peaks at the lateral location of the anomaly and at a skin depth comparable to the target depth.

More recently, DT algorithms have been developed for ground penetrating radar (Molyneux and Witten 1993, Witten *et al* 1994). This work considers broadband electromagnetic wave illumination in a multimonostatic measurement geometry. Since the multimonostatic geometry assumed in the above cited radar-based imaging algorithms is the same as that typically employed in EMI data acquisition, it would seem that these radar algorithms could be extended to the case of a complex background wavenumber and thereby allow imaging with broadband EMI. However, there exists decades of experience in processing wave-based data; and consequently, optimal spatial and temporal sampling is well known. Specifically, in wave-based methods, it is necessary to sample spatially at intervals no greater than one-half of a wavelength. In geophysical EMI measurements, the wavelength is quite large so that the wave characteristics can be resolved with a coarse spatial sampling. It is expected that sampling based on the Nyquist criterion will not yield well resolved images and it remains to establish rules for optimal spatial sampling for EMI imaging. Because most EMI tools operate at relatively low frequencies, up to tens of kHz, an issue of particular importance is whether inhomogeneities, having characteristic depths less than the skin depth associated with the highest frequency, can be imaged.

In this study, a DT-based imaging algorithm is developed for broadband, multimonostatic imaging with EMI. A forward model (Witten *et al* 1994) is first presented that serves as the basis for the subsequent imaging algorithm. This algorithm is then applied to both synthetic and actual field data.

2. The forward model

The background geometry considered (figure 1) is a uniform isotropic space characterized by constant dielectric ϵ_0 , susceptibility μ_0 , and conductivity σ_0 , in which is embedded some localized inhomogeneity characterized by a spatially-variable conductivity, $\sigma(\mathbf{r})$ (and, perhaps $\epsilon(\mathbf{r})$) having support in the half-space $z < 0$. The governing equation for an electric field \mathbf{E} driven at a frequency ω is derived from Maxwell's equations

$$(\nabla \times \nabla \times - k_0^2) \mathbf{E} = f(\mathbf{r}) \mathbf{E} \quad (1)$$

where $k_0^2 = i\omega\mu_0(-i\omega\epsilon_0 + \sigma_0)$ is the background square wavenumber and inhomogeneities are characterized by the object function $f(\mathbf{r}) = i\omega\mu_0(-i\omega[\epsilon(\mathbf{r}) - \epsilon_0] + [\sigma(\mathbf{r}) - \sigma_0])$. For simplicity, a low-frequency approximation is assumed where $\sigma(\mathbf{r}), \sigma_0 \gg \omega\epsilon(\mathbf{r}), \omega\epsilon_0$, so that

$$k_0 \approx \sqrt{i\omega\mu_0\sigma_0} \quad (2)$$

and

$$f(\mathbf{r}) \approx i\omega\mu_0[\sigma(\mathbf{r}) - \sigma_0] = k_0^2 \left[\frac{\sigma(\mathbf{r})}{\sigma_0} - 1 \right] = k_0^2 O(\mathbf{r}) \quad (3)$$

where $O(\mathbf{r})$ is referred to as the object function.

Figure 1. The host geometry under consideration. The y axis (not shown) is into the plane of the figure. A co-located transmitting and receiving coil is located in the box labelled coil pair. Each coil is assumed to have an arbitrary orientation.

Equation (1) can be expressed in the form of an integral equation for the secondary field E_s as

$$E_s(\mathbf{r}) = \int d\mathbf{r}' E(\mathbf{r}') \cdot \mathcal{G}(\mathbf{r} - \mathbf{r}') f(\mathbf{r}') \quad (4)$$

where \mathcal{G} is the dyadic Green function. Assuming that $z' < z$, which will be the case when measurements are made on or above the ground surface and the support of f is entirely in the lower half-space (figure 1), \mathcal{G} can be expressed as the Weyl-type expansion (Morse and Feshbach 1953)

$$\mathcal{G}(\mathbf{r} - \mathbf{r}') = \frac{i}{8\pi^2} \int d\mathbf{K} \frac{1}{m} (\mathcal{I} - \hat{\mathbf{k}}_+ \hat{\mathbf{k}}_+) e^{i\mathbf{k}_+ \cdot (\mathbf{r} - \mathbf{r}')} \quad (5)$$

where \mathcal{I} is the identity dyad, $\mathbf{k}_+ = \mathbf{K} + m(\mathbf{K})\hat{\mathbf{z}}$, $m(\mathbf{K}) = \sqrt{k_0^2 - |\mathbf{K}|^2}$, the imaginary part of $m \geq 0$, the hatted quantities are unit vectors, and \mathbf{K} is the two-dimensional horizontal wavevector.

By assuming that the electric field E changes slowly over the support volume of $f(r)$, the volume over which $f(r) \neq 0$, the field appearing under the integral in (4) can be replaced by the primary field E_0 . This is the Born approximation. The primary field at some r' with $z' < 0$ can be represented in terms of the primary field at $z = 0$ by

$$E_0(r') = \frac{1}{(2\pi)^2} \int dK' e^{ik'_- \cdot r'} \tilde{E}_0(K', z = 0) \quad (6)$$

where \tilde{E}_0 is the two-dimensional, horizontal Fourier transform of E_0

$$\tilde{E}_0(K', z) = \int dx' e^{-iK' \cdot x'} E_0(x', z) \quad (7)$$

$r' = (x', z')$ and $k'_- = K' - m(K')\hat{z}$.

Invoking the Born approximation, taking the primary coil to be located at point r_0 and using (5) and (6) in (4); the horizontally Fourier-transformed secondary field becomes

$$\begin{aligned} \tilde{E}_s(K, z; r_0) &= \int dx E_s(x, z) e^{-iK \cdot x} \\ &= e^{imz} (\mathcal{I} - \hat{k}_+ \hat{k}_+) \cdot \frac{i}{2m} \int dK' \tilde{E}_0(K', 0) e^{-ik'_- \cdot r_0} \int dr' f(r') e^{-i(k_+ - k_-) \cdot r'} \end{aligned} \quad (8)$$

and $\tilde{E}_0(K', 0)$ characterizes the coil used to generate the primary field.

The next steps in the development of the forward model formulation involve the representation of the transmitter and receiver coils in terms of their orientations and their input and output characteristics. The open terminal output voltage from the receiver coil resulting from its response to a secondary field E_s is given by

$$V_{oc}(r_0) = -\frac{1}{I_0} \int dr' J(r') \cdot E_s(r' + r_0) \quad (9)$$

where I_0 is the current across the coil terminals and $J(r')$ is the current distribution within the coil. It has been assumed that the receiver coil is coincident with the transmitter coil at r_0 .

The vector magnetic potential for a current distribution J_0 in the transmitter coil is given by

$$A(r) = \mu_0 \int dr' J_0(r') G(r - r') \quad (10)$$

where

$$G(r - r') = \frac{i}{8\pi^2} \int dK' \frac{1}{m(K')} e^{ik'_- \cdot (r - r')}. \quad (11)$$

Using the relationship between the magnetic potential and electric field

$$E = \frac{i}{\omega\mu_0\epsilon_0} \nabla \times \nabla \times A \quad (12)$$

the two-dimensional, horizontally Fourier-transformed primary field can be written as

$$\tilde{E}_0(K, z) = -\frac{\omega\mu_0}{2m} (\mathcal{I} - \hat{k}_- \hat{k}_-) \cdot \int dr' J_0(r') e^{-ik_- \cdot r'}. \quad (13)$$

The final introduction of coil-specific parameters is made by assuming that a coil (either the transmitter or receiver) is of small radius a , consisting of N turns with its axis pointing in the direction \hat{n} , and is located at some elevation above the ground surface $h \geq 0$. By taking the current to be constant within the coil,

$$(\mathcal{I} - \hat{k}_\pm \hat{k}_\pm) \cdot \int dr' J(r') e^{\pm ik_\pm \cdot r'} = \pm i\pi N a^2 e^{imh} \hat{n} \times \hat{k}_\pm. \quad (14)$$

Substituting (

$$\tilde{V}_{oc}(K) = -ia$$

where $\tilde{V}_{oc}(K)$

N_s is the number of turns of the coil, a_s is the radius of the coil,

$$H(K, K'; k_+)$$

and \hat{n}_s and \hat{n}_0 are the unit vectors in the direction of the transmitter coil and the receiver coil, respectively. The material having a two-layer system

3. Inversion and

The inner integral in the forward model is the form of the forward model of diffraction tomography. The transform of the forward model is a GPST, imaging the forward model. The forward model is a (K') integration. In order to derive

The procedure whereby the outer integral is approximated. This approximation varies slowly compared to the inner integral. This, in turn, requires that the inner integral be approximated by δ where $\delta = 1/\sqrt{\epsilon_0}$. This approximation was used by Witten (1993). It is hoped that this final step in the forward model. Performing the K''

$$\tilde{V}_{oc}(K)$$

where

$$\gamma(K) = \sqrt{4k_0^2 - |K|^2}$$

$$k = K + \gamma(K)\hat{z}$$

$$\tilde{O}_1(k) = \int dr \frac{O_1(r)}{(h - z)}$$

$$\tilde{O}(K, z) = \int dx C$$

Substituting (9), (13) and (14) into (8) yields the final form of the forward model

$$\tilde{V}_{oc}(K) = -i\omega\mu_0(\pi k_0)^4 \int dK' (e^{iQh}/Q) H(K, K'; k_+) \int dr' O(r') e^{-i(K \cdot x + Qz)} \quad (15)$$

where $\tilde{V}_{oc}(K)$ is the horizontally Fourier-transformed output voltage,

$$Q = m(K/2 + K') + m(K/2 - K')$$

N_s is the number of turns in the receiver coil, N_0 is the number of turns in the transmitter coil, a_s is the radius of the receiver coil, a_0 is the radius of the transmitter coil,

$$H(K, K'; k_+) = I_0 N_s N_0 a_s^2 a_0^2 [\hat{n}_s \times \hat{k}_+(K' + K/2)] \cdot [\hat{n}_0 \times \hat{k}_+(K' - K/2)] \quad (16)$$

and \hat{n}_s and \hat{n}_0 are the unit vectors defining the direction of the axis of the receiver and transmitter coils, respectively. Equation (15) assumes that the coils are imbedded in a material having the same conductivity as the material that hosts the support of $O(r)$. A two-layer system, such as air over soil or rock, is considered in appendix A.

3. Inversion and imaging

The inner integral in (15) is a spatial Fourier transform of the object function O . This form of the forward model is similar to a 'generalized projection slice theorem' (GPST) of diffraction tomography. GPSTs are analytic relationships between the spatial Fourier transform of the acquired data and the spatial Fourier transform of the object function. With a GPST, imaging can be accomplished by inversion using standard numerical techniques. The forward model defined by (15) is not suitable for such an inversion due to the outer (K') integration. Thus, it is necessary to seek some closed-form evaluation of this integral in order to derive a GPST for broadband EMI imaging.

The procedure employed here parallels that established by Molyneux and Witten (1993) whereby the outer integration in (15) is performed approximately by the stationary phase. This approximate representation is valid provided that $H/m(K/2 + K')m(K/2 - K')$ varies slowly compared to $[m(K/2 + K') + m(K/2 - K')](h - z)$ over some range of K . This, in turn, requires that there be a large coefficient in the exponential of the integrand and this will be the case when $(h - z)$ is much greater than one-half of the skin depth δ where $\delta = 1/\sqrt{\sigma_0\mu_0\omega}$. Rigorously, at least in the forward sense, this weak far-field approximation may limit the applicability of this imaging algorithm; however, Molyneux and Witten (1993) demonstrated that no such limitation exists in the inverse sense. It is hoped that this finding can be generalized to the case of EMI inversion considered here. Performing the K' integration in (15) by stationary phase yields the approximate relationship

$$\tilde{V}_{oc}(K) \approx \frac{1}{2}\omega\mu_0 k_0^2 \pi^5 \bar{H}(k) \gamma(K) e^{i\gamma h} \bar{O}_1(k) \quad (17)$$

where

$$\gamma(K) = \sqrt{4k_0^2 - |K|^2}$$

$$k = K + \gamma(K)\hat{z}$$

$$\bar{O}_1(k) = \int dr \frac{O(r)}{(h - z)} e^{-ik \cdot r} = \int dz \frac{e^{-i\gamma z}}{h - z} \int dx O(x, z) e^{-iK \cdot x} = \int dz \frac{e^{-i\gamma z}}{h - z} \bar{O}(K, z)$$

$$\bar{O}(K, z) = \int dx O(x, z) e^{-iK \cdot x} \quad (18)$$

and

$$\bar{H}(\mathbf{k}) = I_0 N_0 N_s a_0^2 a_s^2 (\hat{\mathbf{n}}_0 \times \mathbf{k}) \cdot (\hat{\mathbf{n}}_s \times \mathbf{k}) \quad (19)$$

is a coil-specific filter function.

Equation (17) is the final form of the GPST for broadband EMI imaging. This equation can be rewritten as

$$\hat{O}_1(\mathbf{k}) = \frac{2}{\omega \mu_0 \pi^2 k_0^2 \gamma(K)} e^{-i\gamma h} \bar{V}_{oc}(K) \quad (20)$$

to explicitly represent O_1 as a function of V_{oc} . An image of the spatial variations in O_1 and, hence, O or $\sigma(r)$ can be reconstructed by inverting the integral transform

$$\bar{O}_1(\mathbf{k}) = \int d\mathbf{x} e^{-i\mathbf{K} \cdot \mathbf{x}} \bar{O}_1(\mathbf{x}, \mathbf{k}) \quad (21)$$

where

$$\bar{O}_1(\mathbf{x}, \mathbf{k}) = \int dz O_1(\mathbf{x}, z) e^{-i\gamma z} \quad (22)$$

Equation (21) is a horizontal, two-dimensional, spatial Fourier transform that can be inverted by fast Fourier transform (FFT) techniques; however, (22) is a one-dimensional Fourier transform with a complex wavenumber γ and, therefore, cannot be inverted using an FFT. For this reason, the inversion is a two-step process where, in the first step, the integral transform

$$\bar{\bar{O}}_1(\mathbf{k}) = \int dz \bar{O}_1(K, z) \frac{e^{-i\gamma z}}{h - z} \quad (23)$$

is inverted and then $\bar{O}_1(K, z)$ is inverted by a standard two-dimensional FFT. Equation (23) is inverted by approximating the integral by the quadrature formula

$$\bar{\bar{O}}_1(K, \gamma_i) \approx \sum_j A_{ij} \bar{O}_1(K, z_j) \quad (24)$$

where

$$A_{ij} = e^{-i\gamma_j z_i} \quad (25)$$

$$\gamma_i = \sqrt{4i\delta_i^{-2} - |K|^2} \quad (26)$$

$$z_j = z_0 + (j - 1)\Delta z$$

and

$$\delta_i = \delta_0 + (i - 1)\Delta\delta.$$

Equation (24) represents a mapping from uniformly spaced sampling in z , beginning at a minimum depth z_0 , in increments of Δz , into a uniformly spaced sampling in skin depth from δ_0 , in increments of $\Delta\delta$.

Equation (24) could be solved by inverting the matrix A_{ij} ; however, the system of equations is ill-conditioned so that it becomes necessary to seek a less direct method of inversion. The method used here is regularization where, rather than considering (24), the equation

$$\bar{\bar{O}}_1(K, \gamma_i) = \sum_j (A_{ij} - \lambda I_{ij}) \bar{O}_1(K, z_j) \quad (27)$$

is inverted, where I_{ij} is the identity matrix and λ is referred to as the regularization parameter. The inversion of (27) must be optimized with respect to the regularization parameter. If λ is too small, the inversion will be unstable and if λ is too large, the image will be excessively blurred.

Following the inversion of (27) by regularization for each value of K , $O_1(\mathbf{r})$ can be computed by inversion of the two-dimensional Fourier transform. The object function can be reconstructed from $O(\mathbf{r}) = (h - z)O_1$ and the spatial variations in conductivity can, in turn, be computed using $\sigma(\mathbf{r}) = \sigma_0(O(\mathbf{r}) + 1)$.

4. Results

The forward model derived in section 2 and the inversion algorithm derived in section 3 are three dimensional and allow arbitrary primary and secondary coil orientations. These developments are restricted to cases where both coils are in intimate contact with the ground surface. For situations where the coils are above the ground surface, the formulation is slightly more complicated and the forward model for this case is given in appendix A. This model can be used to develop an inversion algorithm following the procedure given in section 3. For all the results presented in this section, a standard numerical scheme (Press *et al* 1992) was used to implement the regularized inversion defined in (27).

4.1. Two-dimensional synthetic data

Images from broadband EMI are presented using (17) to simulate the broadband data, and (20) and (27) are used to reconstruct the image. For simplicity, the targets are taken to be two dimensional, varying only in the x, z plane, and only three coil orientations are considered. These are: vertical coils—both coil axes are vertical, $\hat{n}_0 = \hat{n}_s = (0, 0, 1)$; horizontal coils—both coil axes are horizontal and parallel to the transect line, $\hat{n}_0 = \hat{n}_s = (1, 0, 0)$; and horizontal coplanar coils—both coil axes are horizontal and perpendicular to the transect line, $\hat{n}_0 = \hat{n}_s = (0, 1, 0)$.

Extensive testing was performed on all coil orientations for a variety of targets of simple shapes. Since the vertical coil orientation produces a smaller gradient in the vertical field and a larger gradient in the horizontal field, as compared to either of the horizontal coil orientations, the forward model results exhibited noticeable differences with varying coil orientation. In contrast, reconstructed images were quantitatively similar for all coil orientations and target shapes. For this reason, the results presented here are limited to those associated with variations in the parameters that affect the quality of reconstructed images: these are the choice of regularization parameter λ (27) and the skin depth interval. For all results presented, a horizontal coil orientation was assumed, the inhomogeneity was a 16 by 4 rectangular conducting anomaly centred at $(0, -16)$, and data were synthesized at 32 horizontal measurement points at $z = 0$ and uniformly distributed over the interval $[-32, 30]$.

Figure 2 provides simulated results for the above described target and measurement configuration displaying the effects of varying the regularization parameter. It is expected that, for relatively large values of this parameter, the inversion should be quite stable; however, the image will be blurred as a result of excessive smoothing. For an extremely small regularization parameter, the inversion will be unstable. Figure 2(a) is the real part of the simulated data where the vertical axis is skin depth. For the simulations presented in this figure, 16 skin depths uniformly distributed on the interval $[2, 32]$ were used. As established by Won (1980), the simulated data appear as an out-of-focus image of the

rectangular target, with the target appearing as a negative anomaly. The reconstructed images, figures 2(b) through 2(e), exhibit the expected result of increased image sharpness with decreasing regularization parameter. An important finding is that the inversion is quite stable and reasonable images were reconstructed over a range of regularization parameter that spans six orders of magnitude.

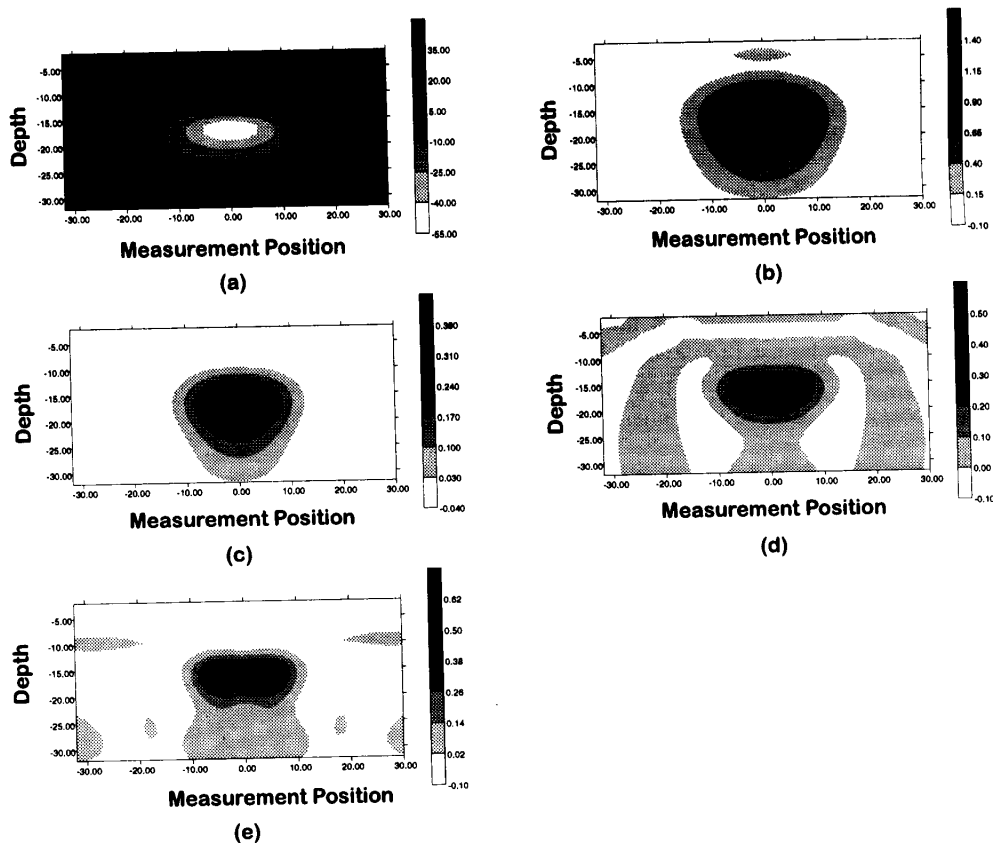

Figure 2. Data and images of a 16×4 conducting rectangle centred at $(0, -16)$ for 32 measurement points uniformly distributed over the interval $[-32, 30]$ along the ground surface, 16 skin depths uniformly distributed on $[2, 32]$ and a horizontal coil axis for (a) the real part of the simulated data and images for regularization parameters of (b) $1e-4$, (c) $1e-6$, (d) $1e-8$, and (e) $1e-10$.

Figures 3 and 4 are reconstructed images displaying the effect of varying the skin depth interval. For all reconstructions, data based on 16 skin depths were used. Figure 3 demonstrates the effect of broadening the range of skin depths and, in this figure, the minimum skin depth is always significantly less than the depth of the conducting rectangle, while the maximum skin depth is progressively increased from 8 (figure 3(a)) to 128 (figure 3(e)). Poor images are obtained when the maximum skin depth is less than the deepest extent of the inhomogeneity (figures 3(a) and (b)). For a maximum skin depth of 8 (figure 3(a)), the reconstructed rectangle has the proper shape, but is too shallow, and increasing the maximum skin depth to 16 (figure 3(b)) results in a reconstruction of the rectangle that is somewhat deeper; however, it is still too shallow and the contrast is reversed. Increasing the maximum skin depth to 24 (figure 3(c)) results in a reasonable reconstruction.

The reconstruction at a maximum skin depth of 128 (figure 3(e)) is a somewhat sharp image, but the contrast is reversed. When the skin depth is 128, the reconstructed image is quite good, but the contrast is reversed. It is clear that a reasonable reconstruction can be obtained for such a coarse set of skin depths.

Figure 4. Data and images of a 16×4 conducting rectangle centred at $(0, -16)$ for 32 measurement points uniformly distributed over the interval $[-32, 30]$ along the ground surface, 16 skin depths uniformly distributed on $[2, 32]$ and a horizontal coil axis for (a) the real part of the simulated data and images for regularization parameters of (b) $1e-4$, (c) $1e-6$, (d) $1e-8$, and (e) $1e-10$.

The reconstructed image is excellent for a maximum skin depth of 48 (figure 3(d)) and even at a maximum skin depth of 128 (figure 3(e)) the reconstructed image is quite good. This is a somewhat surprising result, since for 16 skin depths uniformly distributed on the interval $[2, 128]$, the skin depth increment is almost 8, which is twice the thickness of the rectangular anomaly. While skin depth is somewhat analogous to time in wave-based methods, it is clear that a reflector may be entirely absent in the data for a coarse time sampling; however, such a coarse sampling in skin depths does not profoundly impact the quality of the EMI images.

Figure 3. Images of a 16×4 conducting rectangle centred at $(0, -16)$ for 32 measurement points uniformly distributed on the interval $[-32, 30]$ along the ground surface, a regularization parameter of $1e-8$, a horizontal coil axis, and 16 skin depths uniformly distributed over (a) $[1, 8]$, (b) $[1, 16]$, (c) $[2, 24]$, (d) $[2, 48]$, and (e) $[2, 128]$.

Figure 4 demonstrates the effects of simultaneously varying the minimum skin depth and the skin depth interval. The purpose of these simulations is to investigate implications of using a minimum skin depth that is greater than the target depth. Figure 4(a) is a reconstructed image for a minimum skin depth of 8 and a maximum skin depth of 32. Here, the range of skin depths spans the depth interval of the conductor and the reconstructed image is quite good. When the skin depth does not completely span the vertical extent of the target (figure 4(b)), the image is still good. This is in complete contrast to figure 3(b) where the deeper skin depths, rather than the shallower skin depths, are absent. Increasing the minimum skin depth (figure 4(c)) and further increasing the minimum skin depth and

broadening the skin depth interval (figure 4(d)) results in a progressive blurring of the image. The reason that skin depths less than the target depth are not required to adequately image inhomogeneities is apparent in the simulated data (figure 2(a)). It is clear in this figure that the gradient with respect to skin depth is much steeper for skin depths less than target depth, than for skin depths greater than the target depth. Furthermore, for skin depths less than about one-half the target depth, the secondary field is almost zero. For skin depths substantially larger than the target depth, the secondary field decays slowly with increasing skin depth and there is information regarding target structure encoded in these large skin depths.

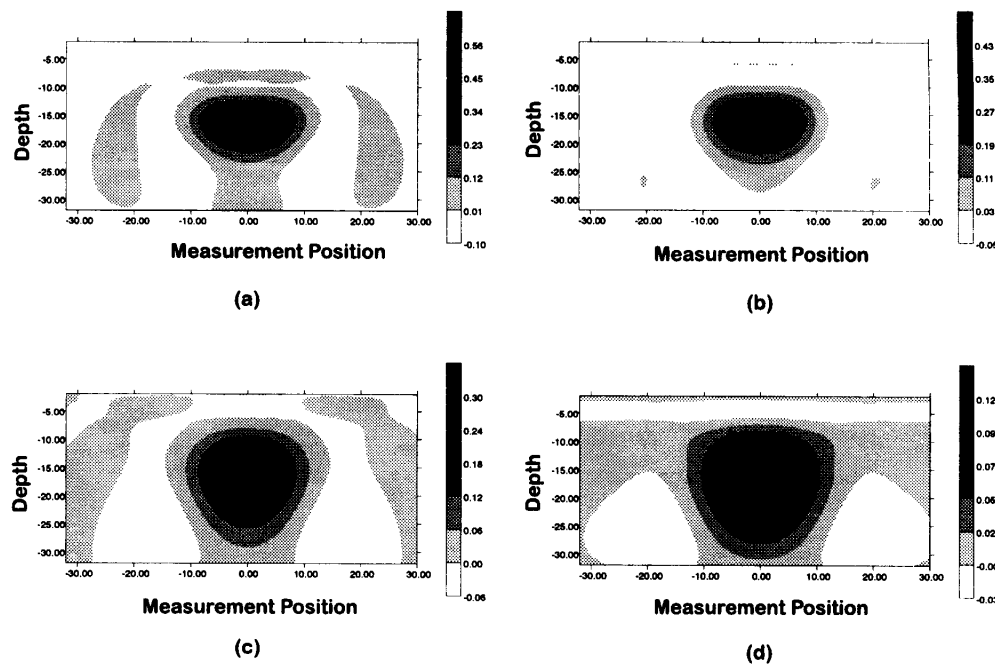

Figure 4. Images of a 16×4 conducting rectangle centred at $(0, -16)$ for 32 measurement points uniformly distributed on the interval $[-32, 30]$ along the ground surface, a horizontal coil axis, and 16 skin depths uniformly distributed over (a) $[8, 32]$, (b) $[16, 48]$, (c) $[32, 64]$, and (d) $[64, 128]$. The regularization parameter used for (a) and (b) is $1e-8$ and for (c) and (d) is $1e-6$.

While the images given above represent quite good reconstructions, they were obtained from noise-free simulated data. Since the inversion of (24) can be ill-conditioned, it can be expected that signal noise can have a profound impact on image quality, particularly when all skin depths are greater than the target depth. To address this problem, additional imaging was performed with noise added to the synthetic data. Two noise models were considered; the relative noise case where the signal-to-noise ratio was defined relative to the maximum signal at each skin depth, and the absolute noise case where the signal-to-noise ratio was defined relative to the maximum signal over all skin depths independent of the skin depths used in the image reconstruction. Noise was added to the signal by first generating a sequence of random numbers uniformly distributed over the interval $[-1, 1]$. After dividing by the signal-to-noise ratio, these random numbers were added to the simulated data. For both noise models, images were reconstructed for a variety of ranges of skin depths. The

results of

- (1) Decrease in the signal-to-noise ratio at a point, can be expected to have a profound impact on image sharpness.
- (2) There is a trade-off between the reconstructed image-to-noise ratio and the signal-to-noise ratio respectively.
- (3) Signal-to-noise ratio is greater than the target depth.

4.2. Two-dimensional

While the results of the two-dimensional imaging are good, the skin depths are small. As the skin depths increase, the signal-to-noise ratio decreases substantially. This is an important issue that needs to be addressed. Images can be reconstructed more importantly, given by (17) and (18), which are required to achieve a target depth of inhomogeneity.

results of these simulations are summarized below.

Figure 5. Plot of the real part of the ratio of primary to secondary field as a function of measurement location and frequency for EMI data acquired over the top of a pair of subway tunnels.

(1) Decreasing the signal-to-noise ratio produces a degradation in image quality that, to a point, can be offset by increasing the regularization parameter but with an associated loss of image sharpness.

(2) There is a signal-to-noise ratio lower limit below which the target cannot be reconstructed no matter how large the regularization parameter. These limiting signal-to-noise ratio values are about 100 and 20 for the absolute and relative noise models, respectively.

(3) Signal noise did not affect the images reconstructed for cases where all skin depths are greater than the target depth more than for cases where the skin depths span the target depth.

4.2. Two-dimensional field data

While the results based on synthetic data establish that images can be reconstructed when all skin depths are significantly greater than the target depth, it must be recognized that, as skin depths increase beyond the target depth, the magnitude of the secondary field decreases substantially. Since the signal-to-noise ratio for synthetic data is essentially infinite, an important issue related to the viability of geophysical EMI imaging is whether adequate images can be reconstructed for large skin depths when the signal-to-noise ratio is finite, or more importantly, small. The synthetic data examples considered here use the forward model given by (17) and, as such, do not address the issue of the weak far-field approximation required to achieve the GPST. The validity of this approximation will be tested provided that all, or some, of the frequencies acquired correspond to skin depths greater than the depth of inhomogeneities.

To address these concerns, broadband EMI data were acquired along a line on the ground surface over a parallel pair of subway tunnels near the Washington, DC, Anacostia Metro station. The broadband geophysical tool used was the GEM-2 (Won *et al* 1996). A subset of this data set was used for imaging. Sixteen measurement points were uniformly distributed over the interval [18 m, 41 m] on the ground surface perpendicular to the axes of the tunnel pair. Sixteen frequencies uniformly distributed over the interval [5010 Hz, 14 010 Hz] were used in the reconstruction. Figure 5 is a display of the real part of the data as a function of measurement location and frequency. Since the range of frequencies shown is quite low, all skin depths are large. As a consequence, the data as displayed do not appear as an out-of-focus image, but rather only the tail of the gradient with respect to skin depth is evident. Thus, this data set represents a good test of both the impact of a low signal-to-noise ratio and the far-field approximation.

Figure 6. Reconstructed image of a pair of parallel subway tunnels near the Washington, DC, Anacostia Metro Station. The tunnel cross sections appear as the near-circular, low conductivity anomalies at a depth of about 12 m. The near-surface high conductivity layer is believed to be saturated soil.

Figure 6 is the image reconstructed from these data based on a regularization parameter of $1e-6$ and an assumed background conductivity of $0.1 \text{ Siemen m}^{-1}$. The cross sections of the two tunnels are clearly evident as the near-circular low conductivity anomalies at a depth of about 12 m. In addition, there is an apparent high conductivity layer in the upper 3 m of the image. There was standing water on the ground at the time the data were

acquired, getting (the right-hand) and near-surface, however, their

4.3. Three-dimensional

acquired, getting progressively deeper to about 0.3 m at one end of the measurement line (the right-hand side of figure 5), and this layer is likely a result of the presence of surface and near-surface water. The depth of the tunnels at the measurement line is not known, however, their imaged depth is consistent with available estimates.

4.3. Three-dimensional synthetic data

To demonstrate EMI imaging in three dimensions, broadband EMI data was synthesized for measurements made over a two-dimensional grid on the ground surface. A 16×16 grid was employed, where $-16 \leq x, y \leq 14$. The target was a rectangular solid conductor with centre at $(0, 0, -16)$ and having dimensions $(8, 16, 4)$. Data were synthesized for eight skin depths uniformly distributed on the interval $[2, 32]$. The three-dimensional reconstruction was based on eight depth points uniformly distributed on the interval $[-9, -23]$ and a regularization parameter of $1e-8$. Figure 7 is a 'chair cut' of the three-dimensional image through the centre of the inhomogeneity. This figure is an accurate representation of the target location and aspect ratio. While this image is not as sharp as the synthetic reconstructions for the two-dimensional rectangle, it must be recognized that this image is based on the equivalent of one-quarter of the data points used in the two-dimensional simulations.

Figure 7. 'Chair cut' through a three-dimensional image of a reconstructed rectangular solid conductor.

5. Conclusions

A three-dimensional imaging algorithm for broadband EMI data has been developed and implemented. This algorithm has been tested on two- and three-dimensional synthetic data and on two-dimensional field data. It has been shown that EMI imaging can yield good reconstructions of both conductive and resistive targets, even for a relatively small number of frequencies. Perhaps the most important finding is that adequate images can be obtained when the highest frequency is so low that all skin depths are greater than the target depth. This is exemplified by the reconstructed image of the tunnels (figure 6) where the tunnels are manifested in the data as only a gradient in frequency (figure 5), rather than a well defined peak in response at a skin depth comparable to the target depth (figure 2(a)). This suggests that there is some hope for imaging relatively small and shallow targets with the relatively low-frequency EMI tools.

The imaging approach is based on the concept of diffraction tomography where an analytic relationship is established between the spatial Fourier transform of the acquired data and a spatial integral transform of the variations in conductivity. For EMI imaging, the integral transform is Fourier (real wavenumber) in the horizontal directions while the vertical component of the integral transform is characterized by a complex wavenumber. For this reason, the full integral transform cannot be inverted by the computationally efficient fast Fourier transform procedure. The mapping from depth into skin depth must be inverted by matrix inversion at every horizontal wavevector point, which is far less efficient. Despite this limitation, the imaging algorithm is computationally efficient. For example, the three-dimensional image reconstruction required only several seconds on a Pentium-based processor. For production-mode processing where image depths and skin depths are fixed, the algorithm can be rendered more computationally efficient by employing the 'pseudo-inverse' concept developed by Deming and Devaney (1996). Using this approach, the matrix inversion becomes independent of the acquired data and, as a consequence, can be pre-computed and stored. Furthermore, the pseudo-inverse explicitly accounts for the band-limited nature of the acquired data and, for this reason, promises better images when a limited bandwidth and a small number of frequencies are used.

In the derivation of the imaging algorithm, it is assumed that the host formation is completely characterized by its conductivity and is manifested in the background wavenumber $k_0 \approx \sqrt{i\omega\mu_0\sigma_0}$. This assumption was made as a matter of convenience rather than necessity. Since this background wavenumber is complex, no complications arise from defining $k_0 = \sqrt{i\omega\mu_0(-i\omega\epsilon_0 + \sigma_0)}$ and thereby characterizing the host formation in terms of both its dielectric and conductivity. Similarly, the object function was assumed real, where $O(\mathbf{r}) = [(\sigma(\mathbf{r})/\sigma_0) - 1]$. The object function is, in general, complex, so that spatial variations in conductivity can be reconstructed from the real part of O , while spatial variations in dielectric can be reconstructed from $\text{Im}(O)$.

Appendix. Introduction of ground-air planar interface effects

In section 2 the formulation for imaging a finite support heterogeneity from a suite of multimonostatic experiments with loop antennas scanning the $z = h, h \geq 0$ was presented, and it was assumed that the background conductivity (and dielectric) was the same for both half-spaces $z \geq 0$ and $z < 0$. The fact that the medium is a good conductor affects the formulation only in modifying the plane wavenumber from purely real in dielectric media to complex with a 45° phase. The 'propagation' effects are now called electromagnetic induction or diffusion, but other than terminology, nothing has essentially

$$\tilde{E}^s(K'; r_0) = (\mathcal{I} -$$

$$\tilde{E}_0(K; r_0) = \tilde{E}_0(K)$$

changed compared to the electromagnetic dielectric case. A significant effect on the problem is that the generalized projection slice theorem (GPST) now relates plane wave spectra of scattered fields to the Fourier transform of the scatterer profile evaluated at complex spatial frequencies, a fact that poses special difficulties for the inverse (imaging) problem.

In this appendix, the work of section 2 is extended to the case where the scatterer is embedded in a conducting half space at $z < 0$, where the access for interrogating the object is limited to the adjacent free space at $z \geq 0$. It is assumed that the scatterer is sufficiently weak, such that its coupling to the $z = 0$ interface is negligible, and also that the antennas themselves are negligibly coupled to this interface (which is always true in the case of loop antennas that are sufficiently small compared to the wavelength and compared to their distance from the interface).

A.1. Dyadic Fresnel coefficients for transmission of plane electromagnetic waves through an air-ground interface

The geometry considered is shown in figure A.1 where the ground at $z < 0$ is characterized by a wavenumber $k_0 = (i\omega\mu_0\sigma_0)^{1/2}$ and the air at $z \geq 0$ is characterized by a purely real wavenumber $k_1 = \omega(\mu_0\epsilon_0)^{1/2}$.

The scalar Fresnel transmission coefficients are readily obtained through application of the continuity condition of the tangential electric field and its normal derivative across the boundary at $z = 0$

$$\begin{aligned}\tilde{T}_+(K) &= \frac{2m_0}{m_0 + m_1} & m_0(K) &= \sqrt{k_0^2 - K^2} & \text{Im}\{m_0\} \geq 0, \text{Re}\{m_0\} \geq 0 \\ \tilde{T}_-(K) &= \frac{2m_1}{m_0 + m_1} & m_1(K) &= \sqrt{k_1^2 - K^2} & \text{Im}\{m_1\} \geq 0, \text{Re}\{m_1\} \geq 0\end{aligned}\quad (\text{A.1})$$

such that the tangential electric fields are related through

$$\begin{aligned}(\mathcal{I} - \hat{z}\hat{z}) \cdot \tilde{E}_1(K) &= \tilde{T}_+(K)(\mathcal{I} - \hat{z}\hat{z}) \cdot \tilde{E}_0^{\text{inc}}(K) \\ (\mathcal{I} - \hat{z}\hat{z}) \cdot \tilde{E}_0(K) &= \tilde{T}_-(K)(\mathcal{I} - \hat{z}\hat{z}) \cdot \tilde{E}_1^{\text{inc}}(K).\end{aligned}\quad (\text{A.2})$$

The full vector electric fields across the $z = 0$ boundary are thus related through a dyadic Fresnel transmission coefficient

$$\begin{aligned}\tilde{E}_1(K) &= \tilde{T}_+(K) \cdot \tilde{E}_0^{\text{inc}}(K) & \tilde{T}_+(K) &= \left[\mathcal{I} - \hat{z} \left(\hat{z} + \frac{K}{m_1(K)} \right) \right] \tilde{T}_+(K) \\ \tilde{E}_0(K) &= \tilde{T}_-(K) \cdot \tilde{E}_1^{\text{inc}}(K) & \tilde{T}_-(K) &= \left[\mathcal{I} - \hat{z} \left(\hat{z} - \frac{K}{m_0(K)} \right) \right] \tilde{T}_-(K)\end{aligned}\quad (\text{A.3})$$

where the z components have been derived by invoking the transversality condition of the electric field with respect to the plane wavevector $(K + m_1\hat{z}) \cdot \tilde{E}_1(K) = 0$ and $(K - m_0\hat{z}) \cdot \tilde{E}_0(K) = 0$.

A.2. Scattered electric field within the Born approximation in the presence of a planar boundary

In section 2, it was shown (8) that the plane wave spectrum of the scattered field at $z = 0$, due to a source antenna positioned at r_0 in a homogeneous background k_0 , is given by

$$\begin{aligned}\tilde{E}^s(K'; r_0) &= (\mathcal{I} - \hat{k}'_0 \hat{k}'_0) \cdot \frac{i}{2m'_0} \int dK \tilde{E}_0(K; r_0) \int dr' f(r') e^{-i(k'_0 - k_0) \cdot r'} \\ \tilde{E}_0(K; r_0) &= \tilde{E}_0(K) e^{-ik_0 \cdot r_0}\end{aligned}\quad (\text{A.4})$$

Figure A.1. Plane wave spectral relations at an interface between air and ground for the geometry under consideration.

where

$$\begin{aligned} k_{0\pm}(K) &= K \pm m_0(K)\hat{z} & m_0(K) &= \sqrt{k_0^2 - K^2} & \text{Im}\{m_0\} &\geq 0 & K &= |K| \\ k'_{0\pm} &= k_{0\pm}(K') & m'_0 &= m_0(K') \end{aligned} \quad (\text{A.5})$$

and $\tilde{E}_0(K)$ is the plane wave spectrum of the electric field emitted by the source antenna when positioned at reference location $r_0 = 0$. $\tilde{E}^s(K'; r_0)$ is the plane wave spectrum of the scattered field at $z = 0$ when the source antenna is located at r_0 .

If it is assumed that the upper half space $z \geq 0$ is free space $k_1 \neq k_0$, and also assumed that the scatterer is negligibly coupled to the $z = 0$ interface, then the above equation provides an expression for the scattered field incident on the $z = 0^-$ boundary with \tilde{E}_0 being the source field transmitted into the lower domain at $z = 0^-$. In terms of the electric fields at $z = 0^+$,

$$\begin{aligned} \tilde{E}_1^s(K'; r_0) &= \tilde{T}_+(K')(\mathcal{I} - \hat{k}'_{0+}\hat{k}'_{0+}) \cdot \frac{i}{2m'_0} \int dK \tilde{T}_-(K) \tilde{E}_1^{inc}(K; r_0) \\ &\times \int dr' f(r') e^{-i(k'_{0+} - k_{0-}) \cdot r'} \end{aligned}$$

$$\tilde{E}_1^{inc}(K; r_0) =$$

In this section we $z = z_0$ in synchr current I_0 .

$$\tilde{E}_1^{\text{inc}}(\mathbf{K}; \mathbf{r}_0) = \tilde{E}^{\text{inc}}(\mathbf{K}) e^{-i\mathbf{k}_1 \cdot \mathbf{r}_0} \quad (\text{A.6})$$

where the plane wavevector in the upper half space is defined by

$$\mathbf{k}_{1\pm} = \mathbf{K} \pm m_1(\mathbf{K})\hat{z} \quad m_1(\mathbf{K}) = (k_1^2 - K^2)^{1/2} \quad \text{Im}\{m_1\} \geq 0. \quad (\text{A.7})$$

For later use, it is desirable to Fourier transform \mathbf{x}_0 , the lateral spatial variable of \mathbf{r}_0 , according to

$$\tilde{\tilde{E}}_1^s(\mathbf{K}'; \mathbf{K}, z_0) = \int d\mathbf{x}_0 e^{-i\mathbf{K} \cdot \mathbf{x}_0} \tilde{E}_1^s(\mathbf{K}'; \mathbf{x}_0, z_0) \quad (\text{A.8})$$

to obtain the doubly Fourier-transformed multimonostatic scattered field

$$\begin{aligned} \tilde{\tilde{E}}_1^s(\mathbf{K}'; \mathbf{K}, z_0) &= (2\pi)^{c-1} \frac{i}{2m'_0} e^{im_1 z_0} \tilde{\mathcal{D}}(\mathbf{K}'; \mathbf{K}) \cdot \tilde{E}_1^{\text{inc}}(-\mathbf{K}) \tilde{f}(\mathbf{k}'_{0+} + \mathbf{k}_{0+}) \\ \tilde{\mathcal{D}}(\mathbf{K}'; \mathbf{K}) &= \tilde{T}_+(\mathbf{K}')(\mathcal{I} - \hat{\mathbf{k}}'_{0+} \hat{\mathbf{k}}_{0+}) \tilde{T}_-(-\mathbf{K}) \end{aligned} \quad (\text{A.9})$$

where the c -dimensional Fourier transform of the object function is defined according to

$$\tilde{f}(\mathbf{q}) = \int d\mathbf{r} e^{-i\mathbf{q} \cdot \mathbf{r}} f(\mathbf{r}). \quad (\text{A.10})$$

The doubly transformed multimonostatic scattered field referenced to $z_0 = 0$ is therefore given by

$$\tilde{\tilde{E}}_1^s(\mathbf{K}'; \mathbf{K}) = (2\pi)^{c-1} \frac{i}{2m'_0} \tilde{\mathcal{D}}(\mathbf{K}'; \mathbf{K}) \cdot \tilde{E}_1^{\text{inc}}(-\mathbf{K}) \tilde{f}(\mathbf{k}'_{0+} + \mathbf{k}_{0+}). \quad (\text{A.11})$$

As found in section 2, the plane wave spectrum of the transmitting antenna (subscripted by 0) field is related to its vector effective height $\tilde{\mathbf{h}}_0$ through

$$\tilde{E}_1^{\text{inc}}(\mathbf{K}) = -I_0 \frac{\omega\mu_0}{2m_1} \tilde{\mathbf{h}}_0(-\mathbf{K}) \quad (\text{A.12})$$

such that, in terms of the vector effective height of the transmitting antenna, it is given by the following expression for the doubly Fourier-transformed multimonostatic scattered electric field

$$\tilde{\tilde{E}}_1^s(\mathbf{K}'; \mathbf{K}) = -(2\pi)^{c-1} I_0 \frac{i\omega\mu_0}{4m_1 m'_0} \tilde{\mathcal{D}}(\mathbf{K}'; \mathbf{K}) \cdot \tilde{\mathbf{h}}_0(\mathbf{K}) \tilde{f}(\mathbf{k}'_{0+} + \mathbf{k}_{0+}). \quad (\text{A.13})$$

Note that this is only the component of the field scattered off the interior of $z < 0$ and does not contain the undesired (strong) component of the field reflected off the $z = 0$ boundary as well as the direct field. The undesired components can be easily incorporated into the formulation or, alternatively, if illuminating the ground with short pulses, the early arrival of these components can be effectively time gated.

A.3. Measured signal in a multimonostatic measurement configuration above ground

In this section we obtain the terminal signal at a receiving antenna, that sweeps a plane $z = z_0$ in synchronization with the transmitting antenna that is excited with a terminal current I_0 .

Assuming that the scattered signal $\tilde{E}_1^s(K; r_0)$ is received by a receiving antenna that is positioned at r_1 such that if it were to transmit, its current distribution would be $J_1(r - r_1)$, with terminal current I_1 . By the Lorentz reciprocity theorem, it is known that the open circuit terminal voltage is given by

$$\begin{aligned} V(r_1; r_0) &= -\frac{1}{I_1} \int d\mathbf{r}' J_1(\mathbf{r}' - r_1) \cdot \mathbf{E}_1^s(\mathbf{r}'; r_0) = -\frac{1}{I_1} \int d\mathbf{r}' J_1(\mathbf{r}') \cdot \mathbf{E}_1^s(\mathbf{r}' + r_1; r_0) \\ &= -(2\pi)^{1-c} \frac{1}{I_1} \int d\mathbf{r}' J_1(\mathbf{r}') \cdot \int d\mathbf{K}' e^{i\mathbf{K}' \cdot (\mathbf{r}' + r_1)} \tilde{E}_1^s(\mathbf{K}'; r_0) e^{im'_1(z' + z_1)} \\ &= -(2\pi)^{1-c} \int d\mathbf{K}' \tilde{h}_1(\mathbf{K}') \cdot \tilde{E}_1^s(\mathbf{K}'; r_0) e^{i\mathbf{k}'_{1+} \cdot r_1} \\ &= -(2\pi)^{2(1-c)} \int d\mathbf{K}' \tilde{h}_1(\mathbf{K}') \cdot \int d\mathbf{K} \tilde{E}_1^s(\mathbf{K}'; \mathbf{K}) e^{i(\mathbf{k}'_{1+} \cdot r_1 + \mathbf{k}_{1+} \cdot r_0)} \end{aligned} \quad (\text{A.14})$$

where the vector effective height of the antenna for fields arriving from $z < 0$ is defined in the usual way (13)

$$\tilde{h}_1(\mathbf{K}') = (\mathcal{I} - \hat{\mathbf{k}}'_{1+} \hat{\mathbf{k}}'_{1+}) \cdot \frac{1}{I_1} \int d\mathbf{r}' J_1(\mathbf{r}') e^{i\mathbf{k}'_{1+} \cdot \mathbf{r}'}. \quad (\text{A.15})$$

To this point, the measured signal is at r_1 due to a source located at r_0 . In the multimonostatic case, $r_1 = r_0$, such that

$$V(r_0; r_0) = V_{\text{mm}}(r_0) = -(2\pi)^{2(1-c)} \int d\mathbf{K}' \tilde{h}_1(\mathbf{K}') \cdot \int d\mathbf{K} \tilde{E}_1^s(\mathbf{K}'; \mathbf{K}) e^{i(\mathbf{k}'_{1+} + \mathbf{k}_{1+}) \cdot r_0} \quad (\text{A.16})$$

where V_{mm} denotes the multimonostatic signal (now dependent on only one set of coordinates). Finally, Fourier transforming with respect to the x_0 variable gives

$$\tilde{V}_{\text{mm}}(\mathbf{K}, z_0) = -(2\pi)^{1-c} \int d\mathbf{K}' e^{i[m'_1 + m_1(\mathbf{K} - \mathbf{K}')z_0]} \tilde{h}_1(\mathbf{K}') \cdot \tilde{E}_1^s(\mathbf{K}'; \mathbf{K} - \mathbf{K}'). \quad (\text{A.17})$$

Now, substituting the expression for the doubly Fourier-transformed field (A.13) yields

$$\begin{aligned} \tilde{V}_{\text{mm}}(\mathbf{K}, z_0)/I_0 &= \frac{i\omega\mu_0}{4} \int d\mathbf{K}' \frac{e^{i[m'_1 + m_1(\mathbf{K} - \mathbf{K}')z_0]}}{m_1(\mathbf{K} - \mathbf{K}')m'_0} \tilde{h}_1(\mathbf{K}') \cdot \tilde{\mathcal{D}}(\mathbf{K}'; \mathbf{K} - \mathbf{K}') \\ &\quad \cdot \tilde{h}_0(\mathbf{K} - \mathbf{K}') \tilde{f}[\mathbf{k}'_{0+} + \mathbf{k}_{0+}(\mathbf{K} - \mathbf{K}')]. \end{aligned} \quad (\text{A.18})$$

This result is in agreement with (15) when z_0 is set to zero and the Fresnel transmission dyads are set to unity. Compared to the result in section 2 (equation (15)), here the effect of the $z = 0$ interface is embodied in the dyadic denoted by $\tilde{\mathcal{D}}$.

This result relates $\tilde{V}(\mathbf{K})$ to the Fourier transform of the object function at spatial frequencies $\mathbf{k}_{0+}(\mathbf{K}') + \mathbf{k}_{0+}(\mathbf{K} - \mathbf{K}')$. It is the \mathbf{K}' integral that prevents this last equation from being an ordinary projection slice theorem relation.

ABSTRACT

Broadband electromagnetic induction is a promising technique for the detection and location of underground structures. Along with being simple to use and allowing rapid data acquisition, underground structures can be detected by this method either because the large volume of air necessary for human occupancy will be manifested as an electrical conductivity low relative to the host formation or because there could exist a large metallic mass associated with either structural support or the mission of the facility that would constitute a relative conductivity high. The use of broadband information literally offers an additional dimension, that being depth, to the level of information that can be gleaned from acquired data since, by varying the operating frequency, the probing depth changes. A three-dimensional tomographic imaging algorithm is applied to broadband data acquired at two underground structure sites to reconstruct the relative spatial variations in electrical conductivity. A pair of parallel subway tunnels exist at one site and a cloud chamber at the other. At both sites, quite good images of the structures were obtained and the structures appeared as relative conductivity lows.

Introduction

Under ideal conditions, almost any geophysical tool can be used to detect and located subsurface structures suitable for human occupancy. In practice, however, the choice of geophysical method will be dictated by the anticipated size and depth of the underground structure as well as site conditions including the mechanical and electrical properties of the host geology, whether data can be acquired directly over the underground structure, and the presence of surface or near surface cultural features.

Beyond the above-cited issues that may influence the choice of geophysical methods, there may be operational constraints that must additionally be considered. There are a number of scenarios under which site access time is severely limited and data must be acquired by operators with no geophysical training. In such cases, electromagnetic induction (EMI) is a strong candidate since EMI tools are relatively simple to operate and data can be acquired quite rapidly. Broadband EMI is particularly attractive since, by its nature, it offers information about target depth with no additional complications in data acquisition.

It has been shown (Won, 1980) that a pseudo cross-sectional image can be obtained from broadband EMI measurements made at intervals along a line. By displaying this

data as a vertical slice having a depth axis inversely proportional to the square root of the acquisition frequency, a crude form of an image of spatial variations in electrical conductivity within the cross-section is produced. This technique is referred to as frequency sounding. In a more recent development, Witten, Won, and Norton (1997) established that frequency sounding produced an out-of-focus image of conductivity anomalies and presented a generalized form of diffraction tomography (Devaney, 1984) whereby focused images may be reconstructed.

In this paper, the general concept of frequency sounding is discussed and a three-dimensional broadband EMI imaging algorithm is summarized. This algorithm is applied to broadband EMI data acquired at two sites known to contain underground structures.

EMI Imaging Concepts

The use of EMI in geophysics exploits the fact that a current will be induced in an electrically conductive anomaly, when immersed in a time-varying electromagnetic field. In turn, the current induced in conductive anomalies will induce a (secondary) time-varying electromagnetic field. Thus, EMI measurements can be used to detect and locate subsurface, electrically conductive features by creating a time-varying field

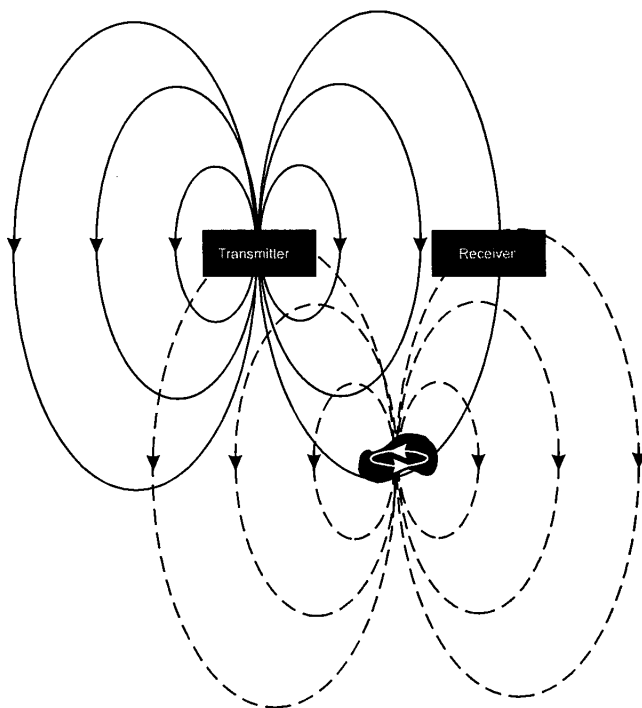

Figure 1. Illustration showing transmitting coil producing a primary field (solid contours). This field induces a current in a conductor (black mass) that, in turn, produces a secondary field (dashed contours) detected by the receiving coil.

using a transmitting coil and measuring the induced secondary field with a receiving coil (fig. 1). Because rock and soil are somewhat conductive and will produce a secondary field when exposed to a primary field, EMI can also be used to detect anomalous features that are more resistive than the background.

In general, there are two methods by which depth information can be extracted from EMI measurements. These are geometrical soundings and broadband soundings. In geometrical soundings, measurements are made at a fixed frequency for a range of separation distances between the transmitting and receiving coils while, for broadband soundings, decreasing the frequency is associating with deeper probing. This study deals only with broadband soundings. In a conducting medium, electromagnetic waves will both oscillate and decay with distance from the source and both the wavenumber and the decay rate are proportional to the frequency. Figure 2 depicts two conducting targets at two different depths below a transmitting coil generating a primary field with conductor 1 being the shallower target. Since this primary field decays with distance, conductor 1 is immersed in a stronger field than conductor 2 and, hence, a stronger current and, consequently, a stronger secondary field is induced in this conductor. Furthermore, there will be greater decay of the secondary field from conductor 2 since it is farther away from a receiving coil taken

to be located alongside the transmitting coil. The receiving coil will measure a secondary field that is a composite of the response of both conductors with this measured response being a depth-integrated function of the conductivity inversely weighted by the depth.

Figure 3 is a sequence of illustrations designed to show how broadband soundings can be used to quantify target depth. In fig. 3a, the driving frequency is sufficiently high that the primary field decays to a negligibly small value before it reaches the depth of the conductive anomaly. Decreasing the frequency (fig. 3b), decreases the rate of decay of the primary field such that a measurable response to the anomaly is produced at the receiver coil. When the frequency is so low that the primary field penetrated to a depth much greater than the conducting target (fig. 3c), the anomaly is only weakly manifested in the measured secondary because, as noted above, this field is depth average and the anomaly occupies only a small portion of the penetration depth. Thus, decreasing the frequency below that shown in fig. 3b will produce a gradual decay in the measured secondary field. Figure 3d shows an idealized magnitude of the measured secondary field as a function of frequency illustrating the broadband sounding concept.

A measure of the penetration depth of a primary field is the skin depth, δ , defined to be

Figure 2. Illustration showing two conductors at different depths below a transmitting coil. Since conductor 2 is further away from the transmitting coil than conductor 1, a weaker current (indicated by the narrower white line depicting the current loop) is induced in this feature.

Figure 3. Illustration showing the oscillation and decay of a time-varying electromagnetic field and a conductor below the transmitting coil for a) a high frequency, b) a moderate frequency, and c) a low frequency. The variation in secondary field strength as a function of frequency is shown in d).

$$\delta = \frac{\sqrt{2}}{\sqrt{\omega \mu_0 \sigma_0}} \quad (1)$$

where ω is the frequency, μ_0 is the background magnetic susceptibility, and σ_0 is the background conductivity. Won (1980) demonstrated that broadband soundings such as that shown in fig. 3d will peak at a skin depth corresponding to the target depth. Figure 4 is simulated data for measurements made by traversing the ground surface with a co-located transmitting/receiving coil pair making measurements every meter for a range of frequencies corresponding to uniformly-spaced skin depths between 1 and 32 meters. The target assumed here is a rectangular conductor dimensioned 12 horizontally by 8 vertically centered at (15.5, -16.5). This figure displays the in-phase component of the output voltage from the secondary coil as gray levels as a function of measurement location and skin depth. It is clear that the data, so displayed, is an out-of-focus image of the rectangular target with the target appearing at a skin depth near the target depth. The phase changes appearing in the

pseudo-image are a result of the fact that both the primary and secondary field are spatially oscillatory. The next section will describe tomographic imaging concepts whereby out-of-focus images, such as that shown in fig. 4 can be sharpened and the phase changes removed.

Broadband EMI Imaging

One means to describe the EMI imaging concept is through the related problem of imaging using seismic reflection and specifically migration. For a co-located seismic source and receiver deployed over the plane $\mathbf{r} = (x, y)$, the spatially and temporally Fourier transformed received signal

$$\tilde{u}(\kappa, \omega) = \int dt e^{i\omega t} \int d\mathbf{r} e^{-i\kappa \cdot \mathbf{r}} u(\mathbf{r}, t) \quad (2)$$

is related to the three-dimensional reflectivity by

$$R(x, y, z) = \frac{1}{8\pi^3} \int d\omega \int d\kappa \exp\{i(\sqrt{4k^2 - \kappa^2} z + \kappa \cdot \mathbf{r})\} \tilde{u}(\kappa, \omega) \quad (3)$$

(Cheng and Coen, 1984), where $k = \omega/c_0$, c_0 is the background wave speed and κ is the magnitude of the two-dimensional vector κ . Spatial variations in reflectivity are recon-

Figure 4. Simulated broadband data for measurements made at uniformly spaced points on the ground surface over the top of 12 by 8 m rectangular conductor buried at an assumed depth of -16.5 m. The horizontal axis is the measurement location and the vertical axis is skin depth. In this form, the data appears as an out-of-focus image. The gray rectangular outline displays the size, shape, and depth of the target.

Figure 5. Vertical cross-sectional image reconstructed from the simulated broadband data shown in Fig. 4. The outline of the actual assumed target is outlined in gray.

structed in Eq. (3) by backpropagating (migrating) the data u downward to some plane $z < 0$ and evaluating this data at time zero. In a similar approach within the framework of diffraction

tomography, the spatial variations of the object function, $O(x, y, z) = 1 - c_0^2/c^2(x, y, z)$, are reconstructed by

$$O(x, y, z) = \frac{1}{8\pi^3} \int d\omega \int d\kappa H(\kappa, \omega) \exp\{i(\sqrt{4k^2 - \kappa^2}z + \kappa \cdot \mathbf{r})\} \tilde{u}(\kappa, \omega) \quad (4)$$

where $c(x, y, z)$ are the spatial variations in wave speed about c_0 and H is measurement geometry-specific filter function. The three-dimensional spatial Fourier transform of Eq. (4) is

$$\tilde{O}(\kappa, \sqrt{4k^2 - \kappa^2}) = H(\kappa, \omega) \tilde{u}(\kappa, \omega) \quad (5)$$

and it is clear that the object function can be reconstructed by applying an inverse Fourier transform to Eq. (5). Equations relating the spatial Fourier transform of data to the spatial Fourier transform of the object function, such as Eq. (5), are known as generalized projection slice theorems (Devaney, 1984).

A generalized projection slice theorem for broadband EMI imaging (Witten, Won, and Norton, 1997) relating the spatially Fourier transformed output voltage from the receiving coil, $V(x, y)$, to an integral transform of the object function, is

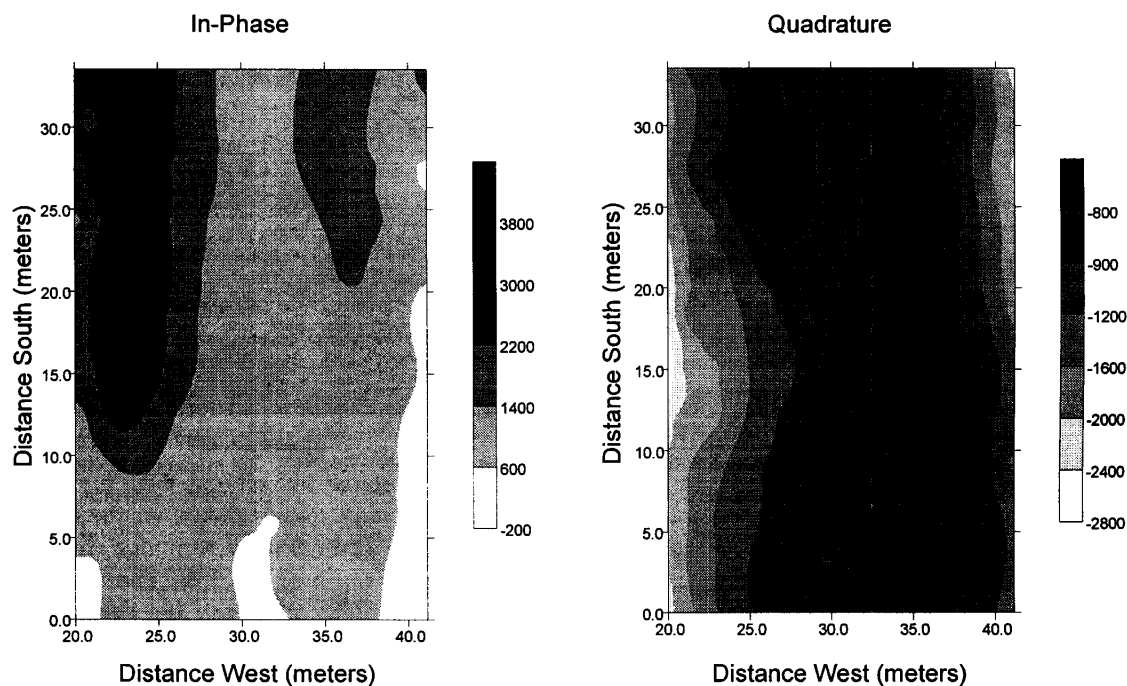

Figure 6. In-phase and Quadrature data at 9810 Hz as measured at the Anacostia tunnel site.

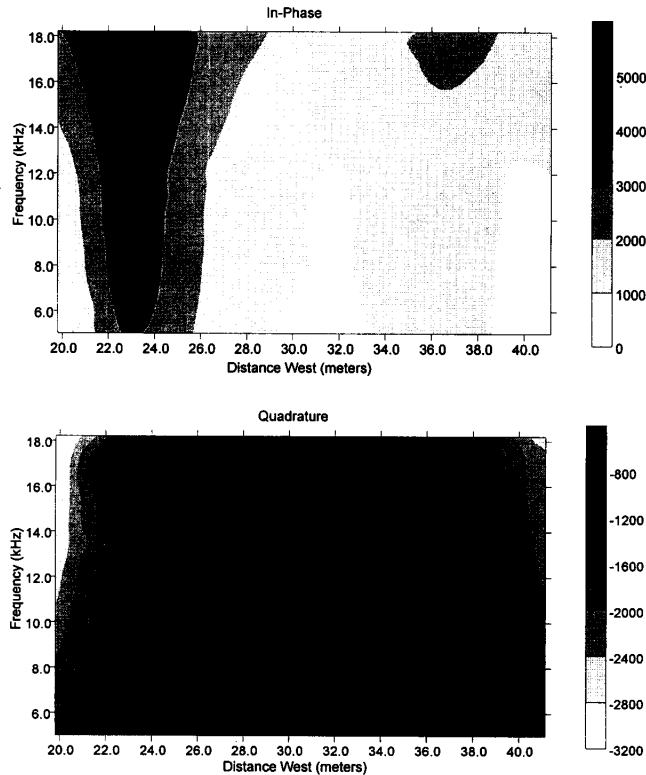

Figure 7. Pseudo image of the Anacostia data presented as measurement location along a line at 21 m north as a function of frequency (the vertical axis).

$$\tilde{O}(\kappa, \sqrt{(32i\pi^2 / \delta^2) - \kappa^2}) = H(\kappa, \omega) \tilde{V}(\kappa, \omega), \quad (6)$$

where $O(x, y, z) = (\sigma(x, y, z) / \sigma_o) - 1$ and $\sigma(x, y, z)$ are the spatial variations in conductivity relative to a background σ_o . The most important difference between this relationship and that for wave-based imaging, Eq. (5), is that the vertical component of the wave vector in Eq. (5) is real while that for EMI imaging, Eq. (6), is complex and cannot be completely inverted by Fourier transform. The inversion of Eq. (6) can be expressed in the form

$$O(x, y, z) = \frac{1}{2\pi^2} \int d\kappa e^{i\kappa \cdot r} \bar{O}(\kappa, z), \quad (7)$$

where the object function is reconstructed by performing an inverse two-dimensional (horizontal) Fourier transform of \bar{O} and \bar{O} is the inverse of the integral transform

$$\begin{aligned} \tilde{O}(\kappa, \sqrt{(32i\pi^2 / \delta^2) - \kappa^2}) = \\ \int dz H(\kappa, \omega) \exp\{-i\sqrt{(32i\pi^2 / \delta^2) - \kappa^2} z\} \tilde{V}(\kappa, \omega). \end{aligned} \quad (8)$$

Equation (8) is a mapping from depth into skin depth and consequently its inverse is a mapping from skin into depth. Since this integral transform is characterized by a complex wave number, it cannot be inverted by Fourier transform. In the algorithm developed here, Eq. (8) is inverted by matrix inversion, however, this procedure is ill-conditioned necessitating the use of a regularization procedure.

Figure 5 is an image resulting from the application of this reconstruction procedure to the broadband data presented in fig. 4. It is clear that this imaging algorithm serves to focus the pseudo-image and removes phase changes evident in fig. 4.

Case Studies

The broadband EMI imaging algorithm has been applied to data acquired at two underground structure sites. At both sites, data were acquired with the GEM-2 sensor (Won, Keiswiter, Fields, and Sutton, 1996). This broadband tool consists of a transmitting and receiving coil located at opposite ends of a boom that is approximately two meters long. A third coil, the "bucking" coil, is used to nullify the primary field at the receiving coil so that this coil responds only to the much weaker secondary field. The GEM-2 can operate at frequencies up to 22kHz.

There are two notable differences between GEM-2's operation and configuration and assumptions made in the imaging algorithm. First, the imaging algorithm assumes that the transmitting and receiving coils are co-located while these coils are separated in the GEM-2. This inconsistency can potentially produce errors in the reconstructed images where

Figure 8: Three-dimensional rendering of the reconstructed image of the subway tunnels at the Anacostia site.

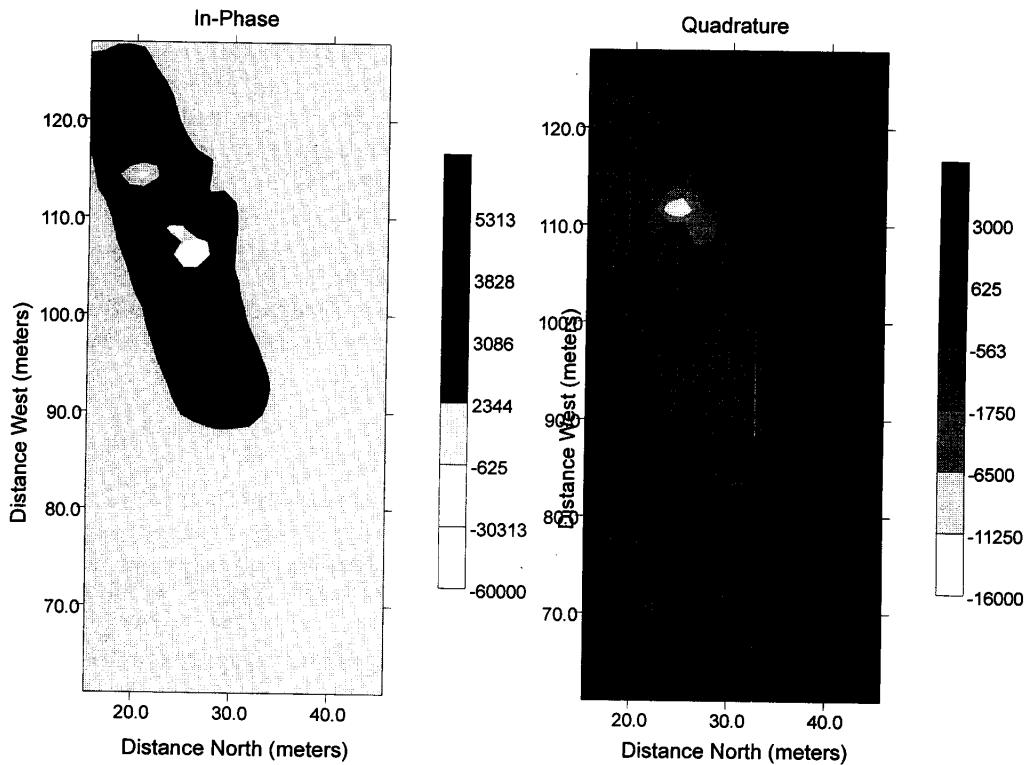

Figure 9: In-phase and Quadrature data at 9270 Hz as measured at the cloud chamber site.

Figure 10: Pseudo image of the cloud chamber data presented as measurement location along a line at 99 m west as a function of frequency (the vertical axis).

the magnitude of such errors will depend on the target depth, the coil separation, and frequencies used in the reconstruction. For the parameters appropriate to the case studies presented here, errors associated with the coil separation can be shown to be negligible. The imaging algorithm described in the previous section is based on output voltage at the receiving coil associated with secondary field. The instrument-specific parameters that influence this voltage are the diameter, number of turns, and orientation of both the transmitting and receiving coils as well as the amperage and frequency applied to the transmitting coil. These parameters appear explicitly in the filter H appearing in Eq. (8). The GEM-2 output is the ratio of the secondary to primary field at the receiving coil in parts per million which is linearly related to receiving coil output voltage. Because of the difference between the actual output from the GEM-2 and that assumed in the imaging algorithm, absolute conductivities cannot be reconstructed, however, reconstructed values of the object function are expected to be correct in a relative sense.

The Anacostia Site

The Anacostia site is vacant lot about 152 m from the Washington, D.C. Anacostia metro station. GEM-2 broadband EMI data were acquired over an area approximately 44 m by 30 m. Part of this area was marshy with standing water varying in depth up to about 0.35 m. The target of interest at this site is a pair of parallel subway tunnels having a center-to-center

Figure 11a. Three-dimensional image of the cloud chamber displayed as 16 uniformly spaced vertical cross-sections at 76.2 through 97.5 m west.

Figure 11b. Three-dimensional image of the cloud chamber displayed as 16 uniformly spaced vertical cross-sections at 100.6 through 121.9 m west.

separation of about 12 m. The axes of these tunnels are oriented in a north-south direction. Each tunnel is approximately 4.5 m in diameter and the tunnel ceilings are believed to be 10 to 13 m below the ground surface. GEM-2 measurements were made at 28 points spaced at 1.524 m in the east-west direction and at 11 points spaced at 3.048 m in the north-south direction. At every measurement point data were acquired with a vertical coil axes orientation for 23 discrete frequencies ranging from 5010 Hz to 18210 Hz in 600 Hz increments.

Figure 6 shows the in-phase and quadrature measurements at 9810 Hz from the Anacostia site. Over the northern half of the survey area both tunnels are manifested in the in-phase data with the western tunnel producing a stronger anomaly. In the southern half, however, there is little evidence of the either tunnel presumably because of an increase in tunnel depth or a change in background conductivity. The existence of the tunnel pair is evident over the entire north-south extent of the quadrature data, however, in this case the individual tunnels are indistinct. This general pattern is typical of data acquired at all frequencies. Figure 7 is a pseudo cross-sectional image of the in-phase component of a slice occurring at 21 m north similar to the synthetic data shown in fig. 4. Here the vertical axis is decreasing frequency and it is expected that there should be a localized anomaly occurring at a frequency associated with a skin depth, Eq. (1), corresponding to the target depth. A localized anomaly does occur for the eastern tunnel at a frequency of about 17 kHz, however, there is no relative high or low for the western tunnel.

Figure 8 is a three-dimensional rendering of the image reconstructed from the GEM-2 data using the imaging algorithm described in the previous section. Sixteen frequencies ranging from 5010 Hz to 14010 Hz were used to compute the object function at 16 depths ranging from 1 to 23.5 m and an assumed background conductivity of 0.1 Siemen/m. In this image, rendered with EarthVision software¹, the lowest values of object function (those associated with the lowest relative conductivity) were removed to give the subway tunnels a hollow appearance. In this image, the tunnels have the correct separation and horizontal diameter. The tunnels are vertically elongated in the image resulting in a vertical dimension that is slightly too large and a depth to tunnel ceilings that is slightly too small, however, the depth to the tunnel centers is approximately correct.

The Cloud Chamber Site

The cloud chamber site exists on the Department of Energy's Nevada Test Site in Nye County, Nevada. As its name implies, the target of interest at this site is cloud chamber original built to measure certain properties of ionized particles. The cloud chamber has not been used since 1968. This underground structure is shaped like a quonset hut, 42.7 m long, 9.75 m wide at its base, with a maximum height of 4.9 m. The depth to the roof of the cloud chamber is about 5 m.

GEM-2 measurements were over a rectangular region approximately 30 m north-south by 67 m east-west. Data were acquired at uniformly spaced intervals of 1.524 m in both directions. Thirty frequencies ranging from 270 Hz to 17670 Hz in intervals of 600 Hz were used for both vertical and horizontal coil axis orientation. Figure 9 shows the acquired in-phase and quadrature data at 9270 Hz for the vertical coil axis orientation. The cloud chamber is clearly manifested in both components of this data as the rectangular anomaly extending diagonally from about 30 m north, 100 m west to about 20 m north, 120 m west. Smaller anomalous features evident in the data are associated with vents and an access shaft. The data presented in this figure is typically of the entire frequency range. Figure 10 displays the entire acquired vertical coil axis frequency band along a line at 99 m west as a pseudo cross-sectional image. As in fig. 7, the vertical axis is decreasing frequency (increasing skin depth). The lateral location of the cloud chamber is clearly resolved, however, the highest frequencies used were too low to allow the resolution of the top of this feature.

A subset of the broadband, vertical coil axis EMI data was input to the above-described imaging algorithm. Here, 16 uniformly-spaced frequencies ranging from 8670 Hz to 17670 Hz were used. The full range of measurement points in the north-south direction were used but data in the east-west direction were limited to a sub-region extending from 76 m to 122 m west at 3.048 m intervals. Figure 11 displays the three-dimensional image reconstructed at a background conductivity of 0.004 Siemen/m as 16 parallel vertical cross-sections. Although the contrast scale changes from cross-section to cross-section, the cloud chamber appears in these images as a relative conductivity low in approximately the proper horizontal location and over the correct approximate depth interval. The width of the cloud chamber is about 50% too small in many of the cross-sections.

Conclusions

Underground structures at two sites have been imaged with broadband EMI data. Based on this experience and in the absence of any horizontally-broad, near-surface high conductivity anomalies, it is possible to image other underground structures of similar size and depth. Furthermore, it is anticipated that deeper underground structures can similarly be imaged since the fundamental limiting parameter in EMI imaging is the penetration depth. At least with the GEM-2 EMI tool, it is possible to acquire data down to the DC level suggesting that great penetration depths can be achieved allowing the imaging of much deeper structures, albeit with an attendant loss of spatial resolution.

The ability to image shallow targets within the frequency range considered here is somewhat speculative. This is because the lack of high frequency information will, in turn, limit mapping between target depth and skin depth to the point

where the inversion of Eq. (8) is no longer robust. Although the bandwidth used here yielded skins depths that were, at best, no less than the target, it is unclear at this time how much shallower the imaging algorithm can be stressed.

ABSTRACT

We present an efficient algorithm for computation of the maximum likelihood estimate of the location of a known target from short pulse scatter data measured in a suite of tomographic experiments. The algorithm consists of a three step procedure: (i) data filtering, (ii) time-domain backpropagation, and (iii) coherent summation and employs of a number of forward and inverse Radon transforms integrated in a tomographic scheme. A computer simulation is included for illustration purposes.

Keywords: Inverse Scattering, Tomography, Filtered Backpropagation, Radon Transform.

1. INTRODUCTION

Inverse Scattering (IS) is the scientific discipline in which an object (scatterer) is probed with waves in an attempt to estimate (reconstruct) its internal structure from scattered field measurements. The scattering object is assumed embedded in a known, non-attenuating background medium and the objective of IS is to quantitatively estimate the spatial distribution of its complex-valued refraction index by inverting the mathematical mapping relating the probing wave, the refraction index, and the measurable total wave [1, 2, 13, 21, 3, 4]. This objective is non-trivial to achieve due to the non-uniqueness of the mapping in any finite set of experiments and its non-linear and non-local character [6, 15, 12]. The non-uniqueness issue can be addressed by employing a multiplicity of experiments, whereby the object is probed from several incident wave directions with pulses of broad bandwidth. However, the issue of non-linearity (and non-locality) is significantly harder to address and, to date, research has only produced mathematical results or

computationally intensive iterative algorithms as opposed to practically implementable inversion algorithms.

Over the past fifteen years, an alternative approach to the IS problem has been followed based on certain linearizing approximations to it [7, 9, 10, 8, 11, 13] (see also [14] for a review of the state-of-the-art in linearized scattering models). This approach has led to an expanded discipline within the regime of tomography, known as *Diffraction Tomography (DT)*, which has reached today the stage of building prototype commercial tomographic scanners for biomedical [17, 18, 29, 28, 19, 27, 30, 32] and underground [35, 37, 25, 36, 34, 33] imaging systems based on the algorithms of the linearized version of the IS problem. Despite the success of the linearized algorithms in several practical applications, their success depends critically on the two assumptions of linearity and availability of multiple experiments. In many cases, the linearity assumption fails, while different constraints (economic, safety, operating, geometric, or physical) [26, p.21] limit the number of scattering experiments that can be performed and/or provide low signal-to-noise ratio data. As a result, practical scatterer reconstruction algorithms often suffer from high noise levels, poor resolution, and artifacts, such as streaking and geometric distortion.

To overcome these limitations, a more modest inverse problem was addressed, originally within the framework of linearized [16] and later exact [31] scattering theory. This inverse problem attempted to *detect* and *classify* a *known* target scatterer and *estimate* its *location* from wave scatter data. It was found that, for monochromatic plane-wave probing, the optimum (in the maximum likelihood sense) location estimate could be obtained via a filtered backpropagation algorithm, in which partial images formed by filtering and backpropagating scatter data for different probing directions were coherently summed. The algorithm is optimum (in the maximum likelihood sense) for additive Gaussian noise and an arbitrary number of scattering experiments and can yield an estimate of all three coordinates of the target even from a single experiment as long as the wavelength of the probing radiation is comparable with the typical dimensions of the target [16].

The work in [31] can be readily extended to the case of probing with multiple frequencies via frequency-domain synthesis. However, a derivation of a time-domain algorithm may be computationally more efficient in the case of probing with short pulses. A time-domain algorithm was recently presented for the classical IS reconstruction problem of DT for cases where the usual frequency-domain algorithms were not computationally efficient [23]. In this paper, we are concerned with the problem of optimally processing (limited and noisy) short pulse scatter data to decide whether a certain target scatterer is present in a region of interest and, if so, determine its location. The problem arises in a number of inverse scattering applications, such as locating subsurface targets in seismic and electromagnetic surveys, detecting tumors in ultrasonic medical imaging, and detecting and identifying radar targets. The main goal of this paper is to extend the single frequency maximum likelihood DT algorithms derived in [16, 31] to the time domain in a similar manner as was done in [23] for the classical DT reconstruction problem.

The paper is organized as follows: Section 2 contains a review of the data measurement configuration, the wave scattering equations, and frequency-domain and time-domain plane-wave spectra of waves. Section 3 is concerned with location estimation algorithms and, including a short review of the frequency-domain solution, derivation of a time-domain filtered backpropagation algorithm. Computer simulations are included in Section 4, while Section 5 contains a summary, a statement of conclusions, and a list of possible research avenues to be followed in the future.

computationally intensive iterative algorithms as opposed to practically implementable inversion algorithms.

Over the past fifteen years, an alternative approach to the IS problem has been followed based on certain linearizing approximations to it [7, 9, 10, 8, 11, 13] (see also [14] for a review of the state-of-the-art in linearized scattering models). This approach has led to an expanded discipline within the regime of tomography, known as *Diffraction Tomography (DT)*, which has reached today the stage of building prototype commercial tomographic scanners for biomedical [17, 18, 29, 28, 19, 27, 30, 32] and underground [35, 37, 25, 36, 34, 33] imaging systems based on the algorithms of the linearized version of the IS problem. Despite the success of the linearized algorithms in several practical applications, their success depends critically on the two assumptions of linearity and availability of multiple experiments. In many cases, the linearity assumption fails, while different constraints (economic, safety, operating, geometric, or physical) [26, p.21] limit the number of scattering experiments that can be performed and/or provide low signal-to-noise ratio data. As a result, practical scatterer reconstruction algorithms often suffer from high noise levels, poor resolution, and artifacts, such as streaking and geometric distortion.

To overcome these limitations, a more modest inverse problem was addressed, originally within the framework of linearized [16] and later exact [31] scattering theory. This inverse problem attempted to *detect* and *classify* a *known* target scatterer and *estimate* its *location* from wave scatter data. It was found that, for monochromatic plane-wave probing, the optimum (in the maximum likelihood sense) location estimate could be obtained via a filtered backpropagation algorithm, in which partial images formed by filtering and backpropagating scatter data for different probing directions were coherently summed. The algorithm is optimum (in the maximum likelihood sense) for additive Gaussian noise and an arbitrary number of scattering experiments and can yield an estimate of all three coordinates of the target even from a single experiment as long as the wavelength of the probing radiation is comparable with the typical dimensions of the target [16].

The work in [31] can be readily extended to the case of probing with multiple frequencies via frequency-domain synthesis. However, a derivation of a time-domain algorithm may be computationally more efficient in the case of probing with short pulses. A time-domain algorithm was recently presented for the classical IS reconstruction problem of DT for cases where the usual frequency-domain algorithms were not computationally efficient [23]. In this paper, we are concerned with the problem of optimally processing (limited and noisy) short pulse scatter data to decide whether a certain target scatterer is present in a region of interest and, if so, determine its location. The problem arises in a number of inverse scattering applications, such as locating subsurface targets in seismic and electromagnetic surveys, detecting tumors in ultrasonic medical imaging, and detecting and identifying radar targets. The main goal of this paper is to extend the single frequency maximum likelihood DT algorithms derived in [16, 31] to the time domain in a similar manner as was done in [23] for the classical DT reconstruction problem.

The paper is organized as follows: Section 2 contains a review of the data measurement configuration, the wave scattering equations, and frequency-domain and time-domain plane-wave spectra of waves. Section 3 is concerned with location estimation algorithms and, including a short review of the frequency-domain solution, derivation of a time-domain filtered backpropagation algorithm. Computer simulations are included in Section 4, while Section 5 contains a summary, a statement of conclusions, and a list of possible research avenues to be followed in the future.

The mapping between the scattered wave ψ^s and the object function O is non-linear and non-local, since the scattered wave appears at both sides of Eq.(2-6). Linearizing approximations of the Born type approximate Eq.(2-6) by replacing the total field in the right hand side has been replaced with the incident field component. A related approximation is the Rytov approximation which has been found more accurate than the Born approximation in several applications [20, 29, 14]. In the present work, we will not make any approximations to Eqs.(2-2) through (2-6) and proceed with exact scattering models.

Our starting point is the “source translation property,” originally derived in [31]. To state the source translation property, consider an object function of the form:

$$O(\mathbf{r}; \mathbf{R}_c) = O_0(\mathbf{r} - \mathbf{R}_c), \quad (2-7)$$

i.e., an object function O_0 that has been shifted in space by a vector \mathbf{R}_c . The induced source corresponding to illumination with a certain incident wave $\hat{\psi}_0(\mathbf{r}, \omega)$ can be expressed as

$$\begin{aligned} \hat{\rho}(\mathbf{r}', \omega; \mathbf{R}_c) &\equiv O(\mathbf{r}'; \mathbf{R}_c) \hat{\psi}(\mathbf{r}', \omega; \mathbf{R}_c) \\ &= e^{ik\mathbf{s}_0 \cdot \mathbf{R}_c} \hat{\rho}(\mathbf{r}' - \mathbf{R}_c, \omega; 0), \end{aligned} \quad (2-8)$$

where \mathbf{s}_0 is the unit vector in the direction of incidence of the illuminating wave and $\hat{\psi}(\mathbf{r}', \omega; \mathbf{R}_c)$ and $\hat{\rho}(\mathbf{r}', \omega; \mathbf{R}_c)$ denote the field and induced source resulting from the object function $O(\mathbf{r}; \mathbf{R}_c)$. Eq.(2-8), which is established in [31], relates the source induced by a plane-wave incident on the scattering object $O_0(\mathbf{r} - \mathbf{R}_c)$ to the source induced by the same illuminating wave but incident on the (centered) object $O_0(\mathbf{r})$. Eqs.(2-6) and (2-8) allow us to express the field scattered by the object $O_0(\mathbf{r} - \mathbf{R}_c)$ to the field scattered by the (centered) object $O_0(\mathbf{r})$. We find that [31]

$$\hat{\psi}^s(\mathbf{r}, \omega; \mathbf{R}_c) = e^{ik\mathbf{s}_0 \cdot \mathbf{R}_c} \hat{\psi}^s(\mathbf{r} - \mathbf{R}_c, \omega; 0). \quad (2-9)$$

Eqs.(2-8) and (2-9) lead to a frequency-domain filtered backpropagation algorithm for the object location estimation problem within exact scattering theory [31]. They will be employed here to derive the time-domain counterpart of that algorithm. For completeness, however, we present their time-domain version, obtained via inverse Fourier transforming Eqs.(2-8) and (2-9). The result is:

$$\rho(\mathbf{r}, t; \mathbf{R}_c) = \rho(\mathbf{r} - \mathbf{R}_c, t - \mathbf{s}_0 \cdot \mathbf{R}_c / c_0; 0) \quad (2-10)$$

$$\psi^s(\mathbf{r}, t; \mathbf{R}_c) = \psi^s(\mathbf{r} - \mathbf{R}_c, t - \mathbf{s}_0 \cdot \mathbf{R}_c / c_0; 0). \quad (2-11)$$

B. Time-Domain Plane-Wave Spectra of Wavefields

Consider a time-domain wavefield $\psi(\mathbf{r}, t)$ propagating into the half-space $z > 0$ and having the boundary value $\psi(\mathbf{x}, t)$ ($\mathbf{x} = x\hat{x} + y\hat{y}$), on the $z = 0$ plane, with equivalent frequency-domain representation

$$\hat{\psi}(\mathbf{x}, \omega) = \int_{-\infty}^{\infty} dt e^{i\omega t} \psi(\mathbf{x}, t). \quad (2-12)$$

The frequency-domain plane-wave spectrum of the wavefield is defined as [24]

$$\hat{\hat{\psi}}(\xi, \omega) = \int d^2x e^{-ik\xi \cdot \mathbf{x}} \hat{\psi}(\mathbf{x}, \omega), \quad (2-13)$$

where $k = \frac{\omega}{c_0}$ and ξ is a frequency-independent wave vector [24]. From Eq.(2-13), one can obtain the frequency-domain representation of the wavefield at an arbitrary point $\mathbf{r} = \mathbf{x} + z\hat{\mathbf{z}}$ in space as

$$\hat{\psi}(\mathbf{r}, \omega) = \left(\frac{k}{2\pi}\right)^2 \int d^2\xi e^{ik(\xi \cdot \mathbf{x} + \zeta z)} \hat{\tilde{\psi}}(\xi, \omega), \quad (2-14)$$

where

$$\zeta = \begin{cases} \sqrt{1 - |\xi|^2}, & \text{if } |\xi| \leq 1 \\ i\sqrt{|\xi|^2 - 1}, & \text{else.} \end{cases}$$

Eq.(2-14) is the, so-called, angular spectrum expansion of $\hat{\psi}(\mathbf{r}, \omega)$ and decomposes the wavefield $\hat{\psi}(\mathbf{r}, \omega)$ into a superposition of propagating (corresponding to $|\xi| \leq 1$) and evanescent (corresponding to $|\xi| > 1$) plane waves.

Eq.(2-13) has a time-domain equivalent, the time-domain plane-wave spectrum of the wavefield:

$$\tilde{\psi}(\xi, \tau) = \frac{1}{2\pi} \int d\omega e^{-i\omega\tau} \hat{\tilde{\psi}}(\xi, \omega). \quad (2-15)$$

Substitution of Eqs.(2-12) and (2-13) into Eq.(2-15) gives

$$\tilde{\psi}(\xi, \tau) = \int d^2\mathbf{x} \psi(\mathbf{x}, \tau + \frac{\xi \cdot \mathbf{x}}{c_0}), \quad (2-16)$$

as the time-domain relation between the wavefield and its plane-wave spectrum. Eq.(2-16) is recognized as a Radon transform [5] of the wavefield $\psi(\mathbf{x}, t)$ in the three-dimensional space (\mathbf{x}, t) and has, thus, been termed a slant-stack transform [23]. Eq.(2-16) can be inverted to give the time-domain equivalent of Eq.(2-14). The inversion formula that includes the evanescent modes requires use of the analytic signal (see [22] for details). Here we will assume that the evanescent modes have been sufficiently attenuated to not contribute to the inversion formula. With this in mind, the result is

$$\psi(\mathbf{r}, t) = -\frac{1}{(2\pi c_0)^2} \int_{|\xi| \leq 1} d^2\xi \frac{\partial^2}{\partial \tau^2} \tilde{\psi}(\xi, \tau = t - \frac{\xi \cdot \mathbf{x} + \zeta z}{c_0}), \quad (2-17)$$

and can be recognized as a bank of inverse Radon transforms, each corresponding to a different z [5].

3. ESTIMATION OF OBJECT LOCATION

A. Data Model

With the definitions and results of Section 2, we are now in position to proceed with the object location estimation problem. Consider a scatterer described by the object function:

$$O(\mathbf{r}; \mathbf{R}_c) = O_0(\mathbf{r} - \mathbf{R}_c), \quad (3-1)$$

where O_0 is a known function and \mathbf{R}_c is an unknown scatterer location. The object is probed with short plane-wave pulses propagating in the direction of unit vectors \mathbf{s}_0 , i.e., plane-wave pulses of the form $p_{\mathbf{s}_0}(t - \frac{\mathbf{s}_0 \cdot \mathbf{r}}{c_0})^1$. We assume

¹The subscript \mathbf{s}_0 is used to indicate that the form of the pulses may, in general, be different from experiment to experiment.

that scattered pulse data are measured over planes perpendicular to the direction \mathbf{s}_0 of propagation of the incident pulses. More specifically, we assume the measurement (data) model

$$y(\mathbf{r}_p, t, \mathbf{s}_0) = r_{s_0}(\mathbf{r}_p, t) \otimes \psi_{s_0}^s(\mathbf{r}_p + l\mathbf{s}_0, t; \mathbf{R}_c) + n_{s_0}(\mathbf{r}_p, t); \quad \mathbf{r}_p \in \mathbf{R}^2, -\infty < t < \infty, \mathbf{s}_0 \text{ in some set of unit vectors,} \quad (3-2)$$

where $r_{s_0}(\mathbf{r}_p, t)$ is a convolutional space-time measurement filter and $\psi_{s_0}^s(\mathbf{r}_p + l\mathbf{s}_0, t; \mathbf{R}_c)$ is the scattered field over the plane $\mathbf{r} = \mathbf{r}_p + l\mathbf{s}_0$. Additionally, $n_{s_0}(\mathbf{r}_p, t)$ is zero-mean Gaussian noise, white² in the variables \mathbf{r}_p , t , and \mathbf{s}_0 , i.e.,

$$\mathcal{E}\{n_{s_0}(\mathbf{r}_p, t)n_{s'_0}(\mathbf{r}'_p, t')\} = \sigma_n^2 \delta(\mathbf{r}_p - \mathbf{r}'_p) \delta(t - t') \delta_{s_0, s'_0}. \quad (3-3)$$

The inverse problem is that of estimating the unknown parameter (object location) \mathbf{R}_c from the measurements $y(\mathbf{r}_p, t, \mathbf{s}_0)$ in Eq.(3-2).

B. Likelihood Function

We obtain an estimate $\hat{\mathbf{R}}_c$ of the unknown \mathbf{R}_c by minimizing the following data functional with respect to a test object location \mathbf{r}_c :

$$\mathcal{J}(\mathbf{r}_c) = \sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} dt \int d^2 r_p |y(\mathbf{r}_p, t, \mathbf{s}_0) - \alpha(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c)|^2, \quad (3-4)$$

where

$$\alpha(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c) = r_{s_0}(\mathbf{r}_p, t) \otimes \psi_{s_0}^s(\mathbf{r}_p + l\mathbf{s}_0, t; \mathbf{r}_c) \quad (3-5)$$

is the scattered pulse on the measurement plane (filtered by the measurement filter) for the object located at \mathbf{r}_c . The estimate $\hat{\mathbf{R}}_c$ returned by the above minimization is also the maximum likelihood estimate (MLE) under the Gaussianity assumption for the measurement noise in Eq.(3-2) [?].

To obtain the MLE $\hat{\mathbf{R}}_c$ directly from Eq.(3-4) is an intensive process, since numerical minimization is required of the functional $\mathcal{J}(\mathbf{r}_c)$. However, expansion of the square term in Eq.(3-4) shows that the MLE $\hat{\mathbf{R}}_c$ is equivalently obtained by maximization of the "log likelihood function" [?]

$$L(\mathbf{r}_c) = \sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} dt \int d^2 r_p y(\mathbf{r}_p, t, \mathbf{s}_0) \alpha(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c) - \frac{1}{2} \sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} dt \int d^2 r_p |\alpha(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c)|^2. \quad (3-6)$$

Next, we will further simplify the expression for the log likelihood function and obtain an algorithm that can be efficiently implemented on the computer.

Theorem 1 *If evanescent plane-wave spectra are ignored, the term $\frac{1}{2} \sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} dt \int d^2 r_p |\alpha(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c)|^2$ in the log likelihood function in Eq.(3-6) is constant with respect to \mathbf{r}_c .*

Proof: From Parseval's theorem:

$$\int_{-\infty}^{\infty} dt \int d^2 r_p |\alpha(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c)|^2 = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \int d^2 r_p |\hat{\alpha}(\mathbf{r}_p, \omega, \mathbf{s}_0; \mathbf{r}_c)|^2.$$

We apply now the fact [31] that, for each temporal frequency ω , $\int d^2 r_p |\hat{\alpha}(\mathbf{r}_p, \omega, \mathbf{s}_0; \mathbf{r}_c)|^2$ is constant with respect to \mathbf{r}_c , as long as the corresponding evanescent spectra are ignored, and the theorem follows. •

²Gaussian noise of arbitrary color can be handled by expanding the algorithm of this section to include a proper whitening filter.

Theorem 2 Ignoring evanescent plane-wave spectra, the term $\sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} dt \int d^2 r_p y(\mathbf{r}_p, t, \mathbf{s}_0) \alpha(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c)$ in the log likelihood function in Eq.(3-6) is equal to

$$\sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} dt \int d^2 r_p y(\mathbf{r}_p, t, \mathbf{s}_0) \alpha(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c) = -\frac{1}{(2\pi c_0)^2} \sum_{\mathbf{s}_0} \int_{|\xi| \leq 1} d^2 \xi \frac{\partial^2}{\partial \tau^2} [\tilde{y}(\xi, \tau, \mathbf{s}_0) \bar{\alpha}(\xi, \tau, \mathbf{s}_0; 0)]|_{\tau = -\frac{\xi \cdot \mathbf{r}_{cp} + \xi \cdot \mathbf{s}_0 \cdot \mathbf{r}_c}{c_0}}, \quad (3-7)$$

where $\mathbf{r}_c = \mathbf{r}_{cp} + \mathbf{s}_0 \cdot \mathbf{r}_c$.

Proof: We start again with Parseval's theorem:

$$\begin{aligned} \int_{-\infty}^{\infty} dt \int d^2 r_p y(\mathbf{r}_p, t, \mathbf{s}_0) \alpha(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \int d^2 r_p \hat{y}(\mathbf{r}_p, \omega, \mathbf{s}_0) \bar{\alpha}(\mathbf{r}_p, \omega, \mathbf{s}_0; \mathbf{r}_p) \\ &= \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \int d^2 r_p \hat{y}(\mathbf{r}_p, \omega, \mathbf{s}_0) \bar{\alpha}(\mathbf{r}_p - \mathbf{r}_c, \omega, \mathbf{s}_0; 0) e^{-i \frac{\omega}{c_0} \mathbf{s}_0 \cdot \mathbf{r}_c}, \end{aligned}$$

where we used the translation property in Eq.(2-9). We now apply Eq.(2-14) and obtain

$$\begin{aligned} \int_{-\infty}^{\infty} dt \int d^2 r_p \hat{y}(\mathbf{r}_p, \omega, \mathbf{s}_0) \bar{\alpha}(\mathbf{r}_p, \omega, \mathbf{s}_0; \mathbf{r}_c) &= \\ \frac{1}{(2\pi)^3 c_0^2} \int_{-\infty}^{\infty} d\omega \omega^2 \int d^2 r_p \hat{y}(\mathbf{r}_p, \omega, \mathbf{s}_0) \int_{|\xi| \leq 1} d^2 \xi e^{-i \frac{\omega}{c_0} \xi \cdot \mathbf{r}_p} e^{i \frac{\omega}{c_0} [\xi \cdot \mathbf{r}_{cp} + (\xi - 1) \mathbf{s}_0 \cdot \mathbf{r}_c]} \bar{\alpha}(\xi, \omega, \mathbf{s}_0; 0) &= \\ \frac{1}{(2\pi)^3 c_0^2} \int_{|\xi| \leq 1} d^2 \xi \int_{-\infty}^{\infty} d\omega e^{i \frac{\omega}{c_0} [\xi \cdot \mathbf{r}_{cp} + (\xi - 1) \mathbf{s}_0 \cdot \mathbf{r}_c]} \omega^2 \bar{\alpha}(\xi, \omega, \mathbf{s}_0; 0) \int d^2 r_p e^{-i \frac{\omega}{c_0} \xi \cdot \mathbf{r}_p} \hat{y}(\mathbf{r}_p, \omega, \mathbf{s}_0) &= \\ \frac{1}{(2\pi)^3 c_0^2} \int_{|\xi| \leq 1} d^2 \xi \int_{-\infty}^{\infty} d\omega e^{-i \frac{\omega}{c_0} [\xi \cdot \mathbf{r}_{cp} + (\xi - 1) \mathbf{s}_0 \cdot \mathbf{r}_c]} [\omega^2 \bar{\alpha}(\xi, \omega, \mathbf{s}_0; 0) \hat{y}(\xi, \omega, \mathbf{s}_0) e^{i \omega \tau}]|_{\tau=0} &= \\ -\frac{1}{(2\pi c_0)^2} \int_{|\xi| \leq 1} d^2 \xi \frac{\partial^2}{\partial \tau^2} [\tilde{y}(\xi, \tau, \mathbf{s}_0) \bar{\alpha}(\xi, \tau, \mathbf{s}_0; 0)]|_{\tau = -\frac{\xi \cdot \mathbf{r}_{cp} + (\xi - 1) \mathbf{s}_0 \cdot \mathbf{r}_c}{c_0}} \end{aligned}$$

from which the theorem follows.

Eq.(3-7) can be interpreted as follows: For each pulse, the scattered pulse data are Radon-transformed with respect to their space-time coordinates,³ filtered in Radon space, and inverse Radon-transformed (one inverse Radon transform per value of $\mathbf{s}_0 \cdot \mathbf{r}_c$) into object space to form partial images of the log likelihood function. The Radon-space filter consists of the complex conjugate of the time-domain plane-wave spectra of the field scattered by the centered object $O_0(\mathbf{r})$. Finally, the partial images are coherently superimposed.

4. COMPUTER ILLUSTRATION

For simulation purposes, we consider a single scattering experiment in a two-dimensional geometry in which a target lies in the (x, z) -plane and is infinitely long and uniform along the y -axis. The probing pulse is incident from the direction of the positive z -axis and data are measured along the line $(x, z = l)$. The target signature (scattered pulse $\psi_0^s(\mathbf{r}, t)$ corresponding to the target located at the origin) is a pulse

$$\psi_0^s(\mathbf{r}, t) = \frac{\sigma^2}{c_0^2} \frac{\ddot{p}(t - \frac{|\mathbf{r}|}{c_0})}{\sqrt{|\mathbf{r}|}}, \quad \mathbf{r} = (x, z), \quad (4-1)$$

³Equivalently, the scatter data are measured in the far field of the scattering object.

where σ^2 is the scatterer cross section,

$$p(t) = \begin{cases} \frac{1}{T} \cos(\beta t^2), & \text{if } 0 < t < T \\ 0, & \text{else} \end{cases} \quad (4-2)$$

and \ddot{p} denotes second derivative, i.e.

$$\ddot{p}(t) = \begin{cases} \frac{2\beta}{T} [\cos(\beta t^2)[1 + 2\beta t^2] - 1], & \text{if } 0 < t < T \\ 0, & \text{else.} \end{cases} \quad (4-3)$$

Eq.(4-1) gives the far field of the Born approximation to the field scattered by a point scatterer of cross section σ^2 when probed with the plane-wave pulse corresponding to $p(t)$. The scattered field for arbitrarily located target is subsequently generated according to Eq.(2-11).

We assumed the scatterer to be located at the origin of the (x, z) -plane and chose the parameters $\sigma^2 = 1$, $c_0 = 1$, $\beta = 1$, $T = 1$, and $l = 5$. For the additive Gaussian noise, we examined three different cases with corresponding variances 0, 0.25, and 1. Figs. 2 show the field at $(x = 0, z = 5)$ for the time interval $0 < t < 16$ for three different noise levels. Finally, the likelihood functions computed via Eq.(3-7) are shown in Figs. 3 for the three noise levels.

5. SUMMARY, CONCLUSIONS, AND FUTURE WORK

In this paper, we derived an efficient algorithm for computation of the log likelihood function for estimation of the location of a target object from noisy short pulse scatter measurements. We assumed that the target object signature, i.e., the wave scattered by the object centered at the origin of the coordinate system was known and established that the log likelihood function could be computed in a three step procedure in which the measured data were firstly convolutionally filtered, then time-domain backpropagated, and finally the partial likelihood functions were coherently summed. The convolutional filter of the first step was the filter matched to the object signature and the procedure was implemented via a sequence of direct and inverse Radon transforms of the space-time measurements. Target identification can also be performed via a similar algorithm, in which a bank is employed of filters matched to various target signatures.

A computer simulation of a single scattering experiment was performed to illustrate the procedure, in which rather than the target object, a target signature was assumed. The simulation revealed very high performance even in the case of very low signal-to-noise ratio. Further performance improvements can be achieved if multiple scattering experiments are utilized.

Further research in this area seems appropriate. Issues to be addressed in the future include the derivation of proper location estimation algorithms for the cases of measurement planes that remain fixed from scattering experiment to experiment. This is the case in geophysical surveys in which the sensor array is fixed in space and several scattering experiments are performed, each with a different probing plane-wave pulse. Another avenue of future research seems to lead to the derivation of nonparametric algorithms for detection, location estimation, and classification of stochastic scattering objects. This problem appears in several underwater surveys. This and related research is currently pursued and its results will be announced shortly.

Hyperspectral IR polarimetry with applications in demining and unexploded ordnance detection

Herman E. Scott, Stephen H. Jones, Frank Iannarilli, and Kurt Annen
Aerodyne Research, Inc., 45 Manning Road, Billerica, MA 01821-3976¹

ABSTRACT

Several years of effort in IR polarimetry have brought us convincing evidence of its effectiveness in differentiating man made objects from natural backgrounds. Adding modern focal plane array (FPA) technology (either cooled or uncooled) makes it possible to combine the benefits of polarimetry with the power of hyperspectral imaging. Aerodyne Research is embarked on a stepwise, controlled-risk development program with the objective of fielding an innovative and affordable hyperspectral imaging IR polarimeter. Proof-of-concept demonstrations are conducted for each significant technology increment as part of the prototype development effort. These steps, two demonstrated and two yet to be demonstrated, are: (1) LWIR (non-imaging) Spectral Polarimeter to demonstrate the effectiveness of combined polarimetric and hyperspectral discrimination capabilities in observations on static scenes; (2) LWIR Uncooled FPA Imaging (broadband) Polarimeter to test the sensitivity of an affordable Uncooled FPA in a broadband configuration against static scenes; (3) Multispectral Imaging Polarimeter to quantify clutter rejection performance improvements to be realized in multispectral polarimetry; and (4) Hyperspectral Imaging IR Polarimeter designed with optimal spatial and spectral resolution and sufficient throughput to achieve the reliable performance required in surface mine and UXO detection applications. Results from the ongoing proof-of-concept demonstrations in simulated surface mine detection will be presented.

Keywords: Infrared polarimetry, hyperspectral imaging, demining, unexploded ordnance

1. INTRODUCTION

1.1 Background

For more than 15 years Aerodyne Research has worked systematically toward the development of passive IR spectral and polarimetric discrimination techniques. In the first 10 years of these activities Aerodyne focussed on the development and validation of a first principles computer model called POLAR¹⁻³ that computes the spectrally dependent Stokes vector and user-selected in-band IR polarimetric images of targets given the geometry, optical properties⁴, and thermal description of the target. Support for the POLAR model came from Northrop⁵, the NADC/Warminster⁶⁻⁹, and internal R&D. Then in recent years, emphasis has turned to the systems applications of polar attributes such as non-cooperative target identification^{9,10} and the discrimination of targets in highly cluttered natural backgrounds.

In 1993 - 95 several important steps were accomplished: Aerodyne and the Boeing Defense and Space Group with the support of NAWC/Warminster used the modified IRAMMP sensor, POLIRAMMP, to collect polar IR imagery of aircraft on the ground to validate the POLAR model.¹¹ Results showed a strong correlation between the analytic model predictions and measured data. Subsequently in 1994 Aerodyne produced a seminal paper¹⁰ on a polarimeter sensor concept (3-Channel Simultaneous Acquisition Polarimeter) specifically designed for the long range Counter-Air Target Identification application. Shortly thereafter, Boeing and Aerodyne applied the Improved POLIRAMMP sensor in the 1994 Navy Long Jump Tests at China Lake to collect surface-to-air polarization imagery of aircraft and thereby further validate the POLAR model.¹² It was at this test site that we conducted our first primitive simulation of surface mine detection using the two-channel POLIRAMMP sensor. Even though this test¹³ simulated only surface mine detection, it provided quite convincing evidence of the clutter suppression capability of IR polarimetry.

In 1997 under a Phase I SBIR for the Air Force Research Laboratory (AFRL), Aerodyne invented a Hyperspectral Imaging IR Polarimeter concept capable of providing the co-registered, polarimetric imagery desired for locating polarized objects in a dynamic scene and cluttered background. We are in the process of building the prototype hyperspectral IR

polarimeter under Phase II SBIR support from the AFRL. In a parallel project sponsored by the Army Research Office (ARO) Humanitarian Demining MURI / Northeastern University (NEU) Team, we are taking incremental steps to demonstrate the value and reliability of LWIR polarimetry in the detection of antipersonnel (AP) mines, especially plastic flush-buried and scatterable types. Our stepwise progress and the LWIR polarimetry proof-of-concept demonstrations in the demining application are the topics of this paper.

1.2 Scope

Many researchers have investigated LWIR and multiband passive infrared sensing techniques for applications in demining;¹⁴ a few investigations have considered passive IR polarimetry and costly hyperspectral imaging methods separately for locating land mines;¹⁵ yet insofar as we have found, no previous investigators have pursued the combination of hyperspectral IR polarimetry and affordable LWIR uncooled focal plane arrays. Effort in this Demining MURI is devoted to deliberate, controlled-risk, proof-of-concept demonstrations that verify our particular innovative combination of LWIR hyperspectral polarimetry and affordable uncooled FPA technology can be reliable and effective in surveying and locating exposed surface mines of any material type. The exploitation of polar attributes that are demonstrated in this project effort were in most cases suggested and supported by our earlier analytic investigations into systems applications of IR polarimetry.^{9, 10, 16} In addition to the proof-of-concept tasks, we are investigating surface optical properties of the relevant classes of materials and coatings for mine fabrication; this is a concurrent laboratory effort to fill the important gaps remaining from prior optical properties measurements.

The present effort is focused on antipersonnel mines, many of which are partially exposed on the surface or are buried in a very shallow manner. Therefore, we are placing much greater emphasis on the optical properties of materials, emissivity and reflectance, and less emphasis than usual on the material thermal properties. We make no claims to be dealing with the full complexity of thermal conduction issues associated with buried mines, consisting of a wide range of materials in all manner of soils and terrain. Many investigators^{14,17} have examined the conductance and differential heating/cooling effects for opportunities to exploit in locating buried mines using passive IR techniques. Our premise is simple; IR Polarimetry is only one of a large arsenal of affordable and reliable technologies required to deal with the extensive, worldwide demining and unexploded ordnance problems. Our objective is to make IR Polarimetry an affordable and reliable technique to locate mines having any significant exposure on the surface, regardless of the material composition and including common types of paints and coatings. If we are successful, our method simultaneously positions us to include and exploit significant thermal effects as well since these effects exhibit themselves in the same LWIR wavelength regime. We must give close attention to the magnitude and impact of the heat transfer effects even as we examine the optical properties of materials and coatings.

Since we are implementing a controlled-risk, step-by-step effort to demonstrate a new combination of technologies including the uncooled focal plane array (uncooled FPA) microbolometer, it is important that we establish the terminology for these steps and the technologies to be demonstrated:

- Step (1) - LWIR Spectral Polarimeter
(8 - 12 μm Spectral Region, Non-Imaging).
- Step (2) - LWIR Uncooled FPA Imaging Polarimeter
(8 - 12 μm Broadband, No Spectral Resolution, Static Scenes).
- Step (3) - LWIR Uncooled FPA Multispectral Imaging Polarimeter
(Multiple Bands in 8 - 12 μm Spectral Region, Static Scenes).
- Step (4) - Uncooled Hyperspectral Imaging IR Polarimeter
(8 - 12 μm Spectral Region, Spectral Resolution $\sim 0.02 \mu\text{m}$, Imaging, Registration and Simultaneity in Polar Channels for Dynamic Scenes).

2. LWIR SPECTRAL POLARIMETER DEMONSTRATION TEST

The data reported in this first proof-of-concept demonstration were collected for a variety of mine-like materials and coatings, including Army CARC (Chemical Agent Resistant Coating, both tan and green), a plastic frisbee, asphalt, and quartz sand. The backgrounds consisted of sand or sandy asphalt in all cases. The asphalt is a particularly challenging background, having a degree of polarization in the infrared that is comparable to or higher than many paints and plastics. Table 1 summarizes the data collection geometries and simulated mine target areas for each location. It is particularly

important to note the ranges and the grazing angles between the sensor (polarimeter) line-of-sight and the target normal. These geometries closely approximate a reasonable deployment geometry for an LWIR spectral polarimeter mounted on either a land vehicle with boom or a low flying UAV platform; however, the modified FTIR spectrometer used in this proof-of-concept demonstration was in no way related to our concept for a field deployable multi-channel polarimeter.

The LWIR spectral polarimeter consisted of an FTIR spectrometer with a wire grid analyzer adapted to it. For this demonstration we used 4 cm^{-1} resolution at 10 scans/sec and collected 200 scans per data point per analyzer angle. The detector was MCT with $D^*_{\text{peak}} = 4 \times 10^{10}\text{ cm Hz}^{1/2}\text{ W}^{-1}$. The wire grid analyzer was 1200 lines/mm on a ZnSe substrate with antireflection coatings on both sides.

As illustrated in Fig 1, reflections from a flat surface produce polarization perpendicular to the plane of incidence (the plane of the page). Emission is polarized parallel to this plane.¹⁸ Wire grid polarizers transmit radiation when the E-vector is perpendicular to the wire and reflect radiation when the E-vector is parallel to the wire. We use the convention of 0-degree polarizer angle to mean the wire grid is oriented vertically. Also, we use the spectroscopic notation $\sigma(\sigma)$ for wavenumber (cm^{-1}), and our plots will appear reversed to many readers. The materials used in this demonstration do not transmit in the spectral region of interest, so the simple relationship between the reflectance and emissivity of the materials applies, $\epsilon(\sigma) = 1 - \rho(\sigma)$.

This proof-of-concept demonstration was set up locally in a parking area (see Fig 2) surrounded by several large white pine trees and on the northwest side by a steep embankment of rock outcroppings, rocky soil and scrubs. The parking surface was asphalt, and in the winter months when these data were collected, the asphalt was lightly covered with a residue of sand. The data of interest were collected at locations 4 and 5 as shown in Fig 2 and consisted of fifty polarimeter spectra for the various combinations of target, background, target angle, wire grid analyzer angle, ambient temperature and cloud cover. Again, the setup geometry details are listed in Table 1. Most of the data for these locations were collected in the late afternoon, both before and after sunset, on two successive days with the ambient temperatures between 0- and 15-C. Each spectrum required 20 sec to collect. Since the data collection time was not a primary driver in this demonstration, we made no effort to minimize the time, but it is quite clear that the SNR achieved will allow the collection time to be less than 2 sec per data point per analyzer angle with no important degradation of the results.

2.1 Interpretation of the LWIR spectral polarimeter data

For a view of the spectral data and an understanding of the analysis procedures, we show several overlays of the spectral data in Figs 3 and 4, each at two angles of the wire grid analyzer. As called for in our analysis procedure discussed below, data were normally collected for wire grid analyzer angles of 0-deg (vertical wire grid) and 60-deg; for verification and redundancy we also collected data intermittently at wire grid orientations of 90-deg and 120-deg. Our convention in this analysis is to use the 0-deg and 60-deg wire grid angles as the orthogonal components to differentiate the reflected and thermal emitted radiation components coming from the target and background sources within the field-of-view. The spectra are plotted with the envelope of the shaded area being the spectrum for 0-deg analyzer angle; this spectrum represents the polarized reflection component in the 'horizontal earth' geometry selected for the demonstration. Relative to this the emission component, passed by the wire grid analyzer in the 60- or 90-deg position, is plotted as a thin solid line lying close to and just above the envelope of the shaded area. The band, or the difference, between these two envelopes is a measure of the degree of linear polarization (DoLP) of the spatially unresolved scene in the field-of-view of the spectral polarimeter. When the source radiation is totally unpolarized, the orthogonal polar component spectra are coincident over the full spectral range of sensitivity for the polarimeter. Here the spectral region of interest is $800\text{ - }1250\text{ cm}^{-1}$ (or $8\text{ - }12.5\text{ }\mu\text{m}$). The general procedure for extracting DoLP from the spectra is given below, and the results are plotted in Fig 5.

Alternatively, the narrow bands in between the shaded area envelope and the line plot above represents the spectrally dependent, available polarimetric signal to be exploited. For any given broadband polarimeter the integrated area under the appropriate greybody plot such as Fig 3(a) is a measure of the total signal while the difference of these integrated areas for the orthogonal polarizations is a measure of the polarization signal or the fraction of target radiation that is linearly polarized. From the integrated areas measured for the materials in Figs 3(c), 3(d) and 4(a), we find the fraction of target radiation that is linearly polarized when weighted to fill the IFOV of the sensor to be of the order of 0.1 or 10%.

Upon closely examining the polar component spectra in Figs 3(a) and 3(b), we find that the 0-deg and 60-deg spectra are coincident over the $800\text{ - }1250\text{ cm}^{-1}$ region for each of these materials - soil and sand near normal incidence, so we may

Table 1. Summary of the Data Collection Geometries and Results of the LWIR Spectral Polarimeter Measurements for the Target and Background Materials at Locations 4 and 5.

Target Name and Location	Sandy Asphalt Location 4	Tan CARC Location 4	Plastic Frisbee Location 5	Green CARC Location 5
Plane of Target Relative to Vertical (deg)	86	66	85	79
Background Type	Sandy Asphalt	Sandy Asphalt	Sand Mound	Sand Mound
Range (ft)	30	30	28	28
Target Total Area (sq in)	737	64	33 Exposed	56
Angle Between Sensor LOS and Target Surface Normal (deg)	79	59	75	69
Target Area Projected onto FTIR FOV (sq. in.)	140	33	9	20
FTIR Weighted FOV Footprint at Target (sq. in.)	140	140	130	130
Fractional Area of Total Weighted FOV Occupied by Projected Area of Target	Do Not Know Frac of Asphalt Covered by Sand	0.24	0.07	0.15
Percent of Target Material Radiation that is Linearly Polarized When Weighted to Fill the IFOV of Sensor, for the Indicated Angle Between Sensor LOS and Target Surface Normal	----	8%	14%	13%
DoLP of Material with DoLP of Sand Removed, for the Spectral Region 800-1250 cm^{-1}	0.02	0.02	0.01	0.02

expect the degree of linear polarization (DoLP) for the materials to be very small or zero. Below, we compute the DoLP spectra and indeed show these materials are substantially unpolarized.

This is not the case, however, when we examine the polar component spectra for the plastic frisbee on sand, CARC on sand and sandy asphalt in Figs 3(c), 3(d) and 4(a), respectively. In Figs 3(d) and 4(a) we find large separations in the polar component spectra indicating that CARC and asphalt exhibit strong LWIR polarization effects. Furthermore, the separations in CARC and asphalt show an interesting spectral dependence, being very strong near the greybody curve peak at 925 cm^{-1} and gradually narrowing until the gap closes at about 1250 cm^{-1} . While the general shape of the spectra are determined by the greybody temperature and the spectral polarimeter response function (including the optics, analyzer, antireflection coatings and detector), the sharp spectral features in the $1100 - 1200 \text{ cm}^{-1}$ region are attributed to quartz sand. Notice these features are not present in the soil spectrum, Fig 3(a). These spectra, rich in features, demonstrate very clearly our interest in the LWIR and our rationale for pursuing hyperspectral polarimetry as a powerful technique to discriminate man made target materials against natural background clutter.

2.2 Analysis of polarimetric measurements

The degree and angle of linear polarization (DoLP and AoLP) of a *partially linearly polarized* wave can be obtained from measurements made at three different analyzer angles. The intensity measured at the output of the analyzer oriented at angle α is given by^{10, 18}:

$$I(\alpha) = \frac{1}{2} I_u + I_p \cos^2(\theta_p - \alpha) \quad (1)$$

where

$$\begin{aligned} I_u &= \text{Polarized light from target} \\ I_{u-igt} &= \text{Unpolarized light from target} \\ I_{u-bkg} &= \text{Unpolarized light from background} \\ I_u &= I_{u-igt} + I_{u-bkg} \\ \text{DoLP} &= I_p / (I_{u-igt} + I_p) = \text{Degree of linear polarization} \\ \theta_p &= \text{Angle of linear polarization.} \end{aligned}$$

As is frequently the case with simultaneous trigonometric equations, general solutions in terms of well known functions are difficult to find; a numerical solution can be obtained by searching for it using Newton's method or, alternatively, minimizing an objective function such as the sum of the squared differences between the measurements and the theoretical value (i.e. left hand side minus right hand side of Eq (1)). The field measurements obtained at Aerodyne were performed such that the surface normal vector of the targets was in the plane of incidence, thereby constraining the emitted light to a 90-degree analyzer angle and the reflected light to a 0-degree analyzer angle. Careful attention was paid to orienting the spectral polarimeter such that cold sky was reflected. Under these circumstances, it is reasonable to make the simplifying assumption that $\theta_p = 90$ degrees. Equation (1) then becomes

$$I(\alpha) = \frac{1}{2} I_u + I_p \sin^2(\alpha) \quad (2)$$

By choosing an analysis angle of 0-degrees, the unpolarized intensity is immediately obtained. The polarized intensity can then be obtained by using any other angle (except 180-degrees). In the present case of 90-degree angle of polarization, the greatest signal to noise ratio is obtained by using 90-degrees for the second analysis angle. A 1.25 dB loss in SNR results from the use of 60-degrees instead of 90 in this case.

2.3 Results

Using the simplified analysis approach represented in Equation (2), we extracted a DoLP spectrum for each of the materials observed in this demonstration. Since the quartz sand background was present in the field of view for all of these data, it was subtracted in each case. Otherwise, its region of low emissivity, 1100 - 1250 cm^{-1} , introduces a substantial step function into the DoLP spectra. Other features in the DoLP spectra deserving comment are:

1. Soil is effectively unpolarized and provides a point of reference for the other materials plotted in Fig 5.
2. CARC and sandy asphalt exhibit essentially the same DoLP, indicating they will not be easily distinguished using a broadband polarimeter. Refer ahead to view the CARC panel on sandy asphalt in Fig 9.
3. In the 1000 - 1100 cm^{-1} region the trace effect of ozone remains visible in the spectrum.
4. Fringes apparent in the spectra are attributed to a polarization sensitive beam splitter effect in the FTIR spectrometer.

2.4 The special case of CARC target on sandy asphalt background

The combination of the CARC target imbedded in a sandy asphalt background is a key piece of data from our proof-of-concept demonstration. The reason for this can be seen in Fig 5. Over the spectral interval 800 - 1250 cm^{-1} the measured DoLPs are the same for CARC on sandy asphalt and sandy asphalt alone; CARC and sandy asphalt cannot be differentiated solely by the linear polarization attribute, i.e. by a single broadband imaging polarimeter. In Section 4 we show image data to confirm this. However, this case provides an excellent example of the powerful tool obtained when the polarimetric and spectral capabilities are combined in an LWIR spectral polarimeter. One set of the data for tan CARC on sandy asphalt collected with our basic combination of FTIR spectrometer and wire grid polarizer are shown on a magnified scale in Figs

4(a), 4(b) and 4(c). Figure 4(c) is an overlay of four plots - two for the 'CARC present' and two for 'only sandy asphalt'. By inspection of their spectral dependence we can easily distinguish the presence of CARC in the sandy asphalt background. At 900 cm^{-1} the 0-deg and the 60-deg analyzer plots are identical with and without the CARC present; no differentiation here. However, as we move along the wave number axis toward 1200 cm^{-1} , two effects are evident. First, the separation by analyzer angle for each pair of curves (with and without the CARC present) is becoming less and washes out completely by 1250 cm^{-1} (see Fig 4(c) for this to be apparent in the 'CARC present' case). Secondly, the 'CARC present' traces are decidedly higher than 'without CARC' plots over the spectral region $1050 - 1250\text{ cm}^{-1}$. This effect is shown clearly in Fig 4(c). Therefore, in the spectral dimension (at $1050 - 1250\text{ cm}^{-1}$, not 900 cm^{-1}) we have a very strong differentiation of the CARC present in the sandy asphalt background even though the DoLP for the combined CARC and sandy asphalt background afforded no differentiation. This is true even though separately both the CARC and the sandy asphalt exhibit strong polarization effects. These data make a clear case for the importance of adding the spectral dimension to the LWIR polarimeter. Our goal in the demining application is to demonstrate an affordable and effective polarimeter having both spectral and imaging capabilities.

3. LABORATORY MEASUREMENT OF GRAZING ANGLE IR SPECULAR REFLECTANCE OF ANTIPERSONNEL MINE CASINGS

In order to exploit unique spectral features (particularly low emissivity regions) of land mine casings and similar man made objects (typical plastics such as ABS and blended polymers) we must know the spectral features of both the man made materials and the natural backgrounds in these spectral regions. Our laboratory measurement of grazing angle specular (80-deg) reflectance of four AP mine casings and several related, simulant materials of interest confirm the availability of many LWIR spectral features to be exploited in multi- or hyper-spectral polarimetry. These reflectance spectra exhibit the characteristic dispersion curve shape near the centers of absorption features in the materials.

Our laboratory grazing angle reflectance spectra were collected with an FTIR spectrometer at a resolution of 4 cm^{-1} and generally covering the range of 3 - 15 microns ($666 - 3333\text{ cm}^{-1}$). In each case the sample spectrum has been ratioed to the spectrum of a front surface gold mirror that has a reflectance greater than 0.99 over the entire spectral range covered here. The inerted AP mine casings that were available for study are listed in Table 2 and pictured in Fig 6. In addition, Table 2 includes several related or simulant materials of interest for which we collected reflectance spectra, but not all of these will be discussed here.

Sample grazing angle reflectance spectra are plotted in Figs 7(a), (b) and (c). To make the examination of these spectra easy it is important first to eliminate from further consideration all spectral features attributed to the incomplete removal of water vapor and carbon dioxide from the optical path in the laboratory spectrometer; even though the path was constantly under purge with dry nitrogen, this did not completely remove all atmospheric gases from the sample compartment of the instrument. The spectral features to be ignored are water vapor bands at 2.7 and 6.3 microns and carbon dioxide bands at 4.3 and 15 microns. Then it is important to remember that the dispersion features in the reflectance spectra mark the locations of absorption features for the material. Since the material does not transmit radiation at these characteristic absorption wavelengths, the grazing angle reflectance, like the index of refraction, shows a strong change across the width of an absorption feature.

Our hyperspectral polarimetry approach to developing a reliable detection method for partially exposed scatterable land mines exploits differences in the emissivity and polar attributes of mine materials and coatings relative to these

Table 2. List of Anti-Personnel Mine Casings and Related Materials Included in Laboratory Measurement of Grazing Angle IR Reflectance Spectra.

Anti-Personnel Mine Component	Related Materials or Simulants
M-14 Plastic	CARC (Chemical Agent Resistant Coating), Both Green and Tan
PFM-1 (Butterfly)	
TS-50 Rubber Center	RTV 3110 Silicone Rubber
TS-50 and VS-50 Plastic	Floppy Diskette Plastic Shell
VS-50 Rubber Center	Rubber Hockey Puck
	Asphalt
	Sand
	Soil

same properties for natural backgrounds. Typically, we will examine the spectral reflectance, and thereby the spectral emittance, of the mine materials for unique spectral features and high grazing angle reflectance compared to the backgrounds. With this in mind the measured reflectance spectra presented in Fig 7 have a number of features of interest. First, examining the spectra in Fig 7(c) for similarities, we find the M-14 and Butterfly (PFM-1) mine casings very similar in having very little spectral structure and a difference in overall reflectance level that is accounted for simply by the difference in surface roughness. Although not shown here, the one band at 14.3 microns is common to both the M-14 mine and the floppy diskette shell, making the latter a very sensible simulant for M-14 surface properties. Also in Fig 7(c) the plastic shells of the TS-50 and VS-50 (not over plotted to avoid confusion) have identical spectral features at 8.1, 8.9 and 10.7 microns and are apparently the same polymer blend. We believe this to be an ABS (acrylonitrile butadiene styrene) plastic, but we have more work to do in matching spectra to polymer blends before claiming to have identified the materials.

Second, examining the spectra of the rubber materials in Figs 7(a) and (c), we find that the TS-50 rubber center and RTV 3110 have the same spectral features at 7.87, 8.96, and 12.2 microns. We conclude the TS-50 center element is actually an RTV silicone rubber. Comparing these same features to the reflectance spectrum for the VS-50 center element in Fig 7(c), we find them to be wholly different and learn by comparison to another spectral database that the VS-50 center element is natural rubber.

In Fig 7(b), we examine the spectrum of an Army camouflage paint of interest, green and tan CARC, because it is a low reflectance coating purposefully formulated to have the optical properties of the natural background. The grazing angle spectral reflectance features measured for tan CARC are located at 9 and 12.5 microns, with the 9 micron feature being very robust. The infrared spectral features of CARC have been studied extensively in the Joint Multispectral Program (JMSP)¹⁹ for the purpose of identifying spectral bands that provide a dependable two-color discriminant for CARC in a variety of backgrounds. Using apparent spectral contrast data collected over a wide range of backgrounds and local meteorological conditions, this study concluded that the 9 micron feature provides a persistent two band spectral contrast discriminant for CARC (8.73 / 9.23 microns). This is a successful illustration of our effort to use narrow band spectral features for discrimination of mines within clutter when broadband polarimetry alone cannot eliminate all of the clutter.

In general, our laboratory measurements of grazing angle specular reflectance for the materials listed in Table 2 compare well to the more comprehensive and dedicated measurement efforts of Salisbury and D'Aria²⁰ on the spectral reflectance of terrain background materials, of Johnson and coworkers²¹ on the spectral emissivity variations in disturbed soils, and of Cederquist and coworkers^{22, 23} on the spectral reflectance of target materials and coatings. For insight into the spectral features of blended polymers we found the book by Garton²⁴ to be very useful. Our purpose in making comparisons to these dedicated studies is to confirm our approach and to put a quantitative foundation under our efforts to apply spectral polarimetry to mine detection.

Given that reliable mine detection has proven to be a difficult and frustrating challenge for many qualified investigators, we stand firmly by our stepwise, controlled risk approach as outlined above, and note here again that our laboratory measurement of mine materials spectral reflectance features is a key element in our approach. These data tell us if and where we can expect to apply spectral polarimetry to antipersonnel mine detection successfully. Overall we are encouraged by the availability and robustness of spectral features for plastic mine casing materials found in the LWIR region of interest.

4. LWIR IMAGING POLARIMETER DEMONSTRATION MEASUREMENTS

A series of demonstration measurements were performed on a sampling of inerted non-metallic antipersonnel (AP) mines in various natural backgrounds. The images were collected using an uncooled microbolometer imager operating in the 8 - 12 μm band. A manually rotated wire grid polarizer (1200 lines/mm) was mounted to the camera in front of a 25 mm focal length f/1.0 germanium lens. Although complete characterization of the polarization state requires four independent measurements (three if partial linear polarization is assumed), only two measurements were made in this proof-of-concept demonstration. The justifications for this are twofold. First, it can be assumed that the elliptical polarization is small. Second, the geometry of the scene was chosen such that the angle of polarization for the objects of interest was either vertical or horizontal, in which case the maximum image contrast will be seen in the difference between images made with the polarizer in these two orientations. A sequence of 10 frames was co-added for each polarization angle before subtraction.

The Fresnel reflectance relations indicate that the angle of polarization of reflected radiation is perpendicular to the plane defined by the incident and reflected beams while that of emitted radiation is parallel to this plane. Wire grid polarizers

transmit radiation when the E-vector is perpendicular to the wire and reflect radiation when the E-vector is parallel to the wire. In this paper we use the convention of 0-degree polarizer angle to mean the wire grid is oriented vertically. Consequently, in the intensity difference images (0 - 90 degrees) shown below, reflected (emitted) polarized regions appear brighter (darker) than unpolarized regions. For smooth, horizontal man made surfaces and observing sensor angles near Brewster's angle, the reflected radiation component (E-perpendicular) is near zero, and the emitted component (E-parallel) dominates.

4.1 Discussion of the LWIR imaging polarimeter data

Figure 8(a) shows four mines, a disk of RTV 3110, and a rubber hockey puck buried flush to the surface in sand. The mines, from front to back, are as follows: TS50, VS50, M14, and PFM-1 (Butterfly), followed by the RTV disk and the puck. It is clear from the image that these materials are easily distinguished from this relatively unpolarized and clutter free background. The polarization appears due to reflection of the warm surroundings. It is noteworthy that the top surfaces of the sandbox frame appear significantly polarized, wood being a material used in the construction of certain land mines. A more subtle, yet equally important feature of this image is the contrast evident between the disturbed and undisturbed regions of the sand. A horizontal (i.e., left to right) strip at the rear of the sandbox, extending to the butterfly mine was purposefully raked with a spring steel rake, and the areas surrounding the mines were disturbed to bury them. These areas are clearly distinguishable in the original images. This effect is attributed to a combination of contrast reduction caused by fine-grained particle coatings on the disturbed soil and the increased moisture content of the surface sand in the disturbed regions.^{20,21} In these measurements the undisturbed sand had received two days of sun since the last rainfall, so the surface was very dry. The disturbed areas brought noticeably moist, but not wet, sand to the surface.

Figure 8(b) shows the sandbox rotated 180° so the objects are in reversed order. In this case, the entire surface was well raked and graded to a uniform depth. The uniformity in the image is evident.

Figure 10 shows the same objects in a more natural background consisting largely of undisturbed aged bark mulch. Other elements in the scene include a rock (about 15 cm diameter), a bush, and some small weeds. The two objects labeled "CARC panel" are metal panels painted with CARC. In this image, the absolute value of the polarization difference is taken so emission and reflection polarization energy both appear bright. The bush, a small central portion of the rock, and the rear CARC panel were deliberately underexposed while the front CARC panel and the left edge of the mulch were overexposed. This was done to achieve maximum sensitivity in the region containing the mines and is a limitation of the 8-bit digitizer in the frame grabber rather than the imaging polarimeter itself. Clearly, the mines are evident in Fig 10, yet there is much less contrast against the bark mulch, which itself yields partially polarized radiation, compared to the sand in Figs 8(a) and 8(b). Although the contrast is low, most of the clutter in the thermal image has been suppressed. By contrast, Fig 11, showing only the 0-degree image component of Fig 10, exhibits the wide range of thermal variations present in the scene. Notice that in polarization the two CARC panels appear very similar on the gray scale in Fig 10 while in the intensity image (Fig 11) the sunlit CARC panel appears quite hot in comparison to the shaded panel near the bush.

Figure 9 shows the sandbox using the same camera and lens but now at a greater range (about 4 m). The mines and soil disturbances are still evident, but the scene also includes a large wood guardrail, a strip of aged bark mulch below it, and a vertical asphalt curbing. For two materials in the scene, wood and asphalt, we have both horizontal and vertical surfaces of the same materials in view at the same time. It is useful to observe how the contrast flips for the same material as the orientation and therefore the plane of incidence changes between horizontal and vertical. The vertical surfaces of the guardrail, sandbox wall, and curbing are bright in this difference image (0 - 90 degrees) because the plane of incidence is now horizontal.

There are several other basic polarization phenomena to be observed in this scene (Fig 9). The railing is painted dark brown and consequently heats up considerably during the day. The left end of the railing is seen to yield polarized emission as the view angle increases off-normal. The mulch exhibits polarized reflection when viewed at this grazing angle. The odd-shaped reflective lines near the sandbox are tar-filled cracks in the asphalt. One of the CARC panels is located on the asphalt just beyond the top left corner of the sandbox. Even though the CARC can be distinguished from the asphalt when we know where to look for it, the two exhibit nearly the same degree of linear polarization as seen here in the gray scale image. This confirms the quantitative DoLP results (Fig 5) obtained earlier in the LWIR spectral polarimeter data for CARC on an asphalt background. The top horizontal edges of the wood sandbox are dark, indicating polarized emission from the wood. Since the wood is in contact with the hot sand and asphalt, it can be expected to be warm; however, when wood is in contact with cool moist soil, this may not be the case. Finally, notice the rings of disturbed soil around the mines in the sandbox. Our

consistency of detecting disturbed soil encourages us to refine our approach by using narrow band filters (multispectral) that are optimized for the characteristic spectral features of various soil types.^{20, 21}

4.2 LWIR imaging polarimeter - importance of spatial scale

These imaging polarimeter data yield an empirical understanding of the spatial scale requirements for a polarization sensor. If the sensor instantaneous field-of-view (IFOV) is too large for the spatial scale of the target features in the scene, the signal at the detector will be a superposition of the polarization contributions within one IFOV (and similarly, for an imaging spectrometer, the spectral features will be a weighted mixture of the target and background features within the IFOV). Consequently, the distinctive polarization attributes of the target can be washed out and lost in the clutter. Even though it does not provide a direct example of a wrong choice of spatial resolution, the degree of polarization exhibited by the bark mulch, that is the clutter, in Fig 10 illustrates the importance of spatial scale. Here the bark mulch and the flush-buried mines are similar in dimensions. As a result the bark mulch is an effective background clutter for mines in this instance where the only attribute being measured is the degree of polarization with a broadband polarimeter. It is correct to infer from this that an investigator who chooses to apply broadband polarimetry alone to scenes of arbitrary spatial scale will fail.

For a more direct illustration of the importance of spatial scale, Figs 12(a) and (b) are polarization difference images, recorded under controlled conditions, of the box of bark mulch shown in the photograph, Fig 13. For Figs 12(a) and (b) the angles between the illuminator, the normal to the bark mulch box and the polarimeter were held constant while the range between the bark mulch and the polarimeter increased from 12 ft in Fig 12(a) to 45 ft in Fig 12(b). The IFOV footprint at the bark mulch is about 1/2 inch in Fig 12(a) and 2 inches in Fig 12(b), compared to a mean dimension of 3/4 inches for the bark mulch chips. As expected the polarized reflectance from individually resolved bark mulch chips are visible in Fig 12(a) but washed out by the coarser spatial resolution in Fig 12(b).

Clearly, in the design of a hyperspectral polarimeter, the spatial resolution is an enabling design parameter, making the spectral and polarization attributes of the target accessible to be used as additional discriminants. At the same time, no amount of effort in tailoring the spatial resolution will help in the event the spatial dimension of the clutter is the same as that of the target. In this situation the broad spectral band imaging polarimeter will not be successful, and the need to invoke hyperspectral polarimetry, thereby adding the spectral attributes for discrimination purposes, is clear.

5. RESULTS

5.1 LWIR imaging polarimeter - performance

The microbolometer FPA demonstrated strong performance when applied in the broad spectral band imaging polarimeter mode with the 1200 line/mm polarizer mounted in the optical train. In addition to the imaging polarimeter that we have assembled around an uncooled FPA being affordable, we can report the following performance on static scenes:

1. With f/1 optics and modest additional effort to hold the temperature of the optics constant when operating in the field, the polarimeter delivered a NEDT $< 0.1^{\circ}\text{C}$.
2. The polarimeter consistently detected disturbances in sand, soil and bark mulch created by burying objects and bringing fresh sample to the surface.
3. The system detected flush-buried antipersonnel mine casings and simulants both night and day, with and without cloud cover.

Even though we are quite pleased with the performance of the uncooled FPA microbolometer in the mode of a broadband imaging polarimeter, we have yet to demonstrate its performance as a multispectral imaging polarimeter. Recognizing that the NEDT of the current uncooled FPA technology is an order of magnitude higher than for cooled FPAs, we know the division of the available polarization signature into say 10 (multispectral) or 100 (hyperspectral) bins implies the best uncooled FPA performance as a multi- or hyper-spectral polarimeter will be marginal. Nevertheless, we intend to determine this experimentally since our experience to date with the uncooled FPA indicates that its actual NEDT performance can be as much as a factor of two better than the nominal specification.

5.2 Polarimeter design process and some useful insights

Our current understanding of the best design process for an imaging multi- or hyper-spectral polarimeter application^{10,15,16,25-28} includes the following points:

1. The spatial resolution will be determined and even constrained by the spatial scale of the target and primary clutter sources in the scenes and scenarios of interest. A polarimeter geared toward mine detection requires a spatial scale consistent with the mine dimensions and respective of the spatial scale of primary clutter sources. Recall the bark mulch images in Figs 12(a) and (b).
2. Given this spatial scale constraint the spectral range, resolution, and choice of detector are a compromise between the need for signal (broadband operation) and the availability of distinguishing "narrow" spectral features to exploit (multi- or hyper-spectral operation).
3. Prerequisite to this process is a very clear realization¹⁰ that at least two, and preferably three, independent polarization measurements must be acquired simultaneously at near perfect registration. Otherwise the polarization signal can be washed out by time-dependent effects such as sensor platform motion, substantial changes in the downwelling radiation incident upon the target, and even small temperature and sensitivity drifts in the detector.
4. Hyperspectral polarimetry offers essential advantages over broadband polarimetry in applications such as demining where small targets occupy one IFOV or less (subpixel) and require the use of spectral discrimination techniques.

6. CONCLUSIONS

6.1 Rationale for combining hyperspectral and polarimetric IR imaging

We have presented several pieces of evidence to motivate the marriage of hyperspectral and polarimetric IR imaging. Basically we recognize that polarimetric and hyperspectral attributes supplement one another, and that all available independent supplemental pieces of information can be used to advantage for discriminating target objects from background clutter. While we expect to exploit the broadband attributes of man made objects, knowledge of the characteristic spectral features for a large number of both man made and natural background materials (for example, quartz sand and the mine casing spectra presented above) enables an additional hyperspectral polarization discrimination capability that comes in the form of the narrow spectral features. The reflected radiation from the sun, sky, clouds and local environment can either enhance or wash out the contrast provided by the target emitted radiation and spectral features, but polarization segregates the emitted and reflected radiation so as to maintain the contrast of the emitted component which is characteristically strong in man made objects. Hyperspectral polarimetry offers one more attribute, angle of polarization (AoP), to be used as a discriminant; AoP is a very sensitive and therefore powerful discriminant, but it also demands the very best in sensor performance to measure.¹⁰

Then, there is the issue of spatial scale. On the one hand, we have confirmed that broadband polarimetry alone cannot eliminate background clutter when the man made objects of interest cover a wide range in size from land mines to trucks. On the other hand, imaging polarimetry relieves the exceedingly heavy computational and signal processing burden of pure hyperspectral sensing while still allowing the sensor to be customized to the application. Neither hyperspectrometry nor polarimetry taken separately is as effective as when these tools are combined.

6.2 Overall status of IR polarimetry effort

More important than any one of the above proof-of-concept demonstrations, each of which represents a successful step in the risk-reduction sense, is to put all these elements together into the same sensor, a Hyperspectral Imaging IR Polarimeter; this is our goal and represents our most significant effort to go beyond state-of-the-art. If we are successful, we will have captured the spectral, spatial and polarimetric attributes in one sensor, all simultaneous in time and perfectly registered spatially.

Going beyond the current proof-of-concept sensor configuration intended for static scenes, we now have an innovative sensor design in hand and are building the prototype hyperspectral imaging IR polarimeter. We have verified in a laboratory

visible-band implementation that our design allows us to extract any angle or degree of polarization in the scene at a frame rate determined by the multiplexer and signal processor. For initial application purposes we are using a cooled FPA in the IR prototype, yet we anticipate the opportunity to test uncooled FPAs for the demining/UXO applications. Having all of the spectral, spatial and polarimetric attributes available to us at the same time provides a powerful discrimination and clutter suppression capability that is quite unique. All indications from analyzing our sequentially collected data are that these attributes taken together will comprise a reliable sensor for the detection of surface and flush-buried land mines, as well as for disturbed soil and shallow-buried mines over diurnal cycles or with microwave enhance heating.

Laboratory measurements or other knowledge of the spectral reflectance and polarimetric properties of the targets in each application are necessary to support hyperspectral polarimetry. Our laboratory data help directly to (a) determine the locations and widths of spectral features needed to infer the value added of hyperspectral over multispectral polarimetry and thereby to (b) determine in potential applications whether broadband, multispectral or hyperspectral polarimetry applies.

In summary, using somewhat sparse, but very reproducible, data from field and laboratory measurements to date, we have presented a case for hyperspectral LWIR polarimetry in applications requiring the detection of plastic, as well as metal, flush-buried and scattered surface mines. This approach applies equally well to partially exposed unexploded ordnance (UXO) and to shallow-buried mines subjected to microwave enhanced heating and diurnal cycles. Our rationale for combining hyperspectral and polarimetric imaging was presented.

ABSTRACT

The problem of low metal content mine characterization from broadband electromagnetic induction (BEMI) data is addressed. A stochastic model describing the spatial distribution of clutter is developed and methods for estimating and removing this unwanted interference are described and tested. After removing the clutter from the signal, a technique is introduced for extracting from BEMI data information describing the location, orientation and structure of the buried object. Examples are provided for spherical and ellipsoidal mines.

1. INTRODUCTION

Broadband electromagnetic induction (BEMI) methods represent a new and very promising sensing technology for the detection, localization, and characterization of buried metallic objects such as landmines and unexploded ordnance.² The data taken over a broad frequency range (tens of hertz to tens of kilohertz) convey information which can be used for not only to detect the presence or absence of an object but also to determine the shape, size, orientation, and material characteristics.

In this paper, we look into problems related to the application of BEMI systems to the characterization and classification of low metal content buried objects. In previous work, we have developed physical models to describe a BEMI system and associated processing methods to extract from BEMI data collected over a grid of points in the neighborhood of the object information regarding the location, orientation and structure of a buried object by estimating dipole moment spectra (DMS).³ We have verified the ability of these methods for purposes of classification using real sensor data for problems where the objects contain significantly metal. However, for problems involving low metal content objects, new processing techniques are needed. In particular, for these cases the signal arising from volumetric inhomogeneities in the electromagnetic properties of the earth (permittivity and conductivity) can be of the same order or magnitude if not larger than the signal arising from the object under investigation. Moreover, this "clutter signal" is known to enter the data *additively* suggesting one method of mitigating the clutter would be to estimate and subtract it from the data.

We propose to model the clutter as a correlated random field which can be described using a polynomial regression model the structure of which is motivated by examination of real clutter data collected with a GEM-3³ sensor. The estimate then subtract processing strategy we propose is designed to reflect the way in which BEMI-type sensors are employed in the field. Currently clutter mitigation amounts to subtracting from data taken in the immediate vicinity of the object target-free secondary data taken on the boundary of this area. Thus, the correlation structure of the clutter is not properly accounted for in the mitigation procedure. Moreover, this approach completely ignores the fact that the sensor is often calibrated in a region close to a suspected target. Thus any information which the calibration data may be able to yield regarding the clutter structure over the object is also absent from the processing.

Here we consider a model-based approach to BEMI clutter mitigation. The data from the calibration region as well as the boundary of the object region are all used to estimate and remove the clutter in the data containing the object signal. After cleaning the data in this manner, we describe a new set of methods for estimating the object characteristics: location, orientation, and DMS. Relative to the statistically optimal algorithm proposed in [3] for this task, the one developed here, though theoretically suboptimal, is faster and still highly accurate.

The remainder of this paper is organized as follows. The BEMI physical model is reviewed in §2. In §3 the clutter model is described while §4 is devoted to the development of our processing methods. Examples demonstrating the performance of this approach are provided in §5. Finally, in §6, we provide conclusions and indicate the future work.

2. PHYSICAL MODEL

We consider an extension of a physical model for EMI proposed in [1] describing the scattering of low frequency electromagnetic radiation by spherical or spheroidal objects of known conductivity and permeability. As seen in Fig. 1 the transmitters and receivers are taken to be square coils (not necessarily co-located) with sides of length $2A$. The target center is located at $r_0 = (x_0, y_0, z_0)$ in the $x - y - z$ coordinate system. We are concerned with processing methods based on multi-frequency data obtained

Figure 1. One sensor comprising sensor coils and target object.

from multiple transmitter/receiver locations. Assuming we collect M frequency samples from each of N combinations of transmitters and receivers positions then under the model the k th frequency sample at the n th position is

$$s_{n,k} = \frac{i\omega_k\mu_0}{I} g_n^T R^T \Lambda_k R f_n + w_{n,k} + c_{n,k} \quad (1)$$

where Λ_k is the normalized polarizability tensor for the k th frequency, R is the rotation matrix, g is a 3×1 vector holding the x , y , and z components of the magnetic field produced at r_0 by a current I flowing in the receive coil, g^T indicates the transpose of g , f is the excitation field vector evaluated at the dipole

position and has a similar functional form to that of g , ω is the operating frequency, $i = \sqrt{-1}$, μ_0 is the permeability of free space, $w_{n,k}$ is measurement noise, and finally $c_{n,k}$ is the clutter in the data for the k th frequency sample at the n th position. Details about f and g are provided in Appendix A of [1]. The matrix Λ takes the form:

$$\Lambda(\omega) = \begin{bmatrix} \lambda_1(\omega) & & \\ & \lambda_2(\omega) & \\ & & \lambda_3(\omega) \end{bmatrix}. \quad (2)$$

The three frequency dependent λ 's (here referred to as dipole moment spectra) each are associated with one of the principal axes of the object. For a sphere, all three are identical and closed form expressions can be found for all orders of multipoles.² Finally, R represents a rotation matrix used to transform field quantities between a global frame of reference and the local frame of the object. Here R is parameterized by 3 Euler angles⁷ and explicitly takes the form

$$R = \begin{bmatrix} \cos \phi \cos \psi - \sin \phi \cos \theta \sin \psi & -\cos \phi \sin \psi - \sin \phi \cos \theta \cos \psi & \sin \phi \sin \theta \\ \sin \phi \cos \psi + \cos \phi \cos \theta \cos \psi & -\sin \phi \sin \psi + \cos \phi \cos \theta \cos \psi & -\cos \phi \sin \theta \\ \sin \theta \sin \psi & \sin \theta \cos \psi & \cos \theta \end{bmatrix} \quad (3)$$

From this data set, our goal is to determine the position, the orientation, and the moment spectra of the buried object.

3. CLUTTER MODEL

For low metal content objects a simple additive white Gaussian noise model is not satisfactory. The interaction of the transmitted signal with the background medium, usually negligible for sensing metal objects, become prominent here. These effects are manifest in the form of additive, correlated noise in the signal which we term "clutter". In this work we develop a stochastic model describing the distribution of clutter which provides for the spatial correlation seen in this portion of the sensor signal.

Specifically, we consider the following polynomial regression model in the spatial variables x_i and y_i , the x and y position of the i th sensor to describe this clutter at frequency ω_k :

$$c(x_i, y_i, \omega_k) = \sum_{p,q} \alpha_{p,q,k} x_i^p y_i^q + n_{i,k} \quad (4)$$

where the α 's are unknown, random expansion coefficients, and $n_{i,k}$ represents residual, "white" variations not captured by the regression. Collecting the clutter samples at all locations and all frequencies into a signal vector we write the overall model as

$$c = X\alpha + n. \quad (5)$$

For M frequencies $X = I_M \otimes X'$ where I_N is the $N \times N$ identity matrix, \otimes denotes the Kronecker product and X is the block diagonal matrix obtained from all the X' 's, where the element of X' for (i, j) th position is $x_i^p y_j^q$, α is the vector containing $\alpha_{p,q,k}$, and n is the noise vector.

As described in §1, we use (5) to describe the distribution of clutter over two regions of space: a calibration area and a region containing an object to be characterized. As illustrated in Fig. 2 the clutter mitigation procedure we propose makes use of *all* the calibration data and the data taken on the *boundary* of the object region to estimate the clutter signal on the interior of the object region. One supposition here is that the boundary data do not contain any mine signal. Another is that there is some correlation in the clutter from one region to the next which can and should be exploited in the processing. Thus,

Figure 2. Clutter Model.

we introduce a simple statistical model linking the α vector from the clutter region to that of the object region. Formally, over the calibration region we write the clutter as

$$c_0 = X_0 \alpha_0 + n_0 \quad (6)$$

while over the object area we have

$$c_1 = X_1 \alpha_1 + n_1 = \begin{bmatrix} X_{1,b} \\ X_{1,i} \end{bmatrix} \alpha_1 + \begin{bmatrix} n_{1,b} \\ n_{1,i} \end{bmatrix}. \quad (7)$$

with $X_{1,i}$ built from points interior to the mine region, $X_{1,b}$ from the boundary points (marked by "X" in Fig. 2), $n_{1,i}$ interior noise samples and $n_{1,b}$ boundary noise samples. To complete the model of the clutter we assume that the vector α_1 is $N(0, \sigma_\alpha^2 I)$, and we hypothesize that α_0 and α_1 are related via random walk type model of the form

$$\alpha_0 = \alpha_1 + n_2 \quad (8)$$

Finally, for simplicity we take $n_j \sim N(0, \sigma_j^2 I)$ for $j = 0, 1, 2$.

4. PROCESSING

4.1. Clutter estimation and mitigation

Given the clutter model described in the previous section, our first objective is to find an estimate of α_1 given c_0 (the calibration region data), and $c_{1,b}$ (the clutter data taken on the boundary of the object region), so that we can estimate the clutter data for the whole mine present region. Toward this end, we substitute (8) into (6) to obtain;

$$c_0 = X_0 \alpha_1 + X_0 n_2 + n_0 \quad (9)$$

Combining this with (7), yields the complete clutter model

$$\underbrace{\begin{bmatrix} c_0 \\ c_1 \end{bmatrix}}_c = \underbrace{\begin{bmatrix} X_0 \\ X_1 \end{bmatrix}}_D \alpha_1 + \underbrace{\begin{bmatrix} I & 0 & X_0 \\ 0 & I & 0 \end{bmatrix}}_E \underbrace{\begin{bmatrix} n_0 \\ n_1 \\ n_2 \end{bmatrix}}_n \quad (10)$$

with $En \sim N(0, R)$ and $R = E \text{ blockdiag}(\sigma_0^2 I, \sigma_1^2 I, \sigma_2^2 I) E^T$. Eq. (10) provides a linear model relating all of the clutter data of interest to the expansion coefficients over the region containing the object. Using this model, the linear least squares estimate of α_1 based on the clutter data taken over the calibration region and the boundary of the mine region is³

$$\hat{\alpha}_1 = (D_r^T R_r^{-1} D_r)^{-1} D_r^T R_r^{-1} M_0 c \quad (11)$$

where M_0 is a selection matrix that extracts from c the c_0 and $c_{1,b}$ subvectors, $D_r = M_0 D$, and $R_r = M_0 R M_0^T$. Then, the estimate of the clutter data for the interior of the mine present region is

$$\hat{c} = X_{1,i} \hat{\alpha}_1 = X_{1,i} (D_r^T R_r^{-1} D_r)^{-1} D_r^T R_r^{-1} M_0 c \equiv M_1 c. \quad (12)$$

We mitigate the clutter in the signal as follows: Collecting the data over all frequencies and positions we write the model in (1) as;

$$s = s_0 + c_{1,i} + \omega = s_0 + M_2 c + \omega \quad (13)$$

with s_0 the vectorized form of the first term in (1), $c_{1,i}$ clutter on the *interior* of the object region, and M_2 the matrix which extracts from c the $c_{1,i}$ subvector. The noise vector ω is $N(0, \sigma_\omega^2 I)$. Then, subtracting \hat{c} from the data vector s yields the clutter mitigated data, or cleaned data, \bar{s} ,

$$\bar{s} = s_0 + M_2 c - \hat{c} + \omega = s_0 + (M_2 - M_1) c + \omega \equiv s_0 + M c + \omega$$

Thus, the cleaned data are $N(s_0, R_{\bar{s}})$ with (after some algebra)

$$\begin{aligned} R_{\bar{s}} &= M R_c M^T + \sigma_\omega^2 I \\ R_c &= \sigma_\alpha^2 D^T D + R \end{aligned}$$

4.2. Target parameter estimation

Given \bar{s} , our aim is to estimate the parameters of the detected object: the co-ordinates of the object center, the moment spectra, and the three rotation angles. Here we take a two-step approach to this procedure. First, we use the data to estimate the three location parameters of the object, (x_0, y_0, z_0) and a collection of quantities related to the Euler angles and the DMS. Second, we use these estimates to separately extract orientation and DMS information. The motivation for this approach is primarily computational. As described in greater detail below, each stage requires the solution of a problem involving a single large parameter vector which is *linearly* related to the data and a substantially smaller set of parameters for which the relationship is *non-linear*. By pursuing a two step strategy, we can exploit this structure to obtain an estimation approach requiring two small non-linear search routines rather than one larger one. Moreover, the first such routine for the location parameters is better behaved in terms of local minima than the second search for the Euler angles. Thus, we are able to effectively partition the overall estimation problem.

Our approach to the first subproblem is to start by defining the symmetric matrix M_k

$$M_k = R^T \Lambda_k R = \begin{bmatrix} \mu_{11,k} & \mu_{12,k} & \mu_{13,k} \\ \mu_{12,k} & \mu_{22,k} & \mu_{23,k} \\ \mu_{13,k} & \mu_{23,k} & \mu_{33,k} \end{bmatrix} \quad (14)$$

Substituting (15) into (1), "stacking" the data from all transmitter-receiver pairs for all frequencies, we arrive at the following model for the cleaned data

$$\bar{s} = B(r_0)\mu + \Omega. \quad (15)$$

where, for M frequencies $B = I_M \otimes B_1$ with B_1 a matrix constructed from the f_n and g_n vectors. The vector μ is comprised of the six *unique* elements of each M_k . Finally, the noise vector Ω is zero mean and Gaussian with variance $R_{\bar{s}}$.

Eq. (15) is used in a least squares approach to determine the location of the object, r_0 and μ , as follows:

$$\hat{\mu}_0, \hat{r}_0 = \arg \min_{\mu, r_0} \|\bar{s} - B(r_0)\mu\|_{R_{\bar{s}}}^2 \quad (16)$$

The solutions³ are found:

$$\hat{r}_0 = \arg \min_{r_0} \|\bar{s} - B(r_0)(B^T(r_0)R_{\bar{s}}^{-1}B(r_0))^{-1}B^T(r_0)R_{\bar{s}}^{-1}\bar{s}\|_2^2 \quad (17)$$

$$\hat{\mu} = (B^T(\hat{r}_0)R_{\bar{s}}^{-1}B(\hat{r}_0))^{-1}B^T(\hat{r}_0)R_{\bar{s}}^{-1}\bar{s} \quad (18)$$

The goal of the second processing step is to use $\hat{\mu}$ to estimate λ and α = the vector of three Euler angles. Via (14), we start by using $\hat{\mu}$ to build \hat{M}_k in the obvious manner. According to (14), we should be able to find a *single* rotation matrix which simultaneously diagonalized *all* of the M_k 's to produce the diagonal Λ_k 's. We use this observation to construct the following penalized least squares cost function

$$C(\alpha_k, \lambda) = \sum_k \|R(\alpha)\hat{M}_k R^T(\alpha) - \Lambda'_k\|_F + \text{penalty} \quad (19)$$

where $\|X\|_F$ is the Frobenius norm of the matrix X ,

$$\Lambda'_k = \begin{bmatrix} \lambda'_{11,k} & \lambda'_{12,k} & \lambda'_{13,k} \\ \lambda'_{12,k} & \lambda'_{22,k} & \lambda'_{23,k} \\ \lambda'_{13,k} & \lambda'_{23,k} & \lambda'_{33,k} \end{bmatrix}$$

is the matrix containing the moment spectra and it is not generally diagonal due to the fact that the noise in the data will prevent the exact simultaneous diagonalization of all the M_k . With this in mind, the goal of penalty is to (a) discourage nonzero off diagonal entries in every Λ'_k and (b) to encourage smoothness in the $\lambda_{i,k}$ from ω_k to ω_{k+1} .³

Stacking the unique unknown $\lambda'_{i,j,k}$'s (6 per frequency) into one large vector λ' , we write (19) as;

$$C(\alpha, \lambda) = \|\hat{\mu}'(\alpha) - \lambda'\|_{R_{\bar{s}}}^2 + \beta_1 \|L_{OD}\lambda'\|_2^2 + \beta_2 \|L_D\lambda'\|_2^2. \quad (20)$$

where $\hat{\mu}'$ is the vector of unique elements from $R(\alpha)\hat{M}_k R^T(\alpha)$ over all k . The L_i are used to regularize the problem; specifically, L_{OD} is for off-diagonal elements, and L_D is for diagonal elements. They are built such that

$$\|L_D\lambda'\|_2^2 = \sum_{k=1}^M \sum_{p=1}^3 (\lambda'_{pp}(w_k) - \lambda'_{pp}(w_{k+1}))^2 \quad (21)$$

$$\|L_{OD}\lambda'\|_2^2 = \sum_{k=1}^M (\lambda'_{12}(w_k))^2 + (\lambda'_{13}(w_k))^2 + (\lambda'_{23}(w_k))^2. \quad (22)$$

The regularization parameters β_i in (20) are used to determine the tradeoff in the reconstruction between the two terms in the cost function. The first term enforces fidelity to the data while the second ensures smooth spectra in (21). We note that in general, the on-line determination of β_i is a well-studied, non-trivial issue beyond the scope of this paper.⁴⁻⁶ For simplicity, in the examples in Section 5, we assume that β is known.

To minimize the cost function, we note first that because (21) is quadratic with respect to λ , $\hat{\lambda}$ can be explicitly stated in terms of α and \hat{r}_0 via

$$\hat{\lambda} = \left(R_s^{-1} + \beta_1 L_{OD}^T L_{OD} + \beta_2 L_D^T L_D \right)^{-1} R_s^{-1} \hat{\mu}' \equiv Q(\hat{r}_0, \alpha) \hat{\mu}' \quad (23)$$

so that we can write:

$$\hat{\alpha} = \arg \min_{\alpha} C(\hat{r}_0, \alpha, Q(\hat{r}_0, \alpha) \hat{\mu}') \quad (24)$$

$$\hat{\lambda} = Q(\hat{r}_0, \hat{\alpha}) \hat{\mu}' \quad (25)$$

In our experiments we have found that C exhibits many local minima in terms of the orientation angles. Thus, we have adopted the following strategy: We first impose a coarse grid on the three dimensional space of all permitted orientation angles, then, for each α -value in the grid, the value of the cost function C is found. We use that α values with the smallest overall cost for that cell to initialize a full 3D non-linear least squares scheme to find the final values of $\hat{\alpha}$. Using these values, we construct $\hat{\lambda}$ according to (25).

5. EXAMPLES

In this section, we compare our processing approach to that of a baseline method in which clutter mitigation is performed by subtracting from the interior data at a fixed y the average of the two corresponding horizontal samples taken on the boundary. We demonstrate and analyze the performance of the parameter estimation of our approach under two mine shapes. We simulate data taken on a 9×9 grid of 81 cm^2 pixels by a monostatic transmit/receive system comprised of square coils 5 cm on a side. Ten frequencies logarithmically spaced between 0 and 4.3 kHz are used. One corner of the grid is taken to be $(-0.4, -0.4) \text{ m}$ while the opposite is at $(0.4, 0.4) \text{ m}$.

As a first example, we consider a spherical object located at $(x_0, y_0, z_0) = (0, 0, .10) \text{ m}^*$, and with radius 5 cm . The medium as well as the object are taken to be non-ferrous and the conductivity of the sphere is 10^6 S/m . We assume that the sphere's response can be modeled as a dipole and we use the results of [2] to compute the dipole moment spectrum (DMS). The real and imaginary parts of this spectrum are shown as a solid line in Fig. 3. Because the sphere is rotationally invariant, for this problem there is no need to estimate the rotation angles so that the problem here reduces to determining the location and the DMS. To demonstrate the performance of our approach, we perform 100 Monte Carlo simulations at a signal to clutter plus noise ratio (SCNR) of 10 dB . In our model, the sample mean of the estimated object center is $(-0.0004, -0.0009, 0.1017) \text{ m}$ with a standard deviation of $\pm(0.0003, 0.0010, 0.0021) \text{ m}$. In the baseline method, it is $(0.0237, -0.0059, 0.1144) \text{ m}$ with a standard deviation of $\pm(0.0156, 0.0035, 0.0123) \text{ m}$. In Fig. 3 the dotted lines show the sample mean of the estimated DMS according to both methods. We see from these results that our approach is highly accurate and better when compared with the baseline method both in terms of estimating the position as well as the moment spectrum.

As a second example, we consider an ellipsoid object again located at $(x_0, y_0, z_0) = (0, 0, .10) \text{ m}$ and which has been rotated using $\phi = 1.70$ radians, $\psi = 1.70$ radians and $\theta = 1.70$ radians. In this case, we

*Increasing depth here corresponds to increasing z

Figure 3. The real and imaginary part of estimated and real moment spectra of sphere mine

presently have no closed form expression for the frequency dependent DMS of such an object. However, under the assumption that the scattering characteristics of an eccentric object will be substantially different among axes, we hypothesizes DMS spectra shown in Fig. 4, Fig. 5, and Fig. 6 as solid lines and examine the performance of our approach under these conditions.

In this case, we estimate the center of object, moment spectra for all three axes and three rotation angles. After performing 100 Monte Carlo simulations at 10 dB SCNR, for our approach the sample mean of the estimated object center is $(-0.0005, 0.0001, 0.0985)m$ with a standard deviation of $\pm(0.0004, 0.0003, 0.0012)m$. For the baseline case the mean is $(0.0578, -0.0011, 0.1107)m$ with a standard deviation of $\pm(0.0562, 0.0025, 0.0129)m$. The sample means of the estimated rotation angles under our processing scheme are $\phi = 1.66751$ radians, $\psi = 1.7163$ radians, and $\theta = 1.9097$ radians with standard deviations of $\pm(0.0041)$, $\pm(0.0014)$, and $\pm(0.0073)$, respectively. Using the simpler clutter mitigation algorithm, the results are means of $\phi = 1.5050$ radians, $\psi = 1.2052$ radians, and $\theta = 2.7402$ radians with standard deviations of $\pm(0.072)$, $\pm(0.0371)$, and $\pm(0.0053)$, respectively. Finally, the real and imaginary parts of the estimated and actual DMS using both clutter reduction methods are shown in Fig. 4–6.

For completeness we have gathered the sample means and standard deviations of our parameter estimates for both objects and both processing methods in the following table. These results along with those seen in Fig. 4–6 clearly point to the utility of taking a rigorous processing approach to clutter modeling and mitigation.

Figure 4. The real and imaginary part of estimated and real moment spectra of spheroid mine for the first axis.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we have presented an approach for the estimation of the dipole moment spectra, the coordinates of the object center, and rotation angles from BEMI data after estimating and removing clutter from the signal. Our work has been aimed specifically to the problem of characterizing low metal content objects. Using simulated data, we have demonstrated some clear performance gains using our method relative to simpler clutter mitigation approaches.

In the future, we plan to extend this work in a number of ways. First, we intend on validating and modifying (as needed) these models and processing methods based on the use of real BEMI sensor data collected for example using a GEM 3 sensor. On the theoretical side, our interests are in the development of performance analysis metrics both for the estimation of the clutter parameters as well as the object characteristics. Specifically, the Cramer-Rao lower bound (CRLB) is a useful statistical tool for this effort.

Figure 5. The real and imaginary part of estimated and real moment spectra of spheroid mine for the second axis.

The information provided by the CRLB can be used for example to optimize sensor configuration for a particular characterization task such as maximally distinguishing object X from Y.

Optimum PML ABC Conductivity Profile in FDFD

Edwin A. Marengo, Carey M. Rappaport and Eric L. Miller

Center for Electromagnetics Research, Northeastern University, Boston, MA 02115

Abstract—We address the problem of optimally choosing the conductivity (σ) profile of a perfectly-matched-layer absorbing boundary condition (PML ABC) with prescribed number of layers so as to minimize reflections for a wide range of incidence angles and for a narrow (CW) or broad frequency-band. A new one-dimensional (1-D), frequency-domain description of 2-D PML performance is developed, validated and used in PML- σ profile optimization. An exhaustive search for PML- σ profiles that minimize reflections over a prescribed wide angle-range is carried out. Our procedure yields PML- σ profiles with better performance than previously reported values, for given number of layers.

Index Terms—Perfectly-matched-layer (PML).

I. INTRODUCTION

The optimal specification of Berenger's perfectly-matched-layer absorbing boundary condition (PML ABC) [1] in finite-difference frequency-domain (FDFD) and finite-difference time-domain (FDTD) EM-field computations is an open question of much interest to the computational electromagnetics community [2]. The challenge translates into profiling the PML conductivity σ so as to minimize discretization and material-contrast reflections (predominant at small incidence angles θ and high frequencies ω) while also allowing strong decay at grazing angles of incidence (say, $\theta > 65^\circ$). In this paper, two-dimensional (2-D) PML performance is modeled using a new 1-D PML formulation which is later used in PML- σ profile optimization. While past efforts [3]–[5], with the exception of Ref.[2], were aimed mostly toward optimizing normal-incidence performance, our focus is on wide-angle and narrow- and/or broad-bandwidth performance.

Our goal is to find conductivity profiles of the form $\sigma_i = \sigma_f \left(\frac{2N-i+1}{2N} \right)^p$, where σ_f and p are parameters that need to be chosen so as to minimize reflections from a PML with N layers and grid-spacing Δ with $i = 1, 2, \dots, 2N$ indicating twice the *half-layer* index in Yee's lattice [6] (with $i = 2N$ at the free space/PML interface). (We associate distinct values of σ to each electric and magnetic field point of the PML, doubling the number of parameters from the original [1].) We consider separately the cases of CW and broad-band operation: In the former, σ -profiles that minimize reflections for a specified incidence angle-range at prescribed, stepped frequencies are computed, which can be used in FDFD; the latter yields a PML that is (globally) optimum over a wide incidence angle-range and a specified broad-bandwidth; hence, it applies to FDTD simulation of broad-band EM pulses. We tackle

both cases numerically by minimizing a cost function, say $F = \int d\omega W(\omega) \int_0^{\pi/2} d\theta \Theta(\theta) \log_{10}[1 + |\Gamma(\theta, \omega)|]$, where $|\Gamma|$ is the PML's reflection coefficient magnitude while $\Theta(\theta)$ and $W(\omega)$ are weighting functions defining, respectively, the relevant ranges of incidence angles θ and frequencies ω . For example, later we will consider hard-weighting functions $\Theta(\theta)$, $W(\omega)$ where $\Theta = 1$ over a prescribed angular range $[0, \theta_{\max}]$ (where, e.g., $\theta_{\max} = 65$ or 75°) and is zero elsewhere, and $W(\omega) = 1$ only within the bandwidth of interest and is zero elsewhere.

The technique developed in the paper is validated with computer-simulated results both in FDFD and in FDTD. We find PML- σ profiles with better performance than previously reported values, for given number of layers. Attention is restricted to the 2-D transverse magnetic (TM) configuration (relative to the PML¹) schematically depicted in Fig. 1. The associated TE results follow by duality.

II. FORMULATION AND VALIDATION

Time-harmonic TM waves inside a PML perpendicular to the x -axis satisfy the equations [7]

$$\begin{aligned} \frac{\partial}{\partial y} \mathcal{H}_z &= j\omega\epsilon_0 \mathcal{E}_x \\ \frac{\partial}{\partial x} \mathcal{H}_z \left(\frac{1}{\epsilon' - j\sigma/\omega\epsilon_0} \right) &= -j\omega\epsilon_0 \mathcal{E}_y \\ \frac{\partial}{\partial x} \mathcal{E}_y \left(\frac{1}{\epsilon' - j\sigma/\omega\epsilon_0} \right) - \frac{\partial}{\partial y} \mathcal{E}_x &= -j\omega\mu_0 \mathcal{H}_z \end{aligned} \quad (1)$$

where ϵ' , considered here to be $\epsilon' = 1$, is the PML dielectric constant. For a y -independent PML configuration such as that in Fig. 1 we obtain, for propagating wave-mode solutions of Eqs.(1),

$$\begin{aligned} \frac{d}{dx} E_y \left(\frac{1}{1 - j\sigma/\omega\epsilon_0} \right) &= -j\omega\mu_0 \cos^2 \theta H_z \\ \frac{d}{dx} H_z \left(\frac{1}{1 - j\sigma/\omega\epsilon_0} \right) &= -j\omega\epsilon_0 E_y \end{aligned} \quad (2)$$

where E_y and H_z are the x -dependent parts of the electric and magnetic field components \mathcal{E}_y and \mathcal{H}_z , respectively, and θ is the propagation angle associated with the propagating wave-mode considered. Next we finite-difference Eqs.(2) while adopting the notation in Fig. 1, obtaining

$$\begin{aligned} E_y^{n+1/2} &= E_y^{n-1/2} + (j\omega + \sigma_{2n}/\epsilon_0)\mu_0\Delta \cos^2 \theta H_z^n \\ H_z^n &= H_z^{n-1} + (j\omega + \sigma_{2n-1}/\epsilon_0)\epsilon_0\Delta E_y^{n-1/2} \end{aligned} \quad (3)$$

¹The configuration in Fig. 1 is TE according to the standard convention wherein the z -axis in Fig. 1 is the reference axis (since 2-D objects associated with Fig. 1 are z -independent). We refer to it as 'TM' to avoid confusion with the mode notation of a parallel plate waveguide configuration to be used later on.

Fig. 1. PML and incident TM wave in 2-D.

for $n = 1, 2, \dots, N$. Any PML analysis based on Eqs.(2,3) can only approximate the numerically-measured value of Γ since Eq.(2) assumes waves with y -dependence $e^{\pm jk \sin \theta y}$ where $k = \omega\sqrt{\mu_0\epsilon_0}$, which are only approximated in the 2-D finite-difference (FD) solution. In particular, Eqs.(3) yield an *approximate* (yet useful) expression for the PML's reflection coefficient Γ , to be discussed next. Numerical FDFD and FDTD experiments are discussed at the end of this section which confirm our model's validity for the purposes of the present study.

By defining the normalized transverse impedance $\eta_n \equiv (E_y^{n-1/2}/H_z^{n-1})/\eta_o$ of one PML layer relative to that of the subsequent layer, where $\eta_o = \sqrt{\mu_0/\epsilon_0}$, one obtains from Eqs.(3)

$$\eta_{n+1} = (j\bar{k} + S_{2n}) \cos^2 \theta + \frac{1}{j\bar{k} + S_{2n-1} + 1/\eta_n} \quad (4)$$

where we have introduced the unitless quantities $\bar{k} \equiv k\Delta$ (the normalized phase constant) with $k = \omega\sqrt{\mu_0\epsilon_0}$ and $S_i \equiv \sigma_i\eta_o\Delta$ (the normalized i^{th} half-layer decay rate). Unless otherwise stated, we will consider perfect magnetic conductor (PMC) loading, $H_z^0 = 0$, so that $\eta_1 = \infty$. In order to obtain an approximate expression for Γ , we compute next the *numerical* transverse free space impedance Z_o defined, following Eq.(4), via

$$Z_o = j\bar{k} \cos^2 \theta + \frac{1}{j\bar{k} + 1/Z_o}, \quad (5)$$

i.e.,

$$Z_o = \frac{2}{-j\bar{k} + \sqrt{-\bar{k}^2 + 4(\cos \theta)^2}} = \cos \theta e^{j \sin^{-1}(\bar{k} \cos \theta/2)} \quad (6)$$

(Z_o is normalized relative to η_o). Termination of a free space FD grid with Z_o (e.g., $\eta_1 = (E_{1/2}/H_0)/\eta_o = Z_o$ in the equations above, with $S_i = 0, i = 1, 2, \dots$) results in a *measured* standing-wave-ratio SWR = 1. Thus, Z_o is the free space impedance in FDFD (again, as described by the model FD equations (3)).

We can now use Eqs.(4,6) to approximate Γ by

$$\Gamma \simeq \frac{\eta_{N+1} - Z_o}{\eta_{N+1} + Z_o}. \quad (7)$$

Z_o behaves like $\cos \theta e^{j\bar{k} \cos \theta/2}$ at low frequencies ($\bar{k} \ll 1$) but its phase differs from the theoretical value for a continuum, $\bar{k} \cos \theta/2$, by about 2% for $\bar{k} = 2\pi/10$ at $\theta = 0$. The additional phase is a consequence of dispersive effects of discretization: It was shown in [8] (see Eq.(2.19), pp. 24) that for a 1-D free space FD grid

$$\omega\sqrt{\mu_0\epsilon_0}\Delta/2 = \sin(\kappa\Delta/2) \quad (8)$$

where $\kappa (\neq k = \omega\sqrt{\mu_0\epsilon_0})$ is the wavenumber in the FD model (i.e., Eq.(8) is the discretization-corrected dispersion relation). Eq.(8) applies to our framework with the substitution $\bar{k} \rightarrow \bar{k} \cos \theta$ (and $\bar{\kappa} \rightarrow \bar{\kappa} \cos \theta$) and thus the discretization-corrected phase-shift between adjacent E- and H-field points in one-way wave-propagation in free space is $\sin^{-1}(\bar{k} \cos \theta/2)$, which is the result in (6).

To examine the validity of the model above we used both FDFD and Fourier-transformed FDTD data. Fig. 2 shows plots of $|\Gamma|$ versus θ and parameterized by various values of \bar{k} for an 8-layer PML proposed in [2]: $\sigma_f = 0.018/\Delta$ and $p = 3.7$. The figure shows data points for $|\Gamma|$ as measured in (2-D) FDFD (using the measured SWR) for a parallel plate waveguide excited by single TM modes and terminated by an x -normal PML with PEC-wall termination. The TM mode corresponding to $\theta = 0$ is the TEM mode. For given TM mode, θ and ω , the transverse waveguide dimensions are given by well known formulas (see [9], pp. 287-290) and can be used to compute other operational parameters [9]. Also shown are values of $|\Gamma|$ corresponding to Fourier-transformed FDTD data. In contrast to the FDFD results – all of which involve a parallel plate waveguide grid – our FDTD simulations correspond to transient plane-wave propagation in a (2-D) PML-terminated free space grid (time-gating was used to isolate the PML reflections). In particular, our FDTD simulations were used to measure the PML response to an incident, wide-band Gaussian pulse of the form $e^{(x-ct)^2/W^2}$ with $c = 1/\sqrt{\mu_0\epsilon_0}$, $W = 6\Delta$ and Courant number $r = c\Delta t/\Delta = 0.08$ (see also [2]). In addition, Fig. 2 provides data points for the reflection coefficient as measured in the time-domain (FDTD) by the ratio of the peak amplitudes of the reflected and incident wave-pulses. The results based on Eqs.(4,6,7) (solid lines labeled $\bar{k} = 2\pi/10$ and $\bar{k} = 2\pi/100$) are seen to follow closely those of FDFD and Fourier-transformed FDTD simulations (the FDFD $|\Gamma|$ -values for $\bar{k} = 2\pi/25$ also agree with Eqs.(4,6,7) (results not shown for clarity)). Those associated with the continuum analog of formula (7) (curves marked with a triangle) differ visibly from the FDFD and Fourier-transformed FDTD results for non-grazing incidence and high \bar{k} (they behave well only for low \bar{k} and high θ (values for $\bar{k} = 2\pi/100$ marked with a small +), as expected (inter-grid phase-shift is then negligible)). Other profiles were studied in a similar fashion and analogous results were obtained where model predictions based on Eqs.(4,6,7) were consistent with FDTD and FDFD reflection coefficient measurements. We may now proceed with confidence to use Eqs.(4,6,7) as design tools in the search for optimum σ coefficients.

Fig. 2. Reflection coefficient results for PML- σ profile in [2].

III. RESULTS AND DISCUSSION

Using the PML-model in Sec. II, an automated search for optimum values of σ_f and p for an N -layer PML profiled via $\sigma_i = \sigma_f \left(\frac{2N-i+1}{2N} \right)^p$, $i = 1, 2, \dots, 2N$ ($i = 2N$ for the half-layer at the free space/PML interface) was carried out both for fixed \bar{k} (CW case) and for $2\pi/100 \leq \bar{k} \leq 2\pi/10$ (broadband case). We considered the cost function $F = \int_{\text{BW}} d\omega \int_0^{\theta_{\max}} d\theta \log_{10} [1 + |\Gamma(\theta, \omega)|]$ defined in Sec. I, where BW is the relevant bandwidth, as well as the L^2 norm of $|\Gamma(\theta, \omega)|$, $R = \int_{\text{BW}} d\omega \int_0^{\theta_{\max}} d\theta |\Gamma(\theta, \omega)|^2$, i.e., the energy reflection coefficient for bandwidth BW averaged over the relevant θ -range, where, e.g., $\theta_{\max} = 65$ or 75° . The later characterization applies to both frequency and time domains. It turns out that for low $|\Gamma|$ (e.g., in the vicinity of the optimized solution) $F \approx \int_{\text{BW}} d\omega \int_0^{\theta_{\max}} d\theta |\Gamma(\theta, \omega)|$ (the L^1 or area norm); it follows that (σ_f, p) -searches based on F and R should yield similar results.

Table I summarizes the results of the search for an 8-layer PML, obtained using both F and R and for $\theta_{\max} = 65$ and 75° . The (σ_f, p) -values in Table I correspond to absolute minima of F and R in $10^{-3} \leq \sigma_f \leq 10^3$ and $0 \leq p \leq 7$ (values obtained via exhaustive numerical search). The search reveals the need for σ -profiles that are low enough to minimize discretization and material-contrast reflections at close-to-normal incidence while being also strong enough to absorb waves propagating at close-to-grazing angles. For example, we see that the best σ -profiles for $\theta_{\max} = 65^\circ$ are consistently lower than for $\theta_{\max} = 75^\circ$. This results in reduced reflections in the small θ region in the $\theta_{\max} = 65^\circ$ case. Besides, the $\theta_{\max} = 75^\circ$ case demands higher σ to enhance wave attenuation in the large θ region $65^\circ \leq \theta \leq 75^\circ$. The results of broad-band optimization are in between those of low- and high-frequencies, as expected. Remarkably, the broad-band case optimization with $\theta_{\max} = 75^\circ$ yielded a σ -profile very similar to that reported in [2] and obtained from wide-band and wide propagation-angle FDTD simulations (the same profile used in Sec. II, i.e., $\sigma_f = 0.018/\Delta$ and $p = 3.7$). We also note that there is little variation among the optimum (σ_f, p) -values corresponding to various values (ranges) of \bar{k} due to the broadband

nature of the PML. Furthermore, we have found by numerical experiments that $|\Gamma|$ varies little with \bar{k} for $\bar{k} \lesssim 2\pi/50$; hence, our results for $\bar{k} = 2\pi/100$ represent well the PML's low frequency behavior.

TABLE I
SUMMARY OF OPTIMIZATION RESULTS

Cost Function	\bar{k}	θ_{\max}	$\sigma_f \Delta$	p
F	$2\pi/10$	75°	0.019	3.49
R	$2\pi/10$	75°	0.018	3.51
F	$2\pi/100$	75°	0.026	3.71
R	$2\pi/100$	75°	0.026	3.72
F	$2\pi/10 - 2\pi/100$	75°	0.022	3.65
R	$2\pi/10 - 2\pi/100$	75°	0.021	3.65
F	$2\pi/10$	65°	0.014	3.47
F	$2\pi/100$	65°	0.020	3.82
F	$2\pi/10 - 2\pi/100$	65°	0.016	3.73

Fig. 3 shows plots of $|\Gamma|$ vs θ and parameterized by various values of \bar{k} for an 8-layer PML with $\sigma_f = 0.019/\Delta$ and $p = 3.49$ (optimum coefficients for $\bar{k} = 2\pi/10$ and $\theta_{\max} = 75^\circ$). Fig. 4 shows analogous results for $\sigma_f = 0.026/\Delta$ and $p = 3.71$ (optimum coefficients for $\bar{k} = 2\pi/100$ and $\theta_{\max} = 75^\circ$). The values of $|\Gamma|$ in the figures were calculated from the measured SWR in FDTD simulation of a parallel plate waveguide excited by single TM modes and terminated by an x -normal PML with PEC-wall termination (the same configuration outlined in connection with Fig. 2). The broadband time-domain performance of $\sigma_f = 0.022/\Delta$ and $p = 3.65$ (results not shown) is similar to that reported in [2] for $\sigma_f = 0.018/\Delta$ and $p = 3.7$. Figs. 3 and 4 show that, for fixed normalized decay rate profile $S_i = \sigma_i \eta_0 \Delta$ and as function of \bar{k} alone, PML performance tends to degrade with increasing \bar{k} as a consequence of discretization (cf. Eq.(4) and associated discussion). The PML performance at grazing incidence is, on the other hand, less sensitive to discretization (since $\bar{k} \cos \theta \rightarrow 0$ as $\theta \rightarrow \pi/2$); the latter effect is also apparent in Figs. 3 and 4. We see that large-angle PML performance improves noticeably for low-frequency optimal profiles (compare results in Fig. 4 to those in Fig. 3) due to reduced optimization-constraints deriving from discretization effects at small θ . When compared to its high-frequency counterpart, the low-frequency-optimized PML design has, thus, higher conductivity, which improves large θ decay rate. For the same reason, however, the $|\Gamma|$ -values for $\bar{k} = 2\pi/25$ at $\theta < 50$ are visibly worse in Fig. 4 than in Fig. 3 (the low-frequency design is too aggressive). The results shown in Fig. 3 are comparable but slightly better than those for $\sigma_f = 0.018/\Delta$ and $p = 3.7$ (see Fig. 2) at the same \bar{k} . Finally, the best PML performance in Fig. 4 (at $\bar{k} = 2\pi/100$) is somewhat better than the best PML performance in Fig. 3 (at $\bar{k} = 2\pi/25$).

Fig. 5 summarizes optimization results for other values of N (in the 0-to- 75° angular range). Similar (σ_f, p) -behavior with N was reported in [5] for normal-incidence PML performance. For 16 layers, we have found that, for the optimum σ -profiles shown, $|\Gamma|$ ranges from -150 to -180 dB for $\bar{k} = 2\pi/100$ and from -130 to -160 dB for $\bar{k} = 2\pi/10$

Fig. 3. $|\Gamma|$ vs θ for $\sigma_f \Delta = 0.019$ and $p = 3.49$.

Fig. 4. $|\Gamma|$ vs θ for $\sigma_f \Delta = 0.026$ and $p = 3.71$.

and the range $\bar{k} = 2\pi/10$ - $2\pi/100$. The figures above correspond to the 0-to-75° angular range.

Finally, the same procedure can be applied to σ -profiles of other forms. For example, next we used the PML-model and performance measures above to search for PML σ -profiles of the form $\sigma_i = \sigma_f^a \left(\frac{2N-i+1}{2N}\right)^{p^a} + \sigma_f^b \left(\frac{2N-i+1}{2N}\right)^{p^b}$. An extensive numerical search based on the cost function F for $N = 8$, $\bar{k} = 2\pi/100$ and $\theta_{\max} = 75^\circ$ with integer p^a and p^b yielded $p^a = 2$, $\sigma_f^a \Delta = 0.0018$, $p^b = 4$ and $\sigma_f^b \Delta = 0.0265$. Plots of $|\Gamma|$ vs θ corresponding to this σ -profile for $\bar{k} = 2\pi/25$ and $\bar{k} = 2\pi/100$ are shown in Fig. 6. The performance of this PML is a little better than that obtained with two search-parameters (i.e., σ_f, p) (compare results in Fig. 6 with those of Fig. 4, both of which correspond to optimization at $\bar{k} = 2\pi/100$). For $\bar{k} = 2\pi/100$, we note improvement of about 10 dB at $\theta = 60^\circ$ and of 2 dB at $\theta = 75^\circ$ with respect to the profile in Fig. 4. On the other hand, for $\bar{k} = 2\pi/25$, $|\Gamma|$ -values for $\theta \leq 30^\circ$ in Fig. 6 are 1 dB lower than in Fig. 4 while for $\theta > 30^\circ$, $|\Gamma|$ -values in Fig. 6 are 2 or more dB below those in Fig. 4. Thus, it appears that there is a limit to PML performance near our optimized solutions (for the number of PML layers considered, $N = 8$). It is expected that for larger N , the increase in number of σ -profile parameters will have greater impact. This subject will be addressed elsewhere.

Despite its simplicity (relative to PML descriptions including 2- and 3-D discrete dispersion [8]), our 1-D based PML performance predictor (i.e., Eqs.(4,6,7)) has been found to work well in connection with 2-D FDFD and FDTD simulations, yielding a powerful tool for PML optimization. The sought-after PML- σ profiles were found

Fig. 5. $\sigma_f \Delta$ and p versus N for $\bar{k} = 2\pi/10, 2\pi/100$ and the range $2\pi/10$ - $2\pi/100$.

Fig. 6. $|\Gamma|$ vs θ for $\sigma_f^a \Delta = 0.0018$, $p^a = 2$, $\sigma_f^b \Delta = 0.0265$ and $p^b = 4$.

to exhibit better CW and/or broad-band and wide-angle performance than the best reported values to date [2]. The optimal σ -profiles reported in the paper were found to be consistent with optimal σ -profile recipes proposed in [3] and [5] for the normal-incidence case. As expected, our PML designs were, however, more aggressive (larger σ) in order to accommodate for large-angle performance which was not addressed before.

IMPLEMENTATION OF A TWO DIMENSIONAL PLANE WAVE FDTD USING ONE DIMENSIONAL FDTD ON THE LATTICE EDGES

Scott C. Winton and Carey M. Rappaport
Center for Electromagnetics Research
Northeastern University
Boston, MA 02115

Abstract Development and testing of angle independent absorbing boundary conditions (ABCs) can be improved by simulating waves incident on the ABC at a single angle. By using one-dimensional Finite Difference Time Domain (FDTD) as the lattice side edge condition, the creation and numerical propagation of a two dimensional plane wave with arbitrary incident angle is possible. The application and extent of usefulness of the method are examined and extensions to increase the range of usefulness are introduced.

I. INTRODUCTION

Until recently, the use of the FDTD method for numerical solutions of electromagnetic scattering problems was severely hampered by the poor performance of absorbing boundary conditions used to prevent reflections of EM waves at the lattice edges. With the advent of the Berenger Perfectly Matched Layer[1], this problem has been significantly reduced and the computational efficiency of FDTD problems has been significantly improved.

Understandably, this has created considerable interest in improving and optimizing the PML and angle-independent ABCs as a whole. But this effort has been impaired by the fact that commonly used excitations, such as point or line sources, generate waves incident on the ABC at all angles. This complicates the analysis of the performance of the ABC and impairs design optimization. The problem is ameliorated by introducing plane wave sources incident on the ABC at a single angle. With such an excitation, the performance of the ABC is clearly defined. However, because of the difficulty in dealing with propagation on the lattice edge, the creating and propagating such a wave is difficult.

For a two-dimensional FDTD simulation using the standard Yee cell formulation[2], the update of a given spatial grid point requires data from the four adjacent grid points. Clearly this creates a problem at the lattice edges. Typically, in scattering simulations, a Mur total/scattered field region separation avoids the need to calculate incident waves on the edges[3]. However, to test ABCs, the incident wave must be a uniform plane wave without deformations along the edge. ABCs cannot be used at these edges since they fail for plane waves propagating at steep grazing angles. Furthermore, the values on the edges must not be specified analytically because the numerical values of the fields inside the discretized ABC under test are not known.

II. INTEGRATION OF ONE-DIMENSIONAL EDGE FDTD WITH A TWO-DIMENSIONAL GRID

For the following discussion, consider a two-dimensional grid on which a boundary value FDTD simulation will be run. The “front” of the grid is the source boundary value while the ABC to be tested is positioned at the “back”. What is desired is to create a plane wave with a phase front at an angle θ with respect to the front wall. For this discussion a transverse electric (TE) wave is considered. The x direction is front to back and the y direction is left to right as shown in Figure 1.

Instead of ABCs at the “left” and “right” edges, 1-D FDTD is used. The update of each spatial point on these edges will require data from only the grid points preceding and succeeding it. At each time step, information from this 1-D FDTD is passed to the larger 2-D FDTD to update spatial points adjacent to the left and right edges. If the wave is normally incident on the ABC, the formulation of the plane wave is quite simple. In this case, H_x is zero and both E_z and H_y are uniform left to right. Therefore, no information is obtained from the transverse difference and the calculations along each grid line running front to back reduces to as a 1-D FDTD algorithm. To illustrate this, consider the time harmonic Maxwell’s curl equations for TE waves in lossless media:

$$\frac{\partial E_z}{\partial y} = -j\omega\mu H_x \quad (1a)$$

$$\frac{\partial E_z}{\partial x} = j\omega\mu H_y \quad (1b)$$

$$\frac{\partial H_y}{\partial x} + \frac{\partial H_x}{\partial y} = j\omega\epsilon E_z \quad (1c)$$

These have the familiar (forward propagating) solutions:

$$E_z = E_o e^{-jk(x \cos \theta + y \sin \theta)} \quad (2a)$$

$$H_y = -\cos \theta \frac{E_o}{\eta} e^{-jk(x \cos \theta + y \sin \theta)} \quad (2b)$$

$$H_x = -\sin \theta \frac{E_o}{\eta} e^{-jk(x \cos \theta + y \sin \theta)} \quad (2c)$$

It is clear that for normal incidence, ($\theta = 0$), this becomes a TEM wave with no y dependence. Equations (1a) and (2c) become unnecessary and the 1-D FDTD and the 2-D FDTD calculations are identical.

The situation is more complicated when θ is nonzero. Now H_x is nonzero and the 1-D wave is no longer identical to the 2-D wave. In order for the 1-D FDTD simulation to supply the correct data to the 2-D grid, the 1-D wave must propagate with a velocity that keeps pace with the 2-D wave. This velocity is simply the phase velocity of the 2-D wave in the x direction, *i.e.* $v_{1D} = v_o / \cos \theta$, where v_o is the velocity of the 2-D wave in the direction θ . This is analogous to taking a slice along the right (or left) edge of the grid, of an infinite 2-D plane wave. Clearly this “slice” must travel along the edge with greater velocity than the the wave traveling an angle θ . Since the velocity, v_{1D} of this wave is given as $v_{1D} = \frac{\omega}{k_x}$, we can write Eq. (2) for the 1-D wave at $y = 0$ as:

$$E_{z_{1D}} = E_o e^{-jkx \cos \theta} \quad (3)$$

$$H_{y_{1D}} = -\cos \theta \frac{E_o}{\eta} e^{-jkx \cos \theta}$$

The solution in Eq.(3) does not satisfy Maxwell’s curl equations. This problem can be addressed by modifying Ampere’s Law. By taking the partial derivative of Eq.(2c) at $y = 0$ one obtains:

$$\frac{\partial H_x}{\partial y} = jk \sin^2 \theta \frac{E_o}{\eta} e^{-jkx \cos \theta},$$

which, using Eq.(2b) becomes

$$\frac{\partial H_x}{\partial y} = \frac{(1 - \cos^2 \theta) \frac{\partial H_y}{\partial x}}{\cos^2 \theta}.$$

Thus,

$$\frac{\partial H_y}{\partial x} + \frac{\partial H_x}{\partial y} = \frac{1}{\cos^2 \theta} \frac{\partial H_y}{\partial x}$$

Now Eq.(1), for the 1-D wave will become:

$$\begin{aligned} \frac{\partial E_{z1D}}{\partial x} &= j\omega\mu H_{y1D} \\ \frac{1}{\cos^2 \theta} \frac{\partial H_{y1D}}{\partial x} &= j\omega\epsilon E_{z1D} \end{aligned} \quad (4)$$

Having described the changes to Maxwell's equations needed to integrate the 1-D FDTD into the 2-D grid, it is worthwhile examining the discretization of the modified 1D curl equations.

III. DISCRETIZATION OF MODIFIED EQUATIONS AND STABILITY CONSIDERATIONS

Through a straight forward discretization process[4], the discretized 1-D modified Maxwell's curl equations for lossless media become;

$$\begin{aligned} E_i^{n+\frac{1}{2}} &= E_i^{n-\frac{1}{2}} + \frac{R}{\cos^2 \theta} \eta (H_{i+\frac{1}{2}}^n - H_{i-\frac{1}{2}}^n) \\ H_{i+\frac{1}{2}}^{n+1} &= H_{i+\frac{1}{2}}^n + \frac{R}{\eta} (E_{i+1}^{n+\frac{1}{2}} - E_i^{n+\frac{1}{2}}) \end{aligned} \quad (5)$$

where n is the time index, i is the space index and $R = v_o \Delta t / \Delta x$ is the Courant Number, and the vector component designations has been suppressed. Note that the velocity of the modified 1-D wave is $v_{1D} = \frac{v_o}{\cos \theta}$ as is apparent in the discretized wave equation based on Eq.(5).

Of particular importance is the Courant Number, R . Stability analysis indicates that for a FDTD simulation to be stable $R \leq 1$. For Equation (5), a new Courant number $R_{1D} = \frac{R}{\cos \theta}$ must be used instead. Since $R_{1D} \leq 1$, the usefulness of this method is limited to smaller angles. For example, let R_g be the Courant Number of the 2-D FDTD simulation. If R_g is chosen to be 0.5, then the largest angle that may be used is 60° . Clearly larger angles may be used if R_g is chosen to be smaller. However, since R_g is also a measure of how fast the wave moves through the grid, choosing it too small increases computational expense for the entire 2-D grid.

IV. LARGE ANGLE SOLUTIONS

For applicability with large propagation angles without decreasing R_g , changes must be made to the method. This is done by adjusting the Courant Number of the 1-D FDTD edge simulation. A smaller Courant number $R'_{1D} = v_o \Delta t' / \Delta x \cos \theta$ may be chosen such that $R'_{1D} \leq R_{1D}$. Since Δx remains the same, two simulations using R'_{1D} and R_{1D} would be spatially similar at the same physical time t , whenever $n' \Delta t' = n \Delta t$ for some different number of new time steps. The the stability condition is now $R'_{1D} \leq 1$ and thus θ may be increased.

Some care must be exercised in order to insure that the correct data is being passed to the 2-D grid. Let $m = \Delta t / \Delta t'$. If m is an integer ($= n' / n$), then the m^{th} iteration of the 1-D FDTD is used to update the 2-D interior of the grid. If m is not an integer, then the correct value of E_z on the

edge of the lattice must be interpolated with respect to time from two or more iterations of the 1-D FDTD and **then** supplied to the 2-D grid.

The interpolation process is quite straight forward, with emphasis given to insuring the correct timing. Assume the 1-D FDTD simulation has a time sample interval of $\Delta t'$ and the 2-D simulation has a time sample interval of Δt . To meet the above criteria, $\Delta t' \leq \Delta t$. In order to insure that interpolation, and not extrapolation, is being performed, the 1-D simulation must be performed until $n'\Delta t' \geq n\Delta t$. The number of previous time values that must be stored in order to perform the interpolation is equal to the order of interpolation desired. Increasing the order will increase accuracy, but since previous values must be stored for **every** point on the 1-D grid, the order should be kept as low as possible.

Once the values needed for interpolation have been identified and calculated, any standard interpolation algorithm, such as Lagrange Interpolation, can be used. After the interpolated edge E_z values have been calculated, they can then be supplied to the 2-D grid. The edge H_y values need not be interpolated.

V. FDTD SIMULATION RESULTS

Several experiments were performed using the methods described above using a variety of parameters. Excellent results were obtained for angles ranging from 0 to 85 degrees. The general method of each experiment was the same. A Gaussian pulse plane wave was created along the initial boundary at $x = 0$ with time variation corresponding to various propagation angles and with various values of R_g . In each of these experiments, the plane wave encounters a PML ABC at the back of the grid. The ABC in question is from [5] with 8 PML layers and conductivity profile $\sigma_i = \sigma_f(i/8)^{3.7}$. Figure 2a shows a 50×50 view sampled from a 200×200 grid. The propagation angle is 45° degrees and the Courant Number R_g is 0.5. Note that the wave propagates without edge distortion. Figure 2b is the same wave 200 time steps later. The wave has encountered the ABC and no reflection is visible, even in the lattice corner, where the 1-D FDTD accurately extends the 2-D ABC interaction calculation to the edge. In the scattered field view 2c, which is at the same time step as 2b, the magnification has been increased by 5 orders of magnitude and the incident field has been removed. The features to note are that the scattered wave satisfies Snell's law and that the scattered wave is uniform along the 45° angle, *i.e.*, the introduction of the 1-D FDTD on the right edge of the grid has not introduced any additional reflection artifacts. Figure 3a is once again a 50×50 view of a 200×200 grid. Here the Gaussian pulse plane wave is incident on the ABC at 70° . Once again R_g is 0.5 but now $R_g' = 0.25/\cos\theta$. The 1-D wave is traveling at one-half the velocity needed to keep pace with the 2-D wave, so only every second time sample is passed to the 2-D grid. Figure 3b is the same wave 150 time steps later. As with 45° wave, the interaction with the ABC has produced no visible reflection. Once again it may be noticed that the scattered wave, Figure 3c, obeys Snell's law and is uniform along the Snell angle. Clearly the visible reflection is due solely to the plane wave interacting with the ABC, which is the desired information.

VI. CONCLUSIONS

A method for testing angle-independent ABCs has been described. By using a one-dimensional FDTD simulation on the left and right edges of a two-dimensional grid, a plane wave incident on a ABC at the back edge of the grid at a single angle can be created and propagated. This method will greatly simplify the analysis of angle-independent ABC performance. The method has been tested using a Gaussian pulse plane wave with a variety of parameters and has been shown to give excellent results. Finally, since all of the desired information is found in the 1-D simulations, it can be concluded that the analysis of angle-independent ABCs may be carried out using only 1-D simulations.

Modeling Dispersive Soil for FDTD Computation By Fitting Conductivity Parameters

Carey M. Rappaport and Scott C. Winton
Center for Electromagnetics Research
Northeastern University
Boston, MA 02115

Abstract The electrical parameters of soils are strongly dependent on their type, physical characteristics, and electromagnetic excitation frequency. When numerically modeling soil for subsurface sensing simulation, it is particularly important to account for this dispersion. When computations are done in the time domain, this dispersion becomes problematic. Using a difference equation relation—and its corresponding Z -transform—to model dispersion between electric field and current leads to an approximation of complex conductivity in the form of a ratio of polynomials in Z^{-1} (where $Z = e^{j\omega t}$).

It is shown that if the real dielectric constant is held constant at an average value and conductivity only is matched with a single (2,2) Padé approximant $\sigma(f) = (b_0 + b_1 Z^{-1} + b_2 Z^{-2}) / (1 + a_1 Z^{-1} + a_2 Z^{-2})$, then the resulting propagation number $\beta(f)$ and decay rate $\alpha(f)$ will both closely match those corresponding to real soil measurements. In particular, a simple relation governing the frequency behavior of conductivity as a function of soil moisture and density is presented, allowing for the efficient numerical prediction of wave propagation in soils of varying environmental characteristics. Computed FDTD results for scattering in soil—with the computational lattice terminated with a “soil-tuned” PML absorbing boundary condition—clearly show the significance of media dispersion

This variant is nontrivial, since unlike with the frequency domain constitutive relation, electric flux and field are related by convolution in the time domain: $\mathbf{D} = \epsilon * \mathbf{E}$. The electric current is also a more complicated function of electric field in the time domain, since conductivity cannot merely be included as part of a complex permittivity.

The standard approaches to modeling dispersion in the FDTD method involve either recursively computing the convolution (as cleverly developed by Luebbers, *et. al.* [1]); or by approximating the frequency domain dispersive complex dielectric constant with a series of simple rational functions (Debye or Lorentz models) of $j\omega$ [2,3], and then by multiplying the constitutive relation by the denominator and inverse Fourier transforming the result into the time domain. While these methods are effective, they suffer from the limitations of numerical computation. Namely, that for good dispersive media modeling, higher-order, multiple-pole dielectric constant functions are necessary; but as the order of the function increases, so does the required storage of previous time field values for the entire grid, along with the sensitivity and numerical instability of the algorithm. In particular, to suit the conceptual elegance and simplicity of the FDTD method, it is important to keep the media model to at worst second-order. This presents a problem for the conventional complex dielectric constant models, which must accurately approximate both real and imaginary frequency dependencies simultaneously, using at most two poles.

I. INTRODUCTION

Recent interest in ground penetrating radar for locating and identifying buried waste, land mines, and excavation obstacles has motivated the development of advanced computational tools to simulate wave propagation in soil. In particular, the need exists to analyze ultra-wideband signals which might balance the trade-off between penetration depth and target resolution. Soil is a difficult medium to model since it is inhomogeneous, lossy, dispersive, and has an irregular surface boundary. For flexibility in predicting radar scattering from both metal and plastic targets buried in soil with rock inclusions and topped with vegetation, the Finite Difference Time Domain offers significant advantages over other standard computational techniques.

To include the effects of frequency-dependent conductivity and dielectric constant, a dispersive variant of the FDTD algorithm must be employed.

For certain types of media, however, it is possible to separate the modeling of real dielectric constant and conductivity. In both biological tissue and soil, for instance, the lossy dispersive wave propagation is governed almost entirely by the frequency-dependent conductivity. For these media, the real dielectric constant, though frequency-dependent, does not significantly affect either the real propagation constant β , nor the decay rate α [4]. As such, their electrical characteristics can be well-modeled with a constant relative permittivity ϵ' , and a second-order-in-frequency conductivity σ . Further, by modeling σ in terms of powers of the Z -transform variable Z^{-1} (which readily transform to time delays), the conversion of the generalized dispersive Ohm's Law $\mathbf{J}(Z) = \sigma(Z)\mathbf{E}(Z)$ to the time domain is particularly straightforward [5]. The problem addressed with this report is the specific selection of modeling parameters for a typical, well-studied soil, that simply and efficiently accounts for variations in density and moisture content.

MODELING PUERTO RICAN CLAY LOAM USING SECOND-ORDER CONDUCTIVITY

Arguably the most widely-cited soil measurement study is that of Hipp [6], which provides conductivity and real permittivity of San Antonio and Puerto Rican clay loam as a function of moisture (as a percent of dry weight) m , and density (g/cc) d , for the frequency range 30 to 3840 MHz. The method for developing the general second-order conductivity soil model is based on this experimental data set. While other soils will have different electrical characteristics, it is expected that general trends will be similar to that of Puerto Rican clay loam. Also, because of the wide variety of soils, and the difficulty in obtaining carefully generated soil measurements, every attempt was made to keep the model parameters as simple as possible, with mostly linear dependence on their physical characteristics.

First, to maintain easy conversion to time domain it is essential that the conductivity for all moisture and density cases have the form:

$$\sigma(Z) = \frac{J(Z)}{E(Z)} = \frac{b_0 + b_1 Z^{-1} + b_2 Z^{-2}}{1 + a_1 Z^{-1} + a_2 Z^{-2}} \quad (1)$$

The b_i and a_i coefficients will each be independent functions of m and d . The actual measured values of conductivity correspond to the real part of $\sigma(Z)$, with $Z = e^{j2\pi f \Delta t}$, for FDTD time step Δt . The imaginary part, divided by $j2\pi f \epsilon_0$ adds to the frequency-independent dielectric constant ϵ' . In the time domain, Eqn. (1) becomes:

$$\mathbf{J}^n + a_1 \mathbf{J}^{n-1} + a_2 \mathbf{J}^{n-2} = b_0 \mathbf{E}^n + b_1 \mathbf{E}^{n-1} + b_2 \mathbf{E}^{n-2} \quad (2)$$

and Ampere's Law, as usual, is given by:

$$\nabla \times \mathbf{H}^{n+1/2} = \epsilon_0 \epsilon' \frac{\mathbf{E}^{n+1} - \mathbf{E}^n}{\Delta t} + \frac{\mathbf{J}^{n+1} + \mathbf{J}^n}{2} \quad (3)$$

In a previous publication [7], the best coefficients for Puerto Rican clay loam were determined for each separate sample of moisture and density. Although useful from a numerical view, these coefficients are not very helpful for the practical problem of determining wave propagation for an intermediate soil condition. To address this difficulty, a more unified approach is developed.

For the various moisture and density cases measured in [6], the best modeling coefficient values of Eqn. (1) vary considerably. However, the denominator coefficients: a_1 and a_2 , only differ at most by about 15%. Choosing fixed values $a_1 = -1.6$ and $a_2 = .64$ and allowing variation of the b_i coefficients gives up a little accuracy but provides a more simple model. Instead of finding the values of b_i which minimize a non-linear cost function for each moisture/density case, the current modeling

method simply solves for b_1 , b_2 , and b_3 by setting the real parts of $\sigma(Z)$ in Eqn. (1) to the measured values, at three particular frequencies: 120, 960, and 3840 MHz. While this method arbitrarily emphasizes the fit at these frequencies, it avoids justifying what type of cost function to use. A least-squares cost function for normalized error in σ and ϵ' , for example, is not as precise as for normalized error in the real and imaginary parts of the wave number $k = \beta - j\alpha$; and neither appropriately weighs the error on decaying wave amplitude across the frequency range.

The b_i coefficients for constant density and moisture levels $m = 2.5, 5, 10$, and 20 are first determined, and then fit to simple functions of m : $b_i \approx b_{i0} + b_{i1} \log m$. It was found that while a very good fit is possible for each b_i , the numerator of Eqn. (1) is small for low frequencies (where $Z \approx 1$), so that small errors in the b_i approximations lead to large errors in $\sigma(f)$. To avoid this cancellation problem, approximations are determined for b_1 , b_2 , and the sum $bs = b_0 + b_1 + b_2$, with the sum having the form $bs \approx bs_0 + bs_1 m + bs_2 m^2$. The resulting coefficients for $d = 1.2, 1.4$, and 1.6 are given in Table 1. The average dielectric constant chosen for these models is simply the measured value at 960 MHz. A quadratic least-squares fit to these data for each density, $\epsilon(m) = \epsilon_0 + \epsilon_1 m + \epsilon_2 m^2$ is given in Table 2.

Out[252]=

$$\sigma(z) = \frac{0.239297 + \frac{0.19435}{z} - \frac{0.432891}{z^2}}{1 + \frac{0.64}{z} + \frac{1.6}{z^2}}, \quad \text{Av. Diel. Const.} = 13.5$$

Figure 1 Complex conductivity, frequency-independent dielectric constant, wave propagation number, decay rate, and normalized error, as a function of log frequency, for conductivity model (—), and measured (· · ·) data for a) $m = 2.5\%$, and b) $m = 20\%$.

α of the model and the measured values of Puerto Rican clay loam as a function of frequency for the entire measured frequency range 30 to 3840 MHz. Also shown in the inserts are the fractional errors $\Delta\beta/\beta$ and $\Delta\alpha/\alpha$. The agreement is surprisingly good for such a simple model across two decades of frequency. It should be noted that the fit is even better for the intermediate moisture values 5 and 10%, and similar for the other density cases.

SOIL-TUNED PML ABC

With all FDTD scattering problems, it is necessary to minimize reflections from the lattice boundaries with absorbing boundary conditions (ABC). A novel ABC, the "soil-tuned" Perfectly Matched Layer (PML), has been developed. The soil-tuned PML is a modified version of the Berenger ABC [8,9] which specifically absorbs waves incident from dispersive media. Since the efficiency of transmission of waves into the PML is dependent on the closeness of match of the transverse wave impedance on both sides of the layer, it is essential to select the electrical parameters of the PML appropriately. For soil parameters ϵ'_{soil} , σ_{soil} , μ'_{soil} , the desired impedance match condition is:

$$\begin{aligned}\eta_{\text{soil}} &= \sqrt{\frac{\mu'_{\text{soil}}\mu_0}{(\epsilon'_{\text{soil}} - j\sigma_{\text{soil}}/\omega\epsilon_0)\epsilon_0}} \\ &= \sqrt{\frac{\mu'_{\text{soil}}\mu_0(1 - j\sigma_P/\omega\epsilon_0)}{(\epsilon'_{\text{soil}} - j\sigma_{\text{soil}}/\omega\epsilon_0)\epsilon_0(1 - j\sigma_P/\omega\epsilon_0)}} \quad (4) \\ &= \eta_{\text{PML}}\end{aligned}$$

where σ_P is the usual increasing conductivity profile of the PML layer. While the relations of Eqn. (4) correspond to the transverse impedance only for normal incidence on the PML layer, the split-field or auxiliary equation PML formulation ensure impedance match for all incidence angles, provided a match occurs for normal incidence.

Eqn. (4) therefore specifies the effective dielectric constant and conductivity in the PML layer,

$$\begin{aligned}\epsilon'_{\text{PML}} &= \epsilon'_{\text{soil}} \\ \mu'_{\text{PML}} &= \mu'_{\text{soil}} \\ \sigma_{\text{PML}} &= \sigma_{\text{soil}} + \epsilon'_{\text{soil}}\sigma_P \\ \sigma_{\text{PML}}^m &= \sigma_P\mu_0/\epsilon_0\end{aligned} \quad (5)$$

where the double conductivity term $-\sigma_{\text{soil}}\sigma_P/(\omega\epsilon_0)^2$ is neglected as negligible compared to ϵ'_{soil} for all but the largest PML conductivity layers. If σ_{soil} were frequency independent, Eqn. (5) would provide constant constitutive parameters for the PML equations which could be used directly in the time domain. Since σ_{soil} is dispersive, however, the PML equations must make use of the auxiliary difference

Eqn. (2), with b_i coefficients in Eqn. (1) adjusted to account for the new conductivity values of Eqn. (5c). The soil-tuned PML can be thought of a modification of the dispersive media calculation with split fields and magnetic loss.

NUMERICAL TEST CASE

Using the formula derived in the above section to specify the electrical characteristics of Puerto Rican clay loam with density 1. g/cc, and 10% moisture, a 2-dimensional FDTD calculation simulating plane wave scattering from a buried one wavelength diameter circular metal cylinder was performed. The geometry of the scattering lattice is shown in Figure 2. The lattice is oversized in width, 500 grid points, to prevent reflections from the sides, and is terminated with an 8-cell soil-tuned PML, to prevent reflections from the back lattice boundary. A 0.96 GHz modulated, gaussian envelope plane wave is initiated along the front grid boundary. One-dimensional FDTD calculations on the left and right edges ensure that the plane wave propagates from front to back without distortion. The time and space steps used are $\Delta t = 20$ ps and $\Delta x = 4.6$ mm, the nominal phase velocity is $v = c/\sqrt{\epsilon'} = .383c$, and the Courant number is held at 0.5.

Figure 2 Geometry of the scattering problem

The four surface plots of Figure 3 show the electric field distribution across the central 200 by 200 grid point section of the computational grid (indicated in Figure 2) at various times. The upper left and right plots show the total and scattered field as the incident wave begins scattering from the circular cylinder. The lower two plots show scattered field 100 and 300 time steps later. The scattering is symmetric, as expected. For the 1100 Δt plot, the residual reflections from the PML ABC, at $x = 100$, are visible. The amplitude of these reflections are of the order of 10^{-3} , which is about 3% of the field amplitude incident on the back boundary. Although

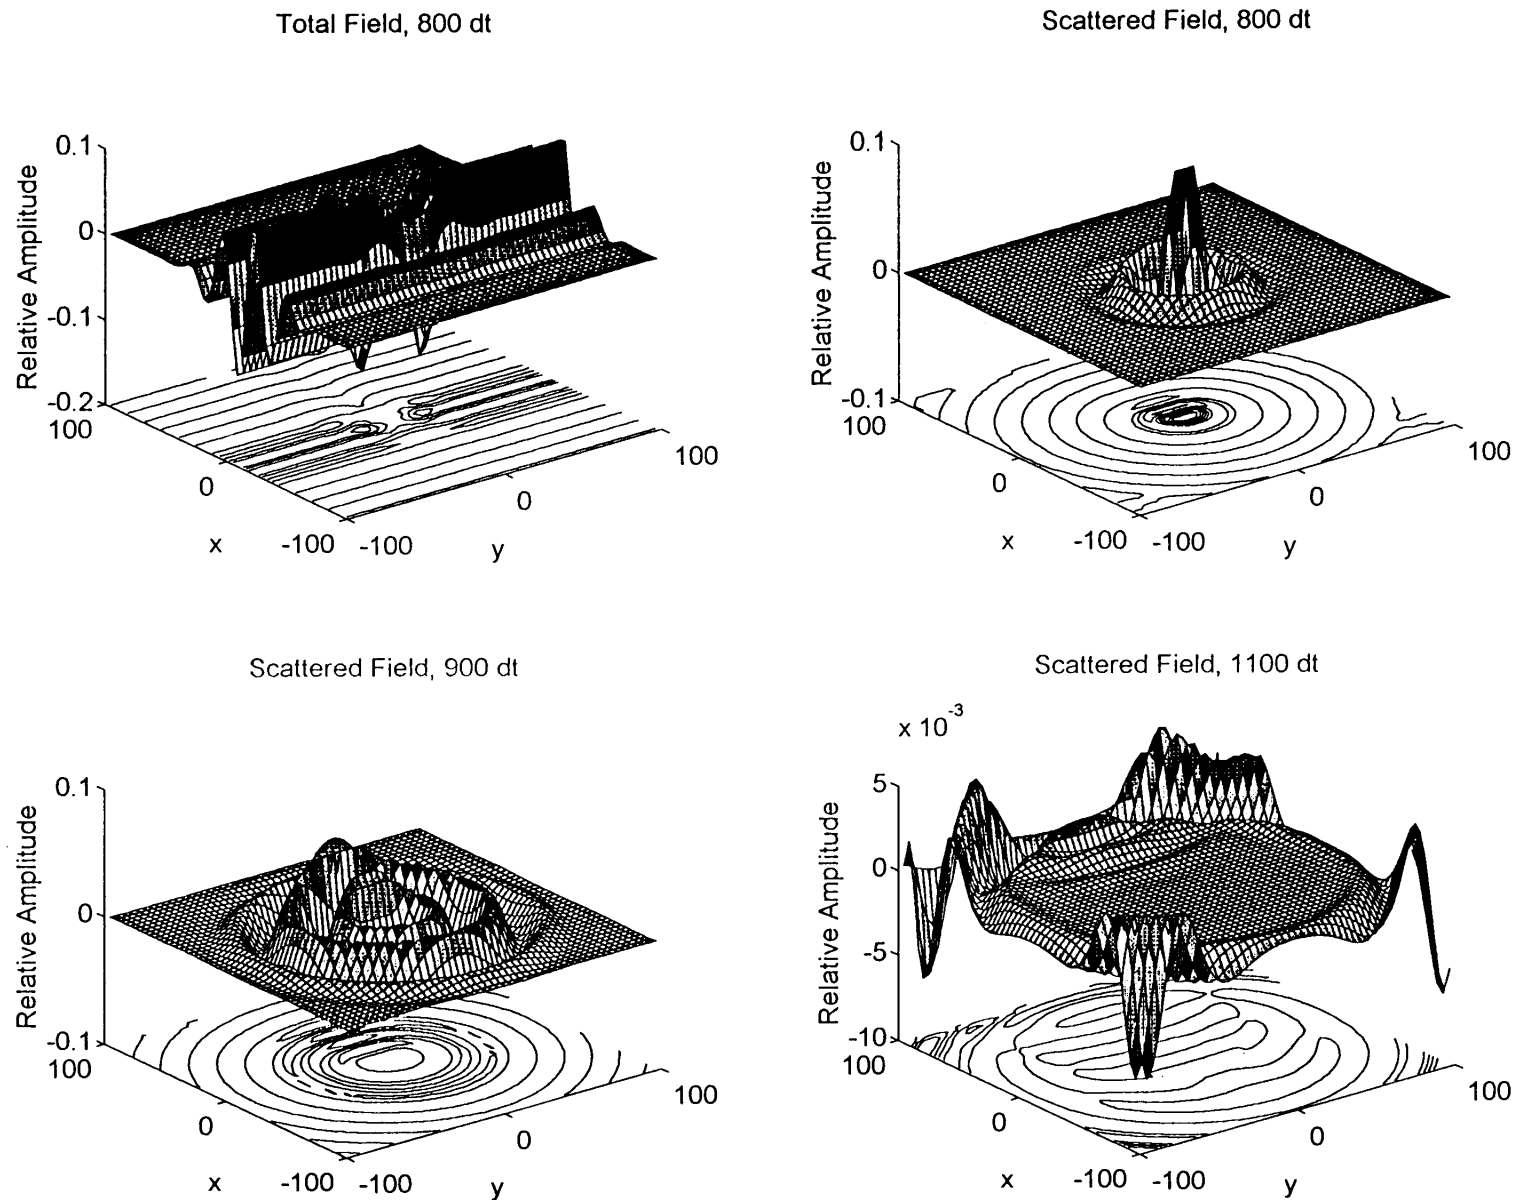

Figure 3 FDTD field plots simulating scattering by a perfectly conducting circular cylinder, surrounded by dispersive clay loam, $d = 1.4$, $m = 10\%$, with plane wave incidence.

still rather significant, the soil-tuned PML generates about one-half the reflections of generated by a conventional PML used to terminate this dispersive medium.

Figure 4 compares frequency independent and dispersive propagation, by showing the received signals at a single point ($R1$ in Figure 2) 150 grid points, directly in front of the circular scatterer. For the frequency independent case (left plots), the conductivity is kept constant at the measured value at 960 MHz, 0.032 S/m. The upper plots give the total field for the two cases, indicating only minor differences in the modulated plane wave propagation. It is interesting to note the much more significant differences in the lower, scattered field plots. In particular, the wave amplitude of the dispersive medium is twice that of the uniform conductivity case, the propagation speed is slightly different, and the higher frequencies have been attenuated—with only nine discernible maxima compared to ten in the uniform case.

CONCLUSIONS

A model of dispersive soil—with simple functional dependence on moisture and density—that can easily be adapted into the FDTD method has been developed. Based on a (2,2) Padé approximant in transform variable Z^{-1} , the model requires storing at most four additional arrays per time calculation. For simplicity, the model maintains constant denominator coefficients, with numerator coefficients being limited to a worst second order in moisture.

Also presented is a soil-tuned PML absorbing boundary condition, which is a modified variant of the PML used to terminate dispersive media lattices. In this new formulation, the PML constitutive parameters are adjusted to ensure transverse impedance matching with the dispersive medium. Its performance for soil is twice as good as the conventional PML.

Clearly, dispersion is important, and may have a greater effect in two or three dimensional scattering applications. Neglecting to model the frequency dependence of soil in wave propagation simulation can lead to significant errors. The current model simply and effectively approximates the dispersion for Puerto Rican clay loam through the entire 30 to 3840 MHz band.

A General Method for FDTD Modeling of Wave Propagation in Arbitrary Frequency-Dispersive Media

William H. Weedon, *Member, IEEE*, and Carey M. Rappaport, *Senior Member, IEEE*

Abstract— A general formulation is presented for finite-difference time-domain (FDTD) modeling of wave propagation in arbitrary frequency-dispersive media. Two algorithmic approaches are outlined for incorporating dispersion into the FDTD time-stepping equations. The first employs a frequency-dependent complex permittivity (denoted Form-1), and the second employs a frequency-dependent complex conductivity (denoted Form-2). A Padé representation is used in Z-transform space to represent the frequency-dependent permittivity (Form-1) or conductivity (Form-2). This is a generalization over several previous methods employing either Debye, Lorentz, or Drude models. The coefficients of the Padé model may be obtained through an optimization process, leading directly to a finite-difference representation of the dispersion relation, without introducing discretization error. Stability criteria for the dispersive FDTD algorithms are given. We show that several previously developed dispersive FDTD algorithms can be cast as special cases of our more general framework. Simulation results are presented for a one-dimensional (1-D) air/muscle example considered previously in the literature and a three-dimensional (3-D) radiation problem in dispersive, lossy soil using measured soil data.

I. INTRODUCTION

THE finite-difference time-domain (FDTD) technique is one of the most popular computational electromagnetic techniques for modeling time-domain wave propagation [1]. One of the advantages to using the FDTD technique is that all of the frequency components of the scattered field resulting from a broadband transmitted pulse may be computed simultaneously. The standard Yee FDTD algorithm [2] models inhomogeneous materials using spatially varying, but frequency-independent permittivity and conductivity. To model dispersive media, the standard Yee time-stepping equations need to be modified.

Several techniques have been introduced recently to incorporate frequency dispersion into FDTD models [3]–[17]. These dispersive FDTD algorithms have been shown to be important for computing optical pulse propagation [7], [11], predicting wave propagation in magnetized plasmas and in biological tissue [8], [14], [15]. One of our interests is in utilizing dispersive FDTD algorithms to model wave propagation in lossy, dispersive, inhomogeneous soils. This type of modeling is extremely useful for predicting the performance of ground-penetrating radar (GPR) systems in specified inhomogeneous environments, computing the electromagnetic fields scattered by various types of scattering objects such as buried waste drums, metallic or dielectric pipes, and pollution plumes, and for testing GPR detection and imaging algorithms with synthetic data.

The existing frequency-dependent FDTD methods can roughly be categorized into three types: 1) methods that efficiently implement a discrete convolution of the dispersion relation $D(\mathbf{r}, t) = \epsilon(t) * E(\mathbf{r}, t)$ [3], [4], [12]–[15]; 2) methods that discretize a differential equation relating $D(\mathbf{r}, t)$ to $E(\mathbf{r}, t)$ [5]–[9], [16]; and 3) Z-transform methods [10], [11]. The discrete convolution methods [3], [4] rely on either a Debye model involving single [3] or multiple [14] first-order poles, a Lorentz model utilizing second-order poles [4], or a Drude model [12], to implement the discrete convolution efficiently with a minimal storage requirement. The differential equation methods offer a more general representation for the dispersion relation, but they typically reduce to using either a Debye or Lorentz model [1]–[9]. One disadvantage of the differential equation method is that it is not clear which discretization formula to use (forward difference or backward difference) when high-order derivatives are involved [16]. In the Z-transform method proposed by Sullivan [10], [11], [17], a Debye or Lorentz dispersion model is converted to the time domain and sampled, a process analogous to impulse-invariance filter design in the signal processing literature.

Here, we present a more general approach for dispersive FDTD modeling, utilizing a Padé approximation of the complex frequency-dependent permittivity or conductivity in Z-transform space. This new method characterizes the dispersive medium as a bank of digital pole-zero infinite-impulse response (IIR) filters [18], which leads directly to FDTD implementations. The generation of appropriate filter functions

Fig. 1. Representation of a dispersion medium as a subwavelength spatial array of linear time-invariant filters.

for specific dispersive media is reduced to a digital-filter design problem, where both the magnitude and phase characteristics are specified.

Two new dispersive FDTD algorithms employing Padé approximations in Z-transform space are developed here. The first method, which we shall refer to as Form-1, utilizes a Padé model of dielectric permittivity $\epsilon(Z)$, while the second, Form-2, utilizes a Padé model of conductivity $\sigma(Z)$. We discuss some subtle differences between the two methods, particularly in terms of their stability and flexibility in fitting measured data.

The design problem of finding optimal filter coefficients to match measured permittivity and conductivity data, that result in stable, accurate FDTD algorithms is touched on briefly here, but shall be considered in more detail in a future paper.

II. DEVELOPMENT OF FORM-1 AND FORM-2 DISPERSIVE FDTD ALGORITHMS

Formulation of the dispersive FDTD algorithms begins with the assumption of a general inhomogeneous, isotropic, and causal dispersive medium. Throughout this paper, attention is restricted to the case of dispersive dielectrics, where we assume that $\mu = \mu_0$. All of the results, however, may be extended to the case of dispersive magnetic media in a straightforward manner.

If a volume V of the dispersive dielectric medium is divided into subwavelength cells of volume $\Delta_x \Delta_y \Delta_z$, as in Fig. 1, each subwavelength cell in the dispersive medium can be thought of as a linear time-invariant filter that acts on the electric field $\mathbf{E}(\mathbf{r}, t)$. The entire medium may be viewed as a spatial filter array, which can be implemented in two particular ways: 1) as a complex permittivity filter $\mathbf{D}(\mathbf{r}, Z) = \epsilon(\mathbf{r}, Z)\mathbf{E}(\mathbf{r}, Z)$ (Form-1 algorithm) or 2) as a complex conductivity filter $\mathbf{J}_c(\mathbf{r}, Z) = \sigma(\mathbf{r}, Z)\mathbf{E}(\mathbf{r}, Z)$ with constant real permittivity $\epsilon(\mathbf{r})$ (Form-2 algorithm).

A. Permittivity Filter (Form-1) Algorithm

In developing the permittivity filter (Form-1) algorithm, we include dispersion in the Maxwell equations as a frequency-dependent permittivity. In the time-domain Ampere law

$$\nabla \times \mathbf{H}(\mathbf{r}, t) = \frac{\partial \mathbf{D}(\mathbf{r}, t)}{\partial t} + \mathbf{J}_s(\mathbf{r}, t) \quad (1)$$

$\mathbf{J}_s(\mathbf{r}, t)$ represents a driving source current and

$$\mathbf{D}(\mathbf{r}, t) = \epsilon(\mathbf{r}, t) * \mathbf{E}(\mathbf{r}, t). \quad (2)$$

In (2), the frequency-dependent dispersion is represented as a temporal convolution of the electric field with a time-dependent permittivity. The convolution integral implied by (2) has limits $t = 0$ to $t = \infty$ since we consider only causal media and do not consider spatial dispersion. The vector \mathbf{r} in (2) is treated only as a parameter.

To derive the dispersive finite-difference algorithms, we first define the Z-transform of the temporal vector field

$$\mathbf{A}^n(\mathbf{r}) = \mathbf{A}(\mathbf{r}, t = n \Delta_t), \quad n = 0, 1, \dots, N_t - 1 \quad (3)$$

with $\mathbf{A}(\mathbf{r}, t)$ representing either $\mathbf{E}(\mathbf{r}, t)$, $\mathbf{H}(\mathbf{r}, t)$, $\mathbf{D}(\mathbf{r}, t)$, $\epsilon(\mathbf{r}, t)$, or $\sigma(\mathbf{r}, t)$ as¹

$$\mathbf{A}(\mathbf{r}, Z) = \Delta_t \sum_{n=0}^{\infty} \mathbf{A}^n(\mathbf{r}) Z^{-n}. \quad (4)$$

Equation (2) becomes

$$\mathbf{D}(\mathbf{r}, Z) = \epsilon(\mathbf{r}, Z)\mathbf{E}(\mathbf{r}, Z) \quad (5)$$

in Z-transform space.

The permittivity Z-transform function $\epsilon(Z)$ may be effectively modeled using a Padé approximation in Z; that is given in

$$\frac{\epsilon(\mathbf{r}, Z)}{\epsilon_0} = \frac{b_0(\mathbf{r}) + b_1(\mathbf{r})Z^{-1} + b_2(\mathbf{r})Z^{-2} + \dots + b_{N_b-1}(\mathbf{r})Z^{-(N_b-1)}}{1 + a_1(\mathbf{r})Z^{-1} + a_2(\mathbf{r})Z^{-2} + \dots + a_{N_a}(\mathbf{r})Z^{-N_a}}. \quad (6)$$

One major advantage to using a Padé approximation in Z is that such a dispersion relation leads directly to a finite-difference implementation.

Consider the one-dimensional (1-D) case of a plane wave (E_x, H_y) traveling in the z direction. The Form-1 dispersive FDTD algorithm may be summarized as follows:

$$H_{y,k}^{n+1/2} = H_{y,k}^{n-1/2} - \frac{\Delta_t}{\mu_0 \Delta_z} [E_{x,k+1/2}^n - E_{x,k-1/2}^n] \quad (7)$$

$$D_{x,k+1/2}^{n+1} = D_{x,k+1/2}^n - \frac{\Delta_t}{\Delta_z} [H_{y,k+1}^{n+1/2} - H_{y,k}^{n+1/2}] - \Delta_t J_{s,x,k+1/2}^{n+1/2} \quad (8)$$

$$E_{x,k+1/2}^{n+1} = \frac{1}{b_{0,k+1/2}} \left\{ \frac{1}{\epsilon_0} [D_{x,k+1/2}^{n+1} + a_{1,k+1/2} D_{x,k+1/2}^n + \dots + a_{N_a,k+1/2} D_{x,k+1/2}^{n+1-N_a}] - b_{1,k+1/2} E_{x,k+1/2}^n - b_{2,k+1/2} E_{x,k+1/2}^{n-1} - \dots - b_{N_b-1,k+1/2} E_{x,k+1/2}^{n+2-N_b} \right\} \quad (9)$$

¹The Δ_t factor [10], [11] in (4) allows us to approximate the continuous-time Fourier transform of $\mathbf{A}(\mathbf{r}, t)$ as

$$\mathbf{A}(\mathbf{r}, \omega) = \int_0^{\infty} dt \mathbf{A}(\mathbf{r}, t) e^{-j\omega t} \approx \mathbf{A}(\mathbf{r}, Z = e^{j\omega \Delta_t})$$

where we assume that $\mathbf{A}(\mathbf{r}, t) = 0$ for $t < 0$.

where the electric field E_x and flux density D_x are evaluated at $t = n \Delta_t$ and $z = (k + 1/2) \Delta_z$, and the magnetic field H_y is evaluated at $t = (n + 1/2) \Delta_t$ and $z = k \Delta_z$ on the staggered Yee grid. The two-dimensional (2-D) and three-dimensional (3-D) Form-1 dispersive FDTD algorithms may be derived in a similar manner.

B. Conductivity Filter (Form-2) Algorithm

For the conductivity filter (Form-2) algorithm, we rewrite Ampere's law (1) as

$$\nabla \times \mathbf{H}(\mathbf{r}, t) = \epsilon_0 \epsilon_r(\mathbf{r}) \frac{\partial \mathbf{E}(\mathbf{r}, t)}{\partial t} + \mathbf{J}_c(\mathbf{r}, t) + \mathbf{J}_s(\mathbf{r}, t) \quad (10)$$

where $\mathbf{J}_c(\mathbf{r}, t)$ represents an induced source current given by

$$\mathbf{J}_c(\mathbf{r}, t) = \sigma(\mathbf{r}, t) * \mathbf{E}(\mathbf{r}, t). \quad (11)$$

and $\mathbf{J}_s(\mathbf{r}, t)$ is again a driving source current. In (10), $\epsilon_r(\mathbf{r})$ is not time-dependent and, therefore, not dispersive. The dispersion is included only in the time-dependent conductivity $\sigma(\mathbf{r}, t)$. In Z-transform space, (11) becomes

$$\mathbf{J}_c(\mathbf{r}, Z) = \sigma(\mathbf{r}, Z) \mathbf{E}(\mathbf{r}, Z). \quad (12)$$

The conductivity Z-transform functions may be effectively modeled using a Padé approximation in Z

$$\sigma(\mathbf{r}, Z) = \frac{d_0(\mathbf{r}) + d_1(\mathbf{r})Z^{-1} + d_2(\mathbf{r})Z^{-2} + \dots + d_{N_d-1}(\mathbf{r})Z^{-(N_d-1)}}{1 + c_1(\mathbf{r})Z^{-1} + c_2(\mathbf{r})Z^{-2} + \dots + c_{N_c}(\mathbf{r})Z^{-N_c}}. \quad (13)$$

Discretizing (10) and, again, examining the 1-D case for brevity

$$\begin{aligned} E_{x,k+1/2}^{n+1} &= E_{x,k+1/2}^n \\ &- \frac{\Delta_t}{\epsilon_0 \epsilon_r, k+1/2 \Delta_z} [H_{y,k+1}^{n+1/2} - H_{y,k}^{n+1/2}] \\ &- \frac{\Delta_t}{\epsilon_0 \epsilon_r, k+1/2} J_{c,x,k+1/2}^n \\ &- \frac{\Delta_t}{\epsilon_0 \epsilon_r, k+1/2} J_{s,x,k+1/2}^{n+1/2}. \end{aligned} \quad (14)$$

The $J_{c,x,k+1/2}^{n+1/2}$ term can be obtained by the usual averaging of the conduction current at time steps n and $n+1$. In Z-transform space, the above becomes

$$\begin{aligned} E_{x,k+1/2} F_{k+1/2}(Z) &= - \frac{\Delta_t}{\epsilon_0 \Delta_z} [H_{y,k+1} - H_{y,k}] \\ &- \frac{\Delta_t}{\epsilon_0} J_{s,x,k+1/2} \end{aligned} \quad (15)$$

where

$$\begin{aligned} F_{k+1/2}(Z) &= \epsilon_r, k+1/2 (1 - Z^{-1}) \\ &+ \frac{\Delta_t}{2\epsilon_0} (1 + Z^{-1}) \sigma_{k+1/2}(Z). \end{aligned} \quad (16)$$

The rational function $F(\mathbf{r}, Z)$ may be written explicitly in the form

$$F(\mathbf{r}, Z) = \frac{e_0(\mathbf{r}) + e_1(\mathbf{r})Z^{-1} + \dots + e_{N_e-1}(\mathbf{r})Z^{-(N_e-1)}}{1 + c_1(\mathbf{r})Z^{-1} + c_2(\mathbf{r})Z^{-2} + \dots + c_{N_c}(\mathbf{r})Z^{-N_c}} \quad (17)$$

where $e_0 = \epsilon_r + (\Delta_t/2\epsilon_0) d_0$, $e_1 = \epsilon_r(c_1 - 1) + (\Delta_t/2\epsilon_0)(d_1 + d_0)$, \dots , $e_n = \epsilon_r(c_n - c_{n-1}) + (\Delta_t/2\epsilon_0)(d_n + d_{n-1})$, etc., and $N_e = \max\{N_c + 1, N_d\}$. Combining (15) and (17), the 1-D Form-2 dispersive FDTD algorithm is then

$$I_{x,k+1/2}^{n+1/2} = \frac{\Delta_t}{\epsilon_0 \Delta_z} [H_{y,k+1}^{n+1/2} - H_{y,k}^{n+1/2}] \quad (18)$$

$$\begin{aligned} E_{x,k+1/2}^{n+1} &= \frac{-1}{e_{0,k+1/2}} \left\{ I_{x,k+1/2}^{n+1/2} + c_{1,k+1/2} I_{x,k+1/2}^{n-1/2} \right. \\ &\quad + \dots + c_{N_c,k+1/2} I_{x,k+1/2}^{n+1/2-N_c} \\ &\quad + e_{1,k+1/2} E_{x,k+1/2}^n + e_{2,k+1/2} E_{x,k+1/2}^{n-1} \\ &\quad + \dots + e_{N_e-1,k+1/2} E_{x,k+1/2}^{n+2-N_e} \\ &\quad + \frac{\Delta_t}{\epsilon_0} [J_{s,x,k+1/2}^{n+1/2} + c_{1,s,x,k+1/2} J_{s,x,k+1/2}^{n-1/2} \\ &\quad \left. + \dots + c_{N_c,s,x,k+1/2} J_{s,x,k+1/2}^{n+1/2-N_c}] \right\} \end{aligned} \quad (19)$$

along with the discretized Faraday's law (7). The 2-D and 3-D dispersive algorithms follow in a similar fashion.

C. Comparison of Form-1 and Form-2 Algorithms

Comparing the Form-1 and Form-2 dispersive FDTD algorithms, it may at first appear that the choice of modeling complex permittivity $\epsilon(Z)$ versus complex conductivity $\sigma(Z)$ is merely definitional. However, there are significant differences in terms of stability² and their ability to model arbitrary dispersion functions.

Beginning with a permittivity function $\epsilon(\mathbf{r}, Z)$ of the form (6), and substituting (5) in (8), (8) may then be written in the form of (15) if we let

$$F_{k+1/2}(Z) = \frac{\epsilon_{k+1/2}(Z)}{\epsilon_0} (1 - Z^{-1}). \quad (20)$$

Then, equating (20) with (16), we find that $\epsilon(Z)$ and $\sigma(Z)$ are related by the bilinear³ form

$$\epsilon(Z) = \epsilon_0 \left[\epsilon_r + \frac{\Delta_t}{2\epsilon_0} \frac{(1 + Z^{-1})}{(1 - Z^{-1})} \sigma(Z) \right]. \quad (21)$$

²Stability relations for Form-1 and Form-2 algorithms are given in Section III. An air/muscle example is shown in Section V-B, whereby stability is improved by converting from a Form-1 to a Form-2 algorithm.

³Equation (21) may also be obtained from the continuous Maxwell equations in the Laplace transform (s) domain with the substitution $s = (2/\Delta_t) [(1 - Z^{-1})/(1 + Z^{-1})]$. This technique, known as the bilinear transform method, is commonly used in signal processing to convert analog filters to digital filters.

Equation (20) allows us to convert between Form-1 and Form-2 dispersive FDTD algorithms. Note, however, that (21) typically increases both the numerator and denominator polynomials by one degree, whether it is used to convert $\sigma(Z) \rightarrow \epsilon(Z)$ or $\epsilon(Z) \rightarrow \sigma(Z)$.

The Form-1 and Form-2 algorithms differ in their ability to match measured data with fixed-order polynomials in the numerator and denominator of $\epsilon(Z)$ and $\sigma(Z)$. This may be seen by examining their asymptotic properties. Setting $Z = e^{j\omega\Delta t}$ and examining the limit $\omega \rightarrow 0$, $\lim_{\omega \rightarrow 0} \Im m[\epsilon(Z)] = \omega \approx 0$ while $\lim_{\omega \rightarrow 0} \Re e[\sigma(Z)] = \text{Constant}$. The imaginary part of $\epsilon(Z)$ gives rise to an effective conductivity, which is zero in the dc limit. Many materials containing polar molecules, such as soil with any significant moisture content, have a nonzero dc conductivity. This finite dc conductivity may be modeled with a Form-1 algorithm with a pole on the real Z-axis, but is more naturally modeled with a Form-2 algorithm.

III. STABILITY CRITERIA

One of the most important considerations for a time-stepping algorithm such as the Form-1 and Form-2 dispersive FDTD algorithms is its stability. Stable physical phenomena can lead to unstable time-stepping algorithms, if algorithmic parameters are not set properly.

The stability formulas for the Form-1 and Form-2 dispersive FDTD algorithms are more complicated than the standard Yee algorithm due to the presence of the IIR filter arrays modeling $\epsilon(\mathbf{r}, Z)$ or $\sigma(\mathbf{r}, Z)$. As shown below, the stability formula is not determined by the poles of $\epsilon(Z)$ or $\sigma(Z)$ alone, but is complicated by the frequency of the wave component and the direction of wave propagation inside the FDTD grid. A similar stability analysis was presented recently for the differential equation methods employing the Debye and Lorentz formulas, although we derived our stability analysis independently.

For a homogeneous dispersive medium, the Ampere and Faraday laws may be written in Z-transform space as

$$\begin{aligned} E_{x,i,j,k+1/2}F(Z) &= \frac{\Delta t}{\epsilon_0} \left\{ \frac{1}{\Delta_y} [H_{z,i,j+1,k} - H_{z,i,j,k}] \right. \\ &\quad \left. - \frac{1}{\Delta_z} [H_{y,i,j,k+1} - H_{y,i,j,k}] \right\} \end{aligned} \quad (22)$$

$$\begin{aligned} (1 - Z^{-1})H_{y,i,j,k} &= \frac{\Delta t}{\mu_0} Z^{-1} \left\{ \frac{1}{\Delta_x} [E_{z,i+1/2,j,k} - E_{z,i-1/2,j,k}] \right. \\ &\quad \left. - \frac{1}{\Delta_z} [E_{x,i,j,k+1/2} - E_{x,i,j,k-1/2}] \right\} \end{aligned} \quad (23)$$

and similarly for the other field components. We now define the time-space transform, analogous to the temporal Z transform as

$$\tilde{H}_y(U, V, W, Z) = \sum_{m=1}^{N_i} \sum_{n=1}^{N_j} \sum_{p=1}^{N_k} H_{y,m,n,p}(Z) U^m V^n W^p \quad (24)$$

where (N_i, N_j, N_k) represent the number of space points in the FDTD lattice. The space-time transform of the other field components follow in a similar fashion. Equations (22) and (23) then become

$$\tilde{E}_x F(Z) = \frac{\Delta t}{\epsilon_0} \left[\frac{1}{\Delta_y} (V^{-1} - 1) \tilde{H}_z - \frac{1}{\Delta_z} (W^{-1} - 1) \tilde{H}_y \right] \quad (25)$$

and

$$(Z - 1) \tilde{H}_y = \frac{\Delta t}{\mu_0} \left[\frac{1}{\Delta_x} (1 - U) \tilde{E}_z - \frac{1}{\Delta_z} (1 - W) \tilde{E}_x \right]. \quad (26)$$

Similarly, we find that

$$(Z - 1) \tilde{H}_z = \frac{\Delta t}{\mu_0} \left[\frac{1}{\Delta_y} (1 - V) \tilde{E}_x - \frac{1}{\Delta_x} (1 - U) \tilde{E}_y \right]. \quad (27)$$

Substituting (26) and (27) into (25)

$$\begin{aligned} (Z - 1) \tilde{E}_x F(Z) &= \frac{\Delta_t^2}{\mu_0 \epsilon_0} \left[\frac{1}{\Delta_y^2} (V - 2 + V^{-1}) \tilde{E}_x \right. \\ &\quad + \frac{1}{\Delta_z^2} (W - 2 + W^{-1}) \tilde{E}_x \\ &\quad - \frac{1}{\Delta_x \Delta_y} (V^{-1} - 1)(1 - U) \tilde{E}_y \\ &\quad \left. - \frac{1}{\Delta_x \Delta_z} (W^{-1} - 1)(1 - U) \tilde{E}_z \right]. \end{aligned} \quad (28)$$

Equation (28) is essentially the time-space transform of the \hat{x} component of the vector wave equation. For a source-free homogeneous medium,⁴ $\nabla \cdot \mathbf{E} = 0$. Enforcing the divergenceless condition on the electric field, we can rewrite (28) as

$$\begin{aligned} (Z - 1) \tilde{E}_x F(Z) &= \frac{\Delta_t^2}{\mu_0 \epsilon_0} \left[\frac{1}{\Delta_x^2} (U - 2 + U^{-1}) + \frac{1}{\Delta_y^2} (V - 2 + V^{-1}) \right. \\ &\quad \left. + \frac{1}{\Delta_z^2} (W - 2 + W^{-1}) \right] \tilde{E}_x. \end{aligned} \quad (29)$$

Setting $\Delta_x = \Delta_y = \Delta_z$, we can rewrite the above as

$$(Z - 1)F(Z) = -4r^2 s^2 \quad (30)$$

where $r = \Delta_t / \Delta_z \sqrt{\mu_0 \epsilon}$ is the usual Courant number and

$$\begin{aligned} s^2 &= -\frac{1}{4} [(U - 2 + U^{-1}) + (V - 2 + V^{-1}) \\ &\quad + (W - 2 + W^{-1})]. \end{aligned} \quad (31)$$

From (24), the choice $U = e^{jk_x \Delta_x}$, $V = e^{jk_y \Delta_y}$, $W = e^{jk_z \Delta_z}$ corresponds to a plane wave with wave vector $\mathbf{k} =$

⁴Imposing the $\nabla \cdot \mathbf{E} = 0$ condition can also be justified by assuming plane wave propagation. If the FDTD algorithm is not stable for plane waves, the algorithm is not stable at all.

$\hat{x}k_x + \hat{y}k_y + \hat{z}k_z$. Then,

$$s^2 = \sin^2\left(\frac{k_x \Delta_x}{2}\right) + \sin^2\left(\frac{k_y \Delta_y}{2}\right) + \sin^2\left(\frac{k_z \Delta_z}{2}\right) \quad (32)$$

and it is clear that s^2 varies between zero and N_{dim} , where N_{dim} is the number of spatial dimensions in the simulation. Moreover, s depends on the frequency of the plane wave as well as the propagation direction, since $\mathbf{k} = \omega/c\hat{\mathbf{k}}$, where $\hat{\mathbf{k}} = \mathbf{k}/|\mathbf{k}|$.

Equation (30) is the discrete dispersion relation for the dispersive FDTD algorithm. The Z variable can be thought of as the gain of the E_x field from time step n to $n+1$. Stability requires that this gain satisfy $|Z| < 1$. Indeed, the discrete dispersion relation (30) will have several roots Z_l , $l = 1, 2, \dots, N_{\text{roots}}$ and the stability criterion for the dispersive FDTD algorithm requires that all of the roots Z_l to (30) satisfy $|Z_l| < 1$, $l = 1, 2, \dots, N_{\text{roots}}$.

We now consider certain special cases of (28). First, for a nondispersive, lossless medium, (16) gives

$$F(Z) = \epsilon_r(1 - Z^{-1}) \quad (33)$$

which reduces (30) to the usual Courant condition. For a Form-1 dispersive FDTD algorithm

$$F(Z) = \frac{\epsilon(Z)}{\epsilon_0}(1 - Z^{-1}). \quad (34)$$

For a Form-2 algorithm

$$F(Z) = \epsilon_r(1 - Z^{-1}) + \frac{\Delta_t}{2\epsilon_0}(1 + Z^{-1})\sigma(Z). \quad (35)$$

The above development of the stability criterion involved the source-free wave equation. The stability criterion given by (28) may also be derived from the poles of the source-driven wave equation. That is, if we add a free source current $J_{s,x}$ term to (22), and solve for the \tilde{E}_x field in terms of the free source current, we find that (28) is exactly the denominator polynomial containing the poles of the transfer function mapping $J_{s,x}$ to E_x .

Because the dispersion relation given by (28) is dependent on the model parameters, the maximum allowable value of r cannot be independently specified as it is with nondispersive media. Given a set of parameters for a second-order filter, the model can be tested for the stability of a particular choice of Δ_t and Δ_x by numerically finding the roots Z_l of the resulting polynomial when s^2 is swept from zero to N_{dim} , and ensuring that all roots are within the unit circle. For a Form-2 dispersion with $N_c = N_d - 1$, $N_{\text{roots}} = N_c + 2$.

IV. MINIMUM STORAGE IMPLEMENTATIONS

The goal of a computationally efficient FDTD algorithm is to perform accurate field calculations with minimal computer time and data storage requirements. The Form-1 and Form-2 dispersive FDTD algorithms require only a few additional

calculations per time step over the standard Yee algorithm. The modification of the standard Yee FDTD algorithm to include dispersion can significantly increase the storage requirement. We can minimize storage while maintaining the accuracy of the computations in two ways: 1) by choosing filter functions $\epsilon(Z)$ and $\sigma(Z)$ that contain just sufficient order to accurately model the wave physics for the frequency range of interest and 2) ensuring that the underlying computer algorithms do not contain unnecessary storage arrays.

Equation (9) appears at first to require storage of the previous time values of both the E_x and D_x fields. This observation was made by Joseph *et al.* [7], and later claimed by Luebbers [4] to be an advantage of the discrete convolution method over the differential-equation method. Similarly, (19) appears to require previous time storage of both the E_x and I_x fields. However, storage of both E_x and D_x or E_x and I_x is unnecessary, as was pointed out by Young [9] using a state-space approach. Other filter implementations may also be used that eliminate the need for storing both D_x and E_x or E_x and I_x .

We illustrate minimum storage implementations of the Form-1 and Form-2 dispersive algorithms. For the Form-1 algorithm, we assume for demonstration a second-order permittivity model. Dropping the space dependence for notational convenience, (9) becomes

$$E_x^{n+1} = \frac{1}{b_0} \left\{ \frac{1}{\epsilon_0} [D_x^{n+1} + a_1 D_x^n + a_2 D_x^{n-1}] - b_1 E_x^n - b_2 E_x^{n-1} \right\}. \quad (36)$$

A direct implementation of (36) above would require five storage arrays: E_x^n , E_x^{n-1} , D_x^{n+1} , D_x^n , and D_x^{n-1} . Storage is not required for E_x^{n+1} since E_x^{n+1} and E_x^n overwrite their previous values stored in E_x^n and E_x^{n-1} , respectively.

Equation (36) above may be rewritten in the form of the following three equations:

$$E_x^{n+1} = \frac{1}{b_0} \left[\frac{1}{\epsilon_0} D_x^{n+1} + W_1^n \right] \quad (37)$$

$$W_1^{n+1} = \frac{a_1}{\epsilon_0} D_x^{n+1} - b_1 E_x^{n+1} + W_2^n \quad (38)$$

$$W_2^{n+1} = \frac{a_2}{\epsilon_0} D_x^{n+1} - b_2 E_x^{n+1}. \quad (39)$$

The filter structure represented by (37)–(39) is known in the signal processing literature as a transposed direct Form-2 structure (not to be confused with a Form-2 dispersive FDTD algorithm). Note that (37)–(39) do not require previous time storage of the E_x or D_x field, but do require storage of W_1^l and W_2^l at time step n only, since W_1 and W_2 overwrite their own previous time values. Hence, (36) may be implemented using four storage arrays instead of five. As usual, $H_y^{n+1/2}$ must also be stored to implement Faraday's law. Although the savings does not appear significant, it would increase with higher order permittivity functions.

For the Form-2 dispersive FDTD algorithm, with a second-order conductivity model, (19) may be rewritten as

$$E_x^{n+1} = \frac{-1}{\epsilon_0} \left\{ I_x^{n+1/2} + c_1 I_x^{n-1/2} + c_2 I_x^{n-3/2} + e_1 E_x^n + e_2 E_x^{n-1} + e_3 E_x^{n-2} + \frac{\Delta t}{\epsilon_0} [J_{s,x}^{n+1/2} + c_1 J_{s,x}^{n-1/2} + c_2 J_{s,x}^{n-3/2}] \right\}. \quad (40)$$

The direct implementation of this equation requires five storage arrays: E_x^n , E_x^{n-1} , E_x^{n-2} , $I_x^{n-1/2}$, $I_x^{n-3/2}$, since only the three most recent E fields need be stored. Equivalently, $H_y^{n-1/2}$ and $H_y^{n-3/2}$ may be stored in place of $I_x^{n-1/2}$ and $I_x^{n-3/2}$, respectively, by (18). The minimal storage representation of the above is then

$$E_x^{n+1} = \frac{-1}{\epsilon_0} \left[I_x^{n+1/2} + \frac{\Delta t}{\epsilon_0} J_{s,x}^{n+1/2} + W_1^n \right] \quad (41)$$

$$W_1^{n+1} = c_1 \left(I_x^{n+1/2} + \frac{\Delta t}{\epsilon_0} J_{s,x}^{n+1/2} \right) + e_1 E_x^{n+1} + W_2^n \quad (42)$$

$$W_2^{n+1} = c_2 \left(I_x^{n+1/2} + \frac{\Delta t}{\epsilon_0} J_{s,x}^{n+1/2} \right) + e_2 E_x^{n+1} + W_3^n \quad (43)$$

$$W_3^{n+1} = e_3 E_x^{n+1}. \quad (44)$$

Four storage arrays are required in the above: E_x^{n+1} , W_1^{n+1} , W_2^{n+1} , and W_3^{n+1} . Again, one additional array is required for $H_y^{n+1/2}$ in implementing Faraday's law. Note that although $N_e = \max\{N_c + 1, N_d\}$, the Form-1 and Form-2 algorithms require the same storage for this case.

V. RELATION TO PREVIOUS METHODS

We now demonstrate that nearly all of the dispersive FDTD methods that have been considered in the literature may be cast as either Form-1 or Form-2 dispersive FDTD algorithms. The advantage to using our approach here is that special algorithms do not have to be developed for Debye, Lorentz, Drude or other media models. Once the Form-1 and Form-2 algorithms are developed, specific $\epsilon(Z)$ or $\sigma(Z)$ model parameters may be generated for a particular situation, without the need to develop a new computer code.

A. Differential Equation-Based Algorithms

We begin by considering the differential equation methods [5]–[8]. The idea behind these methods is that the time-domain dispersion relation is modeled as a differential equation relating $D(\mathbf{r}, t)$ to $E(\mathbf{r}, t)$

$$h_0 E(\mathbf{r}, t) + h_1 \frac{\partial}{\partial t} E(\mathbf{r}, t) + h_2 \frac{\partial^2}{\partial t^2} E(\mathbf{r}, t) + \dots = D(\mathbf{r}, t) + g_1 \frac{\partial}{\partial t} D(\mathbf{r}, t) + g_2 \frac{\partial^2}{\partial t^2} D(\mathbf{r}, t) + \dots \quad (45)$$

TABLE I
COEFFICIENTS OF FORM-1 DEBYE AND LORENTZ MEDIUM-DISPERSIVE FDTD ALGORITHMS CONSIDERED BY JOSEPH *et al.* [7]

Debye Model	Lorentz Model
$b_0 = \frac{\epsilon_s \Delta_t + 2\tau \epsilon_\infty}{\Delta_t + 2\tau}$	$b_0 = \frac{\omega_p^2 \Delta_t^2 \epsilon_s + 2\delta \Delta_t \epsilon_\infty + 2\epsilon_0}{\omega_p^2 \Delta_t^2 + 2\delta \Delta_t + 2}$
$b_1 = \frac{\epsilon_s \Delta_t - 2\tau \epsilon_\infty}{\Delta_t + 2\tau}$	$b_1 = \frac{-4\epsilon_\infty}{\omega_p^2 \Delta_t^2 + 2\delta \Delta_t + 2}$
$a_1 = \frac{\Delta_t - 2\tau}{\Delta_t + 2\tau}$	$b_2 = \frac{\omega_p^2 \Delta_t^2 \epsilon_s - 2\delta \Delta_t \epsilon_\infty + 2\epsilon_0}{\omega_p^2 \Delta_t^2 + 2\delta \Delta_t + 2}$
	$a_1 = \frac{-4}{\omega_p^2 \Delta_t^2 + 2\delta \Delta_t + 2}$
	$a_2 = \frac{\omega_p^2 \Delta_t^2 - 2\delta \Delta_t + 2}{\omega_p^2 \Delta_t^2 + 2\delta \Delta_t + 2}$

In Fourier space, the permittivity function can be seen as a Padé approximation in $j\omega$:

$$\epsilon(\omega) = \frac{h_0 + h_1(j\omega) + h_2(j\omega)^2 + \dots}{1 + g_1(j\omega) + g_2(j\omega)^2 + \dots}. \quad (46)$$

The differential equation is then discretized, using either forward, backward, or central difference approximations for the partial derivatives. There is some discretization error that is introduced by the discretization process, resulting in error between the discrete spectrum and the continuous spectrum. This discretization error has also shown to give rise to a misrepresentation of the actual relaxation time of the medium and to produce phase errors.

One of the benefits of using this technique is that (46) seems to offer flexibility in fitting arbitrary permittivity functions. However, we must keep in mind that when (45) is discretized, a difference equation will result, and the actual discretized permittivity function can be represented as a Padé model in Z-transform space. Hence, for fitting arbitrary media, the differential equation methods offer no advantage over our technique, and it is preferable to optimize the Padé model coefficients in Z-transform space to avoid introducing discretization error.

We have developed the equivalent Form-1 Padé models for $\epsilon(Z)$ directly from the difference equations presented by Joseph *et al.* [7]. For the first-order Debye algorithm, the permittivity function is of the form

$$\epsilon(\omega) = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + j\omega\tau}. \quad (47)$$

For the second-order Lorentz algorithm

$$\epsilon(\omega) = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{\omega_0^2 + j2\omega\delta - \omega^2}. \quad (48)$$

The coefficients of the Form-1 dispersive FDTD algorithms corresponding to (47) and (48) are listed in Table I.

B. Z-Transform Algorithms

The Z-transform algorithms [10] are the most similar to our formulation of all dispersive FDTD algorithms. The essence of the Z-transform method is that one begins with a specific frequency-domain analytic form for the dispersion relation,

such as the Debye or Lorentz model, which is inverse Fourier transformed to obtain a time-dependent permittivity function $\epsilon(t)$. The time-dependent permittivity is then sampled by setting $t = n\Delta_t$, and its Z-transform is computed analytically.

This procedure is exactly analogous to the design of digital filters via the impulse invariance method. One of the advantages to the impulse-invariance technique is that a stable continuous filter always results in a stable discrete filter $\epsilon(Z)$ [18]. However, note that a stable permittivity filter does not guarantee that the resulting FDTD algorithm will be stable. Aliasing problems encountered in the design of high-pass digital filters using impulse invariance are avoided because of the stringent FDTD $\lambda/10$ minimum grid sampling requirement, which ensures that the FDTD algorithms always operate far below the Nyquist frequency.

Sullivan considered a Debye model with an added conductivity term as an approximate model for muscle tissue in the frequency range 10–915 MHz [10]. The model is given as

$$\epsilon(\omega) = \epsilon_r + \frac{\epsilon_1}{1 + j\omega t_1} + \frac{\sigma}{j\omega\epsilon_0} \quad (49)$$

where $\epsilon_r = 50$, $\epsilon_1 = 110$, $\sigma = 0.62$ S/m, $t_1 = 5.88$ ns.

From (49), we apply the impulse-invariance procedure [18] to obtain

$$\epsilon(Z) = \frac{b_0 + b_1 Z^{-1} + b_2 Z^{-2}}{(1 - Z^{-1})[1 - e^{-\Delta_t/t_1} Z^{-1}]} \quad (50)$$

where $b_0 = \epsilon_r + \epsilon_1 \Delta_t/t_1 + \Delta_t \sigma/\epsilon_0$, $b_1 = -[\epsilon_r(1 + e^{-\Delta_t/t_1}) + \epsilon_1 \Delta_t/t_1 + \Delta_t \sigma/\epsilon_0 e^{-\Delta_t/t_1}]$, $b_2 = \epsilon_r e^{-\Delta_t/t_1}$. We have tried implementing this permittivity filter as a Form-1 dispersive FDTD algorithm, but have found that the algorithm is unstable due to the fact that the denominator polynomial of (50) contains a pole on the unit circle. Sullivan was able to implement a stable algorithm by isolating the pole on the unit circle in a parallel filter.

An alternate, more convenient way to implement the dispersive model given by (50) is to convert the Form-1 algorithm to an equivalent Form-2 algorithm, since the conversion factor contains a pole at $Z = 1$. Employing (20)

$$F(Z) = \frac{b_0 + b_1 Z^{-1} + b_2 Z^{-2}}{1 - e^{-\Delta_t/t_1} Z^{-1}}. \quad (51)$$

Note that the pole at $Z = 1$ in (51) has been cancelled by a zero at $Z = 1$ that is inherent in the Form-2 algorithm. The Form-2 algorithm with $F(Z)$ given by (51) was found to be numerically stable.

We simulated wave propagation in a medium consisting of a 1-D air/muscle interface. For this problem we chose a 1000 cell simulation and chose time and space step sizes of $\Delta_t = 6.65$ ps and $\Delta_z = 2.0$ mm. Sullivan [10] reported using a grid-space size of $\Delta_z = 10.0$ mm. However, this space step size is too large for this problem since it does not satisfy the $\Delta_z < \lambda_{\min}/10$ grid-dispersion requirement for this medium. For example, at 915 MHz, the permittivity may be determined from (49) to be $\epsilon(\omega) = 50.096 - j15.448$, which corresponds to a wavelength of $\lambda = 44.78$ mm in the medium.

Fig. 2. Magnitude of reflection coefficient for air/muscle interface computed using analytic solution and Form-2 dispersive FDTD algorithm. Solid line is analytic solution, Form-2 dispersive FDTD algorithm results are represented by (+) symbols for $\Delta_z = 2.0$ mm and (o) for $\Delta_z = 10.0$ mm. Sullivan's algorithm [10] gives identical results to Form-2 dispersive algorithm.

The reflection coefficient for the air/muscle interface computed using the Form-2 dispersive FDTD algorithm is shown in Fig. 2 and is compared against the analytic frequency-domain normal-incidence reflection coefficient, where the permittivity was determined from (49). Note in Fig. 2 that we calculated the reflection coefficient for both $\Delta_z = 2.0$ mm and $\Delta_z = 10.0$ mm. The reflection coefficient with $\Delta_z = 2.0$ mm is very close to the exact result, while the result for $\Delta_z = 10.0$ mm contains significant error at the higher frequencies. We have implemented Sullivan's model for this case, and it yields identical results.

C. Discrete Convolution Algorithms

In the discrete convolution approach, the dispersive FDTD problem is solved by first assuming a particular analytical form for the permittivity function $\epsilon(\omega)$ in the frequency-domain, and implementing a discrete convolution using only a very small time history. We examine two discrete convolution approaches: one based on the Debye model [3], and the other based on a multiple Lorentz approximation [4].

The algorithm involving a first-order Debye model [3] may be implemented exactly using our general framework. The algorithm that involves multiple Lorentz poles [4] involves a complex filter operation. We have successfully modeled the air/fourth-order medium using a Form-1 dispersive algorithm with a real filter. However, we shall defer discussion of this example to another paper since the implementation is somewhat involved and the example does not illustrate how to model arbitrary media.

We have converted first-order Debye model algorithm into the form of our Form-2 dispersive algorithm, with the parameters of $F(Z)$ listed in Table II. In the limit $\Delta_t \ll t_0$, which is generally true when the dispersion occurs within the operating frequency band of the FDTD algorithm, we have that $\chi_0 \approx (\epsilon_s - \epsilon_\infty) \Delta_t/t_0$. The above algorithm is then identical to the algorithm that we used to model the air/muscle interface without the conductivity term.

PARAMETERS FOR $F(Z)$ FOR FORM-2 DISPERSIVE FDTD ALGORITHM
CORRESPONDING TO LUEBBER'S FIRST-ORDER DEBYE MODEL ALGORITHM [3]

$$\begin{aligned} b_0 &= \chi_0 + \epsilon_\infty & a_1 &= -e^{-\Delta t/t_0} \\ b_1 &= -\left[\chi_0 + \epsilon_\infty(1 + e^{-\Delta t/t_0})\right] & \chi_0 &= (\epsilon_s - \epsilon_\infty)\left[1 - e^{-\Delta t/t_0}\right] \\ b_2 &= \epsilon_\infty e^{-\Delta t/t_0} \end{aligned}$$

TABLE III
MODEL COEFFICIENTS FOR FORM-2 DISPERSIVE FDTD ALGORITHM MODELING
PUERTO RICO CLAY LOAM WITH $D = 1.4$ g/cc AND $M = 10\%$

$$\begin{aligned} d_0 &= .0901332 & c_1 &= -.87 \\ d_1 &= -.0792821 & c_2 &= .06 \\ d_2 &= -.00947176 & \epsilon_r &= 6.2 \end{aligned}$$

VI. DISPERSIVE SOIL MODELING

We now consider the problem of modeling wave propagation in an arbitrary dispersive dielectric based on measured data. In particular, we investigate the modeling of wave propagation in dispersive, lossy soils. The permittivity and conductivity of soils at microwave frequencies is known to vary with density D and moisture M as well as frequency. Representative variations for San Antonio and Puerto Rico clay loam, as functions of D , M , and f , are given in [19]. This soil medium is notoriously difficult to model with a low-order Debye, Lorentz, or Drude model. Finding parameters which provide adequate simultaneous agreement for both the real and imaginary permittivity functions is problematic.

To model the wave propagation, we use a Form-2 dispersive FDTD algorithm that is second-order in both numerator and denominator. A conductivity function of the form given by (13) is used with $N_d = 3$, $N_c = 2$. The specific model coefficients that we have obtained for Puerto Rico clay loam with $D = 1.4$ g/cc and $M = 10\%$ are given in Table III. The time and space step values used are $\Delta t = 20$ ps and $\Delta x = \Delta y = \Delta z = 5$ mm. The design problem of obtaining the model coefficients will be discussed in a following paper.

Fig. 3 shows the real components of the effective relative permittivity (a) and conductivity (b) for the clay loam based on the Padé approximation given by (6) and the data in Table I (solid lines), where we have substituted $Z = e^{j2\pi f \Delta t}$ in (13). The data measured by Hipp is indicated by the crosses (x) in Fig. 3.

It is interesting to note in Fig. 3 that although we specified a real frequency-independent relative permittivity ϵ_r (see Table III), there is some variation in the Padé model's effective permittivity. The reason is that the conductivity filter $\sigma(Z)$ has an imaginary component that gives rise to an effective permittivity. This is a direct result of the fact that it is not possible to design a causal, stable IIR filter with zero phase [18].

To illustrate that our Form-2 dispersive FDTD algorithm is accurate and stable for 3-D wave propagation, we investigated the fields radiated by a short electric dipole. The electric field

(a)

(b)

Fig. 3. (a) Real component of relative permittivity. (b) Conductivity for clay loam with density $D = 1.4$ g/cc and moisture $M = 10\%$. Padé model (solid) is compared to measured data (x) [19].

radiated by the dipole is given as

$$\mathbf{E}(\mathbf{r}, \omega) = -j\omega\mu\left(\bar{\mathbf{I}} + \frac{\nabla\nabla}{k^2}\right) \cdot \hat{\mathbf{z}} I l \frac{e^{-jk r}}{4\pi r} s(\omega) \quad (52)$$

where $\bar{\mathbf{I}}$ is the identity operator and $s(\omega)$ is the source frequency spectrum. The time-domain analytic solution for the 3-D radiated fields from the small dipole was generated by numerically inverse Fourier transforming the field computing using (52). The source function $s(t)$ was derived from a Kaiser wavelet with a passband extending from 30.0 MHz to 2.5 GHz.

Fig. 4(a) shows the E_y component of the 3-D Form-2 FDTD solution and the analytic solution for the fields radiated by the short dipole located at the origin, and observed at $(x = 1.10$ m, $y = .420$ m, $z = .420$ m) in the clay loam. Note in the figure that only the time window [10 ns, 18 ns] is shown, since the fields are insignificant outside this region. Fig. 4(b) shows the difference between the numerical and analytic solutions. The E_x and E_z components were computed and have similar characteristics, but are not shown here.

VII. CONCLUSION

We have developed a new method for modeling wave propagation in arbitrary frequency-dispersive dielectric media using a FDTD methodology. This new method involves

Fig. 4. E_y component of electric field radiated by a small z -directed electric dipole in dispersive clay loam with $D = 1.4$ g/cc and $M = 10\%$. Dipole is located at origin, and E_y computed at $(x = 1.10$ m, $y = .420$ m, $z = .420$ m). (a) Numerical solution (solid) computed using 3-D Form-2 dispersive FDTD and analytic solution (dashdot) superimposed. (b) E_y field error for numerical solution.

modeling the simulation region as a spatial array of IIR digital filters, whereby a Padé approximation in Z-transform space is used to model arbitrary permittivity and conductivity functions. Two algorithms were developed, one involving a Padé approximation for $\epsilon(Z)$ (Form-1), and the other for $\sigma(Z)$ (Form-2). Differences between the Form-1 and Form-2 algorithms were discussed in terms of their stability and ability to model arbitrary data. Stability formulas were derived for both the Form-1 and Form-2 algorithms. Minimum storage implementations were also presented.

Our algorithms were compared to several previous methods for FDTD modeling of dispersive media. These algorithms were classified as discrete convolution methods, differential equation methods, and Z-transform methods. We have demonstrated that all of the previously published dispersive FDTD algorithms of which we are aware, with the exception of the discrete convolution algorithm involving a complex filter operation, may be cast in our more general framework using their exact implementation. In this sense, the Form-1 and Form-2 dispersive FDTD algorithms may be seen as a generalization of previous algorithms.

The main advantage of our new formulations is in their ability to more directly model arbitrary dispersive dielectrics based on measured data. We demonstrated that the permittivity

and conductivity filters lead directly to FDTD implementations without introducing discretization error. An accurate model for Puerto Rico clay loam was presented and demonstrated in a 3-D FDTD simulation. The radiation from a small vertical electric dipole was considered, and the FDTD solution compared against the analytic solution. The agreement was found to be excellent.

ACKNOWLEDGMENT

The authors would like to thank D. Silevitch for his assistance with the stability analysis.

William H. Weedon (S'86-M'94) was born in [redacted]. He received the B.S. (*summa cum laude*) and M.S. degrees in electrical engineering from Northeastern University, Boston, MA, in 1989 and 1990, respectively, and the Ph.D. degree in electrical engineering from the University of Illinois at Urbana-Champaign, in 1994.

From 1985 to 1989, he worked as a co-op student at Raytheon Submarine Signal Division, Portsmouth, RI, in surface systems development. During the Master's degree program at Northeastern (1989-1990), he worked on the problem of selecting optimal measurement configurations for microwave reflectometry. He spent the summer of 1990 at the MITRE Corporation, Bedford, MA, working on phased-array radar tracking. From 1991 to 1994, he was a Research Assistant at the University of Illinois, where he developed a broadband microwave inverse-scattering imaging system, including an 11-element Vivaldi antenna array—a network analyzer programmed to operate as a step-frequency radar—and computational inverse-scattering algorithms. He also developed several computational electromagnetic algorithms, including a 3-D FDTD code employing the Berenger perfectly matched layer (PML) implemented on the Connection Machine CM-5 massively parallel supercomputer and a 2.5-D spectral Lanczos decomposition method (SLDM) code. From 1994 to 1996, he was a Visiting Assistant Professor in the Electrical and Computer Engineering Department at Northeastern University, where he taught undergraduate electrical engineering and worked as a Research Scientist in the Center for Electromagnetics Research. His research focused on ground-penetrating radar modeling and data interpretation. He was the Technical Director on research grants from the United States Department of Energy, United States Army Research Laboratory, and the New England Transportation Consortium. Currently, he is a Technical Consultant specializing in electromagnetic and acoustic sensor modeling and data interpretation.

Dr. Weedon is a member of Tau Beta Pi, Eta Kappa Nu, and Phi Kappa Phi honor societies.

Carey M. Rappaport (SM'96) received the S.B. degree in mathematics, the S.B., S.M., and E.E. degrees in electrical engineering, all in 1982, and the Ph.D. degree in electrical engineering, in 1987, all from the Massachusetts Institute of Technology (MIT), Cambridge.

He has worked as a Teaching and Research Assistant at the Massachusetts Institute of Technology (MIT) from 1981 until 1987, and (during the summers) at COMSAT Labs, Clarksburg, MD, and the Aerospace Corporation, El Segundo, CA. He joined the faculty at Northeastern University, Boston, MA, in 1987, and has been an Associate Professor of electrical and computer engineering since 1993. During the fall of 1995 he was a Visiting Professor of electrical engineering at the Electromagnetics Institute of the Technical University, Lyngby, Denmark, as part of the W. Fulbright International Scholar Program. He has authored more than 80 technical papers in the areas of microwave antenna design, electromagnetic scattering computation, and bioelectromagnetics, and has received two reflector antenna patents and one biomedical device patent.

Dr. Rappaport was awarded the IEEE Antenna and Propagation Society's H. A. Wheeler Award for the best applications paper of 1985. He is a member of Sigma Xi and Eta Kappa Nu professional honorary societies.

A Common Framework of Subsurface Sensing and Imaging

M. B. Silevitch*, S. W. McKnight, and C. Rappaport

Center for Subsurface Sensing and Imaging Systems (CenSSIS)
Northeastern University, Boston, MA 02115

ABSTRACT

Subsurface sensing and imaging problems arise in a variety of contexts: underground, underwater, inside the human body, and inside a cell or a collection of cells. All of these problems require reconstruction of internal structures or functions from a highly distorted probe or wave sampled outside of an obscuring surface. There is an emerging common framework of physics-based signal processing which will allow progress in any of these areas to be applied to create advances in the other areas. The recognition of the essential similarity of these problems and the development of the common framework is a key to the next generation of environmental and biomedical imaging systems.

Keywords: Subsurface sensing and imaging, tomography, inverse problems, underground, underwater, and medical imaging, 3D microscopy.

1. INTRODUCTION

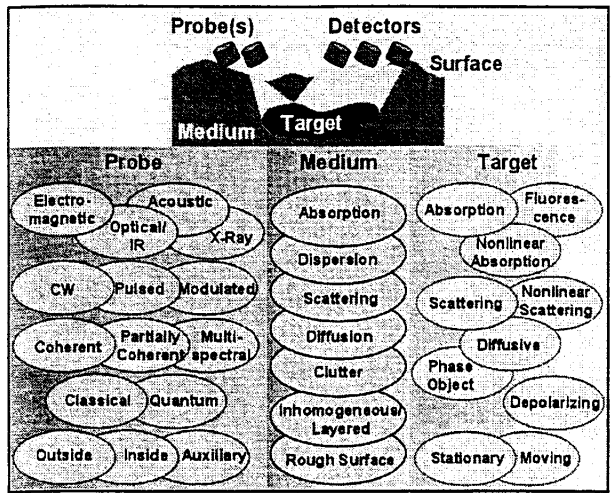

The problem of imaging under a surface arises in a wide variety of contexts, and these problems are among the most difficult and intractable system challenges known. Spread one hundred plastic landmines on top of a farmer's field and they can be safely removed in hours by a worker with a minimum of training. Bury them under one centimeter of soil, and you have a problem that has been the subject of intensive research for over half a century and remains far from solved. State-of-the-art inductive sensors in the hands of an experienced operator can detect non-metallic mines from the signal received from the firing pin and other small metal parts. In typical operation, however, over 300 false alarms are recorded for every mine identified, each requiring lengthy and delicate examination. In the end, operational mine detection systems have little, if any, advantage over probing each square centimeter of the ground with a titanium rod, a process that can clear a field at a rate of 1 meter by 25 meters of ground per person per day. No one has any idea how the three million landmines buried in Bosnia or the 10 million in Cambodia can be removed at any reasonable cost.¹

De-mining, in common with nearly all subsurface sensing and imaging problems, is an *information* problem. If we knew where the mines were buried, world-wide humanitarian de-mining would require relatively few physical resources. Yet in an Information Age, when the cost of computation and communications is reduced by a sizable fraction each year, the full potential of applying our exponentially expanding information technology sector to subsurface problems has not been realized because of lack of equivalent progress in subsurface detection and identification.

In addition to the technical problems of probes and processing that we will discuss below, we identify two major systems obstacles to progress in subsurface sensing and imaging:

- 1) the problems of sensor design, modeling, image processing, and recognition have been compartmentalized, viewed as separate disciplines rather than as integrated parts of a *system* optimization problem.
- 2) the subsurface problems in different media and different length scales are commonly viewed as unrelated problems and addressed with *ad hoc* solutions. Lessons learned in one subsurface technology are rarely applied to other problems, and no overarching theory exists to identify fundamental limitations, predict what can be detected and the optimal way to do it.

NU-011

Figure 1. Subsurface problems can be classified on the basis of the probe-medium-target interactions.

NU-001

Figure 2. A unified physics-based approach can unite subsurface problems from many domains at different length scales.

The subsurface sensing and imaging problem is to extract information about a subsurface target from scattered and distorted waves received above the surface. Imaging techniques, whether ultrasound sensors in tissue or electromagnetic probes in soil, can be described by the properties of probe wave, the wave propagation characteristics of the medium and surface, and the nature of target/probe interaction as shown in Figure 1.

The framework of Figure 1 describes not only underground imaging, but also underwater imaging, medical imaging inside the body, and 3D biological microscopies inside a cell or collection of cells. A unified theory of subsurface sensing and imaging, as illustrated in Figure 2, should encompass all of these applications and permit progress in one domain to be transparently applied in other domains with similar elements in the taxonomy of Figure 1.

For example, diffusive wave optical imaging for medical diagnosis and crosswell radar/EMI tomography for geophysical exploration both involve extracting an image of, or information about, anomalous regions (e.g., diabetic lesions under the skin or oil-bearing rock formations under the ground; see Figure 3). Although the problems occur on vastly different length scales, both require solution of the frequency-domain diffusion equation in the presence of an inhomogeneous, layered medium, and a need to filter large data sets from multiple transmitters and receivers that are, nevertheless, sparse compared to the information set sought. Attacking these two problems within the same framework allows the synergy of the two solutions to be exploited. Thus, even the critical differences between the two problems (lossy vs. lossless propagation, Poisson vs. Gaussian noise statistics, the diffusion equation as a limit of the radiative transfer equation vs. the diffusion equation derived by neglecting the displacement current in Maxwell's Equations) become a basis for more complete understanding of the unified problem, rather than just an obstacle to applying the same specialized algorithm to each problem.

NU-014

Figure 3. The physical/mathematical framework of diverse problems can be very similar.

2. PHYSICS-BASED SIGNAL PROCESSING

It is rarely the case that we cannot get any information from the subsurface region. The concealing media, while not transparent, can usually be penetrated to a considerable depth by a variety of acoustic and electromagnetic wave probes. The problem is that the target signal is distorted by complex absorption, dispersion, diffraction, and refraction of the wave through the media and obscured by surface reflection, subsurface clutter, and scattered energy from unknown inhomogeneities on many scales. The signal received, y , depends on the target information x and various signal-dependent clutter and nuisance parameters z through the function C which describes the physics of the probe-wave generation, propagation, and target and clutter interaction:

$$y = C(x, z) + n \quad (1)$$

The inverse problem of un-encoding the signature of the target object x from the received signal y in the presence of unpredictable clutter signals due to z and noise, n , is the challenge of subsurface sensing and imaging.

Since the mapping from the target to the sensor depends on unknown information about the subsurface media and target, the inversion from the scattered wave to the target properties is a nonlinear mathematical problem.^{2,3} The use of appropriate physical models of the probe/surface/media/target/receiver interaction (C in Equation 1) to assist in the solution of that inverse problem is what is referred to as physics-based signal processing (PBSP). PBSP has been identified in a seminal 1998 review article as a key to progress in image formation in complex media.⁴ Physics-based reasoning through the entire image understanding process and goal-directed processing will produce algorithms which are robust to modeling errors and generate accurate reconstructions of the critical information.

The fundamental problem of subsurface sensing and imaging is to differentiate the target of interest from irrelevant clutter and scatter, to distinguish a landmine from roots, stones, shell-casing, or ground-surface reflections. In the pulse-reflection ground-penetrating radar (GPR) simulation in Figure 4, for example, the signal from the plastic cylinder in the lower figure is obscured by the rough-surface reflection in the upper figure. The task is to extract the signal from the complex scattered field of random surface irregularities. In principle, if the surface profile and the soil dielectric properties were precisely known, one could subtract the background from the received signal to extract the target signature, but a full 3D calculation of the scattered field for a single pulse could take on the order of 10 hours on a 450 MHz desktop Pentium computer. Problems where the target distinguishing features are comparable to the clutter size, such as demining, are among the most challenging subsurface problems that exist.

One of the primary differentiating features is *shape*. Since resolution in the far-field is limited to order of the wavelength, it is desirable to use probes with wavelengths smaller than the size of identifying features. Unfortunately in most subsurface modalities, absorption increases with increasing frequency (smaller wavelengths). For example, the attenuation of medical ultrasound increases at the rate of 1dB/cm for every megahertz of frequency. Arterial plaque, which can be resolved by inserting catheters containing 30 MHz ($\lambda = 50 \mu\text{m}$) ultrasonic probes, cannot be noninvasively imaged from outside the body because the

Figure 4. Clutter from rough-surface reflection in the top frame obscures the signature of the buried object in the bottom frame in this pulse GPR simulation.

attenuation is too severe (about 30 dB per centimeter of depth at 30 MHz). This range/resolution trade-off is a fundamental limitation on many subsurface modalities including underground seismic imaging and underwater sonar imaging.

Alternatively, probes which are sensitive to target *material properties*, such as to material spectral response (color), conductivity, or magnetic susceptibility, can offer advantages for target differentiation. For example, medical imaging probes such as magnetic resonance imaging or nuclear medicine molecular tags which are sensitive to target chemistry can be used to differentiate targets on the basis of *physiology* (functioning) instead of *anatomy* (structure). Imaging the subtle physiological differences between cancerous cells and normal cells would be a medical breakthrough.

Nonlinear material properties are used for subsurface discrimination in two-photon microscopy^{5,6,7} or ultrasonic harmonic imaging. Harmonic imaging can yield diagnostically useful information on the 25% to 30% of the population that cannot be imaged well by ultrasound due to high clutter levels, distortions, and artifacts. Although harmonic imaging is already commercially available, the physical mechanisms behind it are poorly understood.

3. INFORMATION EXTRACTION STRATEGIES

Despite the bewildering variety of imaging modalities and techniques covered in the Figure 1 taxonomy, subsurface problems can be organized into a relatively small number of *information extraction strategies* which use similar algorithmic tools. Three broad information extraction strategies are discussed here.

Localized probing and mosaicking (LPM) concentrates the probe wave on a local subsurface region by focusing or time-gating and then assembles these individual pieces of information into an information mosaic. Common to these techniques are problems of concentration, aberration, and

registration which may use tools as simple as a lens or as complex as three-dimensional image matching and reconstruction. For example, medical reflection ultrasound and confocal microscopy both collect scattered energy from a subsurface target voxel. In both cases, precise focusing assumes a uniform homogeneous wave velocity, rarely the case in subsurface imaging, and resulting aberrations impede accurate imaging. LPM techniques are subject to obstruction by opaque objects (e.g., bones), and because reflection geometries are sensitive to high spatial frequencies (interfaces) LPM techniques are poor at detecting low-contrast or phase-only objects.

Wide-scan, high resolution LPM imaging usually requires mosaicking of multiple frames. Figure 5 shows an image of an ocean-floor hydrothermal vent assembled in this way by our collaborators at Woods Hole Oceanographic Institution. Errors in image registration and composition techniques contribute to errors on the scale of meters in the large-scale representation of imaged objects, reducing their utility in quantitative oceanography. The use of high-resolution sonar maps to register the optical images is a multi-modality path to the desired capability for high-resolution mapping of hundreds of thousands of square meters with an accuracy of centimeters.

Figure 5. High-resolution underwater optical image of an ocean-floor thermal vent is assembled by 3D photo-mosaicking techniques. (Photo courtesy of Woods Hole Oceanographic Institution.)

In contrast to LPM where the sensor information is spatially isolated, in *multi-view tomography* (MVT) correlated information from multiple sensors is combined mathematically to create a virtual map of the physical properties of the target. These systems all involve mathematical inversion of integral

equations through linearization, regularization, and integral transforms. Examples include x-ray CAT scanning, diffraction tomography, and synthetic aperture radar.

If multiple view angles are possible, MVT techniques can image obstructed/occluded objects and yield quantitative maps of wave velocity as well as absorption, allowing imaging of phase-only objects. For wavelengths that are short compared to feature dimensions, as in CAT scans^{8,9}, Radon convolution-backprojection algorithms combined with Fast Fourier Transforms (FFT) can achieve 3D feature imaging.

Diffraction tomography¹⁰ is the technique of image reconstruction and resolution enhancement by multiple-view imaging when the wavelength is comparable to feature size. The development of the theory of diffraction tomography by the linearization and Fast Fourier Transform (FFT) inversion of the wave diffraction equations using the filtered back-propagation algorithm was pioneered in the early 1980s.^{11,12} Diffraction tomography has been successfully applied for seismic imaging of near-surface objects, including fossil dinosaur bones¹³ and to ultrasonic imaging^{14,15,16}. Applications of diffraction tomography with limited or obstructed field-of-view or with higher-order, non-linear models is at the forefront of the state-of-the-art.

When the wavelength is long compared to feature size, *near-field* tomographic techniques can still yield useful information in geophysical or medical applications. In Electrical Resistance Tomography and Electromagnetic Induction Tomography, quasi-static probes and models are used to image contaminants in soil and groundwater and leaks from storage tanks on scales much smaller than the electromagnetic wavelength.^{17,18} Applications in medical imaging include Electrical Impedance Tomography¹⁹ and Cardiac Electrical Imaging^{20,21,22}. Figure 6 shows the electric potential on the heart imaged from the measured potential on the torso by Cardiac Electrical Imaging. The potential benefits of the enhanced information gained by this technique over standard electrocardiograms (ECGs) are enormous. ECGs have a rate of false diagnosis of myocardial infarctions ("heart attacks") as high as 30% which results in unnecessary health-care costs in the U.S. estimated at \$4 billion per year²³, while up to 25% of actual heart attacks go unnoticed until evidence of cardiac damage is detected in annual checkups.

NU-008

Figure 6. In Cardiac Electrical Imaging (CEI), near-field MVT inversion yields the electric potential on the heart from measured voltages on the torso.

Multi-spectral discrimination (MSD) adds the element of frequency discrimination to the spatial resolution sought by LPM and MVT giving a 4-dimensional map (3-space plus frequency) of the object. Combinations of MSD with LPM are common (a color photograph or hyperspectral image are examples). Joint methods for MSD and MVT have received little attention. MSD information extraction methods focus on material dispersion, parameter estimation, image registration, and fusion. Multi-sensor fusion can be viewed as an MSD problem involving, in some cases, probes that differ in modality (acoustic and optical, for example) as well as frequency.

For example, the work illustrated in Figure 7 shows that subtractive imaging at two nearby optical wavelengths can map specific chemical concentrations, such as oxygenated/deoxygenated hemoglobin (Hb).²⁴ This use of optical spectroscopy to detect chemical indicators of physiological function *in vivo* is promising for diagnostic discrimination. The rich spectral interaction of IR-VIS-UV light with biological molecules, however, causes absorption and strong scattering in tissue^{25,26,27} and makes the localization of emergent light difficult. Diffusive Wave Imaging^{28,29} in strongly scattering media is the focus of much current research, including optical coherence tomography^{30,31,32} and CenSSIS work in *dual-wave* acousto-phonic imaging which seeks to improve spatial resolution from centimeters to millimeters for precise quantitative diagnosis.

Satellite hyperspectral imaging of the Caribbean Basin has been used to determine the health of coral reef ecosystems and measure coastal erosion³³. Reflected light is strongly scattered in the water column, by the ocean surface, and by the atmosphere, distorting the frequency spectral information as well as the position of underwater objects. This problem is similar to medical diffusive imaging except on a length scale that differs by orders of magnitude. The physics of both are modeled by the radiative transfer equation (RTE)³⁴. However, in diffusive medical imaging, the ratio of absorbed to scattered light is assumed to be small leading to the diffusion equation, while in ocean scattering Beer's law is often applied by assuming the ratio is large. In reality, the physical situation in both cases may be intermediate, and there is a need for more rigorous forward models and more robust inversion algorithms. Current spatial resolution from space-based platforms is approximately 1 meter; processing techniques that take advantage of accurate physical models may improve the resolution limit to 10 centimeters.

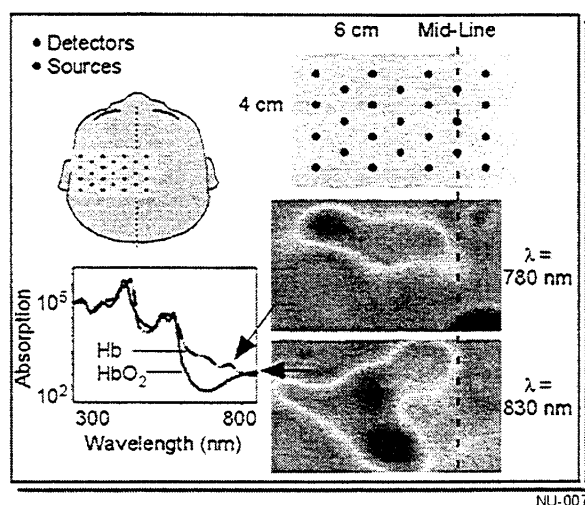

Figure 7 MSD analysis of diffusive optical waves images areas of activity (high blood oxygenation levels) in infant brain.

4. RESEARCH NEEDS AND BARRIERS TO PROGRESS

Progress in subsurface sensing and imaging approaches within these information extraction strategies has been documented in the feature articles in a recent issue of *Science* ("*Imaging: New Eyes on Hidden Worlds*")³⁵. Key elements in these advances include the increase in computation power, the application of new mathematical algorithms and advanced sensing strategies, the exploitation of wave coherence, and the fusion of multiple sensing modalities (e.g., microwave and infrared) to extract increasingly detailed information from physical systems.

Still, the need for new technologies is clear. The General Accounting Office has stated, "the dimensions and potential costs of cleaning up our environment are so great that, without innovative technologies, we may find the solution cost prohibitive and impacting on our ability to address other national needs." By using current technologies, the costs of remediating Superfund and Resource Conservation and Recovery Act sites, Federal facilities, and other known hazardous waste sites may total \$750 billion over the next 30 years³⁶. Humanitarian de-mining remains an unsolved problem. No current imaging technique can adequately detect precancerous cell masses in soft tissue or noninvasively diagnose arteriosclerosis, and there is no way to collect and correlate the images from different modalities to automatically identify incipient health problems.

Barriers to such advanced civil-environmental and biomedical detection systems lie both in unsolved fundamental research problems and in lack of adequate technology tools. Some of the major barriers are:

Barrier 1: Fundamental knowledge is lacking about nonlinear interactions, dual-wave sensing mechanisms, and coherent imaging in scattering media. While linear acoustic and electromagnetic interactions can be modeled and characterized by well-understood linear response functions, advanced imaging techniques using non-linear or dual-wave (e.g., acoustic/optical) probes require fundamental investigations to determine appropriate physical models.

Barrier 2: The present formulation of coherent inverse scattering is inadequate to quantitatively image objects in highly-scattering random inhomogeneous and cluttered environments. In these situations the non-linear character of the inverse problem defeats tomographic reconstruction and adequate alternatives do not yet exist.

Barrier 3: Recognition strategies for obscured and limited-view subsurface applications are not well developed, and we have no theory for combining different sensor inputs to optimize the information obtained.

Barrier 4: Forward modeling of large complex scattering geometries is too slow for real-time inverse-processing applications.

Progress is required in both efficient approximate forward solvers and in hardware/software implementation of processing.

Barrier 5: There are few widely-available test facilities with sufficient flexibility and sensor reconfigurability to permit the optimization of sensor modality/configuration and processing strategies based on recognition and decision objectives.

Barrier 6: Techniques for rapid processing, cataloging, storage and retrieval of large image databases are not sufficiently developed. Data and metadata standards will need be instituted so that processing algorithms can be routinely tested on experimental results from diverse experimental domains.

5. CONCLUSION

The pieces are in place for a major advance in the field of sensing and imaging. The development of a common framework and unified discipline of subsurface sensing and imaging promises to allow the field to emerge as a co-pillar of the Information Age, along with computation and communications. We can look forward to systems-level advances such as integrated, field-tested, algorithmic and computational tools for the entire range of subsurface problems, and standards and criteria for the use of multiple sensing modalities to achieve subsurface sensing system goals. These, in turn, will open the door for the next generation of systems for environmental sensing underground or under the water, medical imaging and automatic diagnosis inside the body, and biological microscopy to reveal fundamental processes inside living cells.

ACKNOWLEDGEMENTS

We would like to acknowledge the invaluable assistance of our many CenSSIS colleagues in developing the concepts presented in this paper. In particular, we would like to thank Bahaa Saleh for the concept of Figure 1, Eric Miller for Figure 3 and the related discussion, Hanu Singh and Jon Howland of Woods Hole Oceanographic Institution for Figure 4, Charles DiMarzio and David Boas for Figure 6, and Dana Brooks for Figure 5. We are especially in the debt of David Castanon for his elucidation of the concept of information extraction strategies. Valuable communications with Ron Roy, Robin Cleveland, and Tom Szabo are gratefully acknowledged.

ABSTRACT

In this paper, we develop a statistical detection system exploiting sensor fusion for the detection of plastic A/P mines. We design and test the system using data from Monte Carlo electromagnetic induction (EMI) and ground penetrating radar (GPR) simulations. We include the effects of both random soil surface variability and sensor noise. In spite of the presence of a rough surface, we can obtain good results fusing EMI and GPR data using a statistical approach in a simple clutter environment.

More generally, we develop a framework for simulation and testing of sensor configurations and sensor fusion approaches for landmine and unexploded ordnance (UXO) detection systems. Exploiting accurate electromagnetic simulation, we develop a controlled environment for testing sensor fusion concepts, from varied sensor arrangements to detection algorithms. In this environment, we can examine the effect of changing mine structure, soil parameters, and sensor geometry on the sensor fusion problem. We can then generalize these results to produce mine detectors robust to real-world variations.

Keywords: mine, sensor fusion, statistical, radar, induction, model, UXO, detection

1. INTRODUCTION

The need for mine and unexploded ordnance (UXO) detection and removal is growing in both military and humanitarian applications. Civilian casualties from landmines are on the order of hundreds per week, and in some locations around the world, landmines are emplaced faster than they can currently be removed. The current U.N. standard for humanitarian mine detection probability is set at 99.97%. But with any single current buried object detection technology, such a high P_d results in an unacceptably large number of false alarms, particularly when searching for plastic anti-personnel (A/P) mines. However, through information fusion, we can combine the best aspects of multiple sensor technologies to achieve the goals of landmine removal.

To achieve an optimal information fusion system, we must start from fundamental, controlled studies of system design tradeoffs, taking into account every aspect of the problem, from sensor physics and configuration to fusion and detection. Unfortunately, little work has been done to date on such a comprehensive approach to system design. While some researchers have studied individual sensors and detection schemes extensively, sensor fusion researchers have not conducted necessary controlled studies of the effects of design choices on the fusion and ultimate detection problems.

This paper represents a first effort toward filling in this gap in our knowledge. Our goal is to develop a framework for mine detection system research and design that includes the critical aspects of a sensor fusion scenario. We have chosen to focus on detecting plastic A/P mines because their detection represent a particularly challenging problem for which there is currently no satisfactory fielded solution. Information fusion appears to be the solution for this difficult detection problem.

In this work, we concentrate on fusing information from two sensors, a Ground Penetrating Radar (GPR) and an Electro-Magnetic Induction Spectroscopy (EMIS) sensor. We demonstrate that even a simple sensor fusion design can be quite successful over either individual sensor when the physics of their operation provides complementary information. However, we show that individual sensors can be strongly affected by variations in soil parameters and sensor configuration, and this in turn can affect our design choices sensor fusion and detection, which supports our contention that more extensive controlled studies are necessary.

*Correspondence: Email:lorax@bu.edu; WWW: <http://mdsp.bu.edu/lorax.html>

2. BACKGROUND

Our current approach to detecting plastic A/P mines is based on fusing data from two sensors, a Ground Penetrating Radar (GPR) array similar to that operated by Geocenters¹ and an Electro-Magnetic Induction Spectroscopy (EMIS) sensor such as those developed by Geophex.² Each type of sensor has its advantages and drawbacks, but neither alone is sufficient to the problem of reliably detecting plastic A/P mines with sufficiently low false alarm rates. A visualization of the basic GPR sensing concept appears in Figure 1(a) and a photo of one kind of EMIS sensor appears in Figure 1(b).

Figure 1. Ground penetrating radar and electromagnetic induction spectroscopy sensors

To date, GPRs have been the favored electromagnetic technology for detecting plastic A/P mines.³ GPRs operate by emitting wideband electromagnetic pulses, which propagate into the earth and reflect from subsurface structures. The reflections are then measured and, in the case of arrays, fused. GPRs are good for detecting shallow dielectric cavities, of which plastic A/P mines are examples. Unfortunately, plastic A/P mines are not the only examples of dielectric cavities, with rocks representing a significant potential confusing class of objects. This potential confusion is especially true since random reflections from a rough air/ground interface can swamp the mine or discrete clutter signatures, making distinguishing between these two classes difficult. Similarly, soil inhomogeneity, such as soil compaction or moisture content, can lead to numerous false alarms. Also, very small metallic objects, such as the firing pin found in many plastic A/P mines, are almost invisible to GPR, which would remove a significant potential characteristic for discerning plastic landmines if GPR were used alone.

An EMIS sensor can complement a GPR by detecting and recognizing the small metal content of many plastic A/P mines. By emitting sinusoidal signals and sweeping across multiple frequencies, an EMIS sensor can obtain information that depends on metal material properties and spatial structure, even for very small amounts of metal.² Also, EMIS sensors are less likely to be affected by soil variations, unlike GPR. However, at gains high enough to see the small metal content of many plastic A/P mines, such an inductive sensor is also highly sensitive to, and frequently confused by, discrete metallic clutter such as small shell fragments, pop-tops from soda cans, or many other kinds of metallic clutter. Additionally, EMIS sensors cannot distinguish landmines with zero metallic content. Thus, an EMIS sensor alone also cannot successfully discriminate plastic A/P mines. But many potential false alarms in the GPR domain are not the same as those in the EMIS domain, and vice versa, i.e. we expect that in most cases, dielectric cavities and metallic objects that coincide in space are likely to be plastic A/P mines and not random clutter.

3. METHOD

As stated in Section 1, our goal is to develop a framework for testing a wide range of possible sensor and fusion scenarios for landmine detection, far more cases than is possible with currently available landmine data sets. By providing an environment in which we can control every aspect of the problem, from rough soil surfaces and soil inhomogeneity to variations in mine pose and sensor geometry to different clutter environments, we can conduct

fundamental tradeoff studies for sensor fusion. With this approach, we will be able to find optimal solutions that account for the wide range of possible situations that can arise in real, practical problems. In this paper, we present an initial study that uses this approach to examine array GPR and EMIS data fusion.

3.1. Sensors

Our detection system consists of two sensors, one a GPR array and the other an electromagnetic induction spectroscopy (EMIS) sensor, and a set of detection and fusion algorithms. Figure 2 shows the basic sensor and landmine geometry.

Figure 2. Geometry of the sensor/mine configuration

Our GPR array uses four antennae with transmit/receive capability. We locate these sensors approximately 30cm from the nominal soil surface, corresponding to a vehicular mounting arrangement. The antennae are spaced at 20cm intervals. We choose to use a short, wideband pulse. Our pulse width is about 0.8ns, corresponding to a 1.25GHz band width. The observed signal from the GPR consists of 16 time traces, one for each transmitter/receiver pair. It is important to note here that we are not explicitly focusing the array. We simply transmit a pulse from a single antenna while receiving at all four antennae, and then transmit from the next antenna while again receiving with all four, and so on. This approach maximizes the amount of information available to the detection algorithm. We show a noiseless example set of time traces for one transmit/receive pair in Figure 3. The two overlaid traces correspond to the cases with and without a mine in dispersive soil for a single example of a rough ground surface.

Our EMIS sensor is a single square induction coil located approximately 30cm above the nominal soil surface. The frequency is swept over a 30Hz-20kHz range, which we have sampled logarithmically. Multiple such sensors could be placed in an array, but here we have only considered the single coil case. Our observed data is a vector of samples of the observed EMF signal, logarithmically spaced over the frequency range.

3.2. Physical Models

To generate our data, we use accurate electromagnetic software tools. In the case of the GPR array, we use a Finite Difference Time-Domain (FDTD) algorithm.⁴ With FDTD, we can generate data corresponding to a variety of

Figure 3. Noiseless GPR time traces; transmitter 2, receiver 3

situations that we can control explicitly: varying rough ground surfaces, different soil parameters, and alternative sensing geometries, for cases with plastic A/P landmines or discrete clutter such as rocks or no subsurface objects at all. For the EMIS sensor, we use a quasi-static magnetic moment physical model, for which we can control sensing geometry and the properties of mine or clutter.⁵ For this study, we choose to assume that our sensors are centered over the section of ground we are testing, and that we are merely trying to test whether or not a landmine is located directly below the sensors at a known depth.

For the GPR, we include a random, but correlated, air/ground interface as a source of uncertainty, as well as white, Gaussian sensor noise of about 20dB per channel signal to noise ratio. In our physical GPR model, we construct three cases. In the first, we include a plastic landmine of known shape, using a relative permittivity of 2.9, corresponding to TNT. In the second, we include a discrete clutter object, with a relative permittivity of 2.8, that is approximately an ellipsoid of roughly the same size as the landmine. In the last case, we modeled no discrete object at all, measuring the response from the empty, homogeneous soil. The soil's relative permittivity is 2.6, and we studied both dispersive, lossy and non-dispersive, lossless cases.

For the EMIS sensor, we model the plastic landmine as having a small, steel firing pin centered in the mine, approximately 1cm in size, with a relative permeability of 5000 and a conductivity of 10^7 S/m. We assume the earth is essentially invisible to the sensor at such low frequencies. We also model a discrete metal fragment as approximately 4cm in size, with the same material properties as the firing pin. For sensor noise, we include white, Gaussian noise for 14dB signal to noise ratio. Note here that, at this noise level, the resulting clutter object looks indistinguishable from the firing pin. In addition to the mine and clutter situations, we include empty soil by simply using the sensor noise with zero mean.

In modeling this system, we only include single objects within the field of view. Thus, the landmine and discrete clutter cases are mutually exclusive. To stress this physical model of clutter versus target, we include the chart of Figure 4, showing how the GPR and EMI clutter characteristics relate. We also never vary the pose of the objects; we assume they lie flat. We will explore more complicated models in future work.

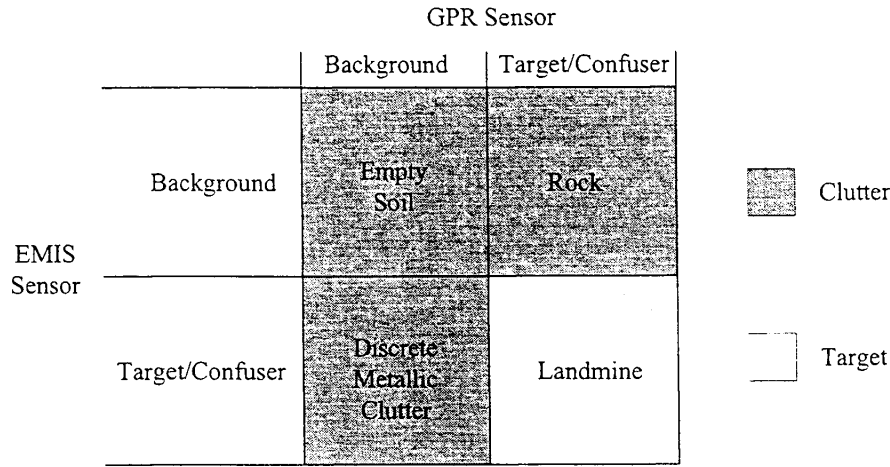

Figure 4. Clutter versus target domains

3.3. Statistical Models

Our statistical models are related to, but quite distinct from, our physical models. Our goals in doing statistical modeling are threefold. First, by allowing statistical error into the problem, we can make our approach robust to modeling error. Thus, the statistics can absorb any differences between our physical model and reality, particularly difficult-to-manage nonlinearities. Second, statistical approaches usually can provide measures of error, so that we can estimate how well we are doing. Third, by using a statistical approach, we open a wealth of available techniques and knowledge for sensor fusion and detection.

For the GPR, our statistical model assumes that the data comes from three additive vector sources: the rough ground return, \underline{g} ; white Gaussian sensor noise, \underline{w} ; and possibly a buried landmine, \underline{s} . We formulate our two detection hypotheses by the presence or absence of the landmine signal, \underline{s} :

$$\begin{aligned} H_{r,0} : \quad \underline{y}_r &= \underline{g} + \underline{w} \\ H_{r,1} : \quad \underline{y}_r &= \underline{s} + \underline{g} + \underline{w} \end{aligned} \quad (1)$$

where \underline{s} , \underline{g} , and \underline{w} are simply the time signals corresponding to the mine signal, the ground return, and the white sensor noise, fused at the data level by vectorization:

$$\underline{s} = [s_{j,k}(n)] \quad \underline{g} = [g_{j,k}(n)] \quad \underline{w} = [w_{j,k}(n)] \quad \begin{cases} j, k = 1, 2, 3, 4 \\ n = 1, \dots, 750 \end{cases} \quad (2)$$

where j and k denote the specific transmit/receive antenna pair, and n is the time sample. The sum of these signals, \underline{y}_r , is what we can observe as output from the antenna array. We assume that these signals are independent Gaussian random vectors, distributed as follows:

$$\underline{s} \sim N(\underline{\mu}_s, \Sigma_s) \quad \underline{g} \sim N(\underline{\mu}_g, \Sigma_g) \quad \underline{w} \sim N(\underline{0}, \Sigma_w) \quad (3)$$

where $\underline{\mu}_s$ and $\underline{\mu}_g$, and Σ_s and Σ_g , are the means and covariances, respectively, of their distributions, and the elements of \underline{w} are zero-mean and identically distributed, so $\Sigma_w = \sigma_w^2 I$. For computational tractability, we currently assume Σ_s and Σ_g are diagonal, though in future work we may introduce tractable correlation structure.

For EMIS, we have a single sensor, with data from a sweep over frequency, and this data is corrupted by Gaussian noise. Going immediately to vector notation, we assume that the signal \underline{c} is a known deterministic signal and that \underline{u} is independent and identically distributed, zero-mean, Gaussian noise, so our two cases are simply:

$$\begin{aligned} H_{e,0} : \quad \underline{y}_e &= \underline{u} \\ H_{e,1} : \quad \underline{y}_e &= \underline{c} + \underline{u} \end{aligned} \quad (4)$$

where

$$\underline{u} \sim N(0, \Sigma_u) \quad \Sigma_u = \sigma_u^2 I \tag{5}$$

It is important to note that in this preliminary study, we elected not to explicitly model the discrete clutter in our statistical detection problem, but we do include such clutter in the physical model for generating the data. Nowhere in any of the statistical models do we include a discrete clutter case, i.e. a rock or metallic clutter. We did this because we wanted to explore the problem of model mismatch and the advantages of detection-level fusion when discrete clutter models are unknown or ignored.

3.4. Detectors

Given the statistical models above, it is relatively easy to formulate an “optimal” maximum likelihood detector, based on a likelihood ratio test. In the GPR case, we assume the three Gaussian signals are independent, so we can simply add their means and covariances

$$\begin{aligned} H_{r,0} : \quad & \underline{y}_r \sim N(\underline{\mu}_g, \Sigma_g + \Sigma_w) = N(\underline{\mu}_0, \Sigma_0) \\ H_{r,1} : \quad & \underline{y}_r \sim N(\underline{\mu}_s + \underline{\mu}_g, \Sigma_s + \Sigma_g + \Sigma_w) = N(\underline{\mu}_1, \Sigma_1) \end{aligned} \tag{6}$$

The detector resulting from this model and a likelihood ratio test is the full quadratic classifier:

$$\left(\underline{y}_r - \underline{\mu}_0\right)^T \Sigma_0^{-1} \left(\underline{y}_r - \underline{\mu}_0\right) - \left(\underline{y}_r - \underline{\mu}_1\right)^T \Sigma_1^{-1} \left(\underline{y}_r - \underline{\mu}_1\right) \underset{H_0}{\overset{H_1}{\geq}} \gamma_r \tag{7}$$

We estimate the parameters from a large number of Monte Carlo runs by estimating $\underline{\mu}_g$ and Σ_g for the case with empty soil, and $\underline{\mu}_s + \underline{\mu}_g$ and $\Sigma_s + \Sigma_g$ for the landmine case. These parameters are averaged over many different, random rough soil/air interfaces. Because we control the sensor noise, we can add the known white noise covariance to each case ourselves.

Similarly, we develop the maximum likelihood detector for the EMIS case. However, because the signal is a known deterministic signal and we control the noise, we can simplify both the equations and the detector:

$$\begin{aligned} H_{e,0} : \quad & \underline{y}_e \sim N(0, \Sigma_u) \\ H_{e,1} : \quad & \underline{y}_e \sim N(\underline{c}, \Sigma_u) \end{aligned} \tag{8}$$

$$\underline{c}^T \Sigma_u^{-1} \underline{y}_e \underset{H_0}{\overset{H_1}{\geq}} \gamma_e \tag{9}$$

While this approach is adequate for our current simulations, in practice, our detector and noise parameters will need to be estimated from data.

From these models, we perform three detection experiments to demonstrate the advantages of fusion. First we test the GPR alone, then we test the EMIS sensor alone. Lastly, we fuse the two sensing modalities with detection-level fusion, using an AND detector. To build an appropriate optimal detector, we need to explicitly model the confusing clutter classes statistically. The advantage of the AND detector is that it can approximate the optimal multi-class detector without explicit clutter models. While it is always better to obtain the optimal detector by explicitly modeling clutter, in cases where this is infeasible, an AND detection rule will win. In future work, we intend to formulate an optimal detector by determining and using appropriate multi-class clutter models.

4. RESULTS

We conducted three major experiments, over which we varied soil parameters and mine depth. In each of our experiments, we ran 400 Monte Carlo runs with different rough air/soil interface and sensor noise realizations. In 100 cases, we placed a landmine. In another 100 cases we placed the GPR clutter object (the “rock”). In the next 100 cases, we used the EMIS clutter object (the small metal fragment). In the last 100 cases, we included no discrete clutter or mine at all, only empty soil. In each of the three experiments, we used each of the three detection methods: GPR alone, EMIS alone, and their detection-level fusion.

For each of the 400 Monte Carlo runs, we generated the random soil surface using a correlated Gaussian random model with approximately $\pm 5\text{cm}$ of deviation from nominal, maximum, and an 8cm correlation length. In every case, we set the soil's relative permittivity to 2.63, but in two cases we used a lossless, non-dispersive soil model, while in the third, we implemented a lossy, dispersive model based on data from the Bosnia Steele Castle site. In this case, the moisture content was 4.7% and the density was 1.181 g/cm^3 , and we modeled the loss and dispersion using a 2-1 Padé approximation.

In one of the two lossless, non-dispersive cases, we placed a landmine with its upper surface at a depth of 8cm below the nominal soil surface, while in the other we placed it 12 cm below the nominal soil surface. In the lossy, dispersive case we placed the landmine 8cm below the surface. Our landmine was 6cm in thickness, with a diameter of 15cm. Except for the firing pin, we assumed the mine was filled with TNT, with a relative permittivity of 2.9, relative permeability 1, and conductivity 0. We also assumed that the mine contained a small, 1cm firing pin with a relative permeability of 5000 and a conductivity of 10^7S/m .

For our clutter, we assumed that the rock was roughly the same size and shape as the mine, but approximately ellipsoidal with major axis 17cm and minor axis 7cm, oriented similarly to the landmine. We assumed the rock had a relative permittivity of 2.8, with relative permeability of 1 and no conductivity. We assumed that the metal fragment clutter about 4cm in size with the same material properties as the landmine firing pin.

Figure 5 shows the ROC curves for the case of a mine at a depth of 8cm in lossless, non-dispersive soil. First, note that the ROC curve for the EMIS sensor alone shows good correspondence to what we expect for the case that the metal clutter object is nearly indistinguishable from the landmine. The straight line ROC is indicative that guessing is as good as any other technique when trying to distinguish the metal clutter from the firing pin when using the EMIS sensor. The GPR is better at distinguishing between the rock and the landmine than the EMIS sensor is for the metal clutter, but it still has a significant number of false alarms for $P_d \approx 0.99$. However, the detection-level fusion scheme has a much lower false alarm rate for comparable P_d .

Figure 5. ROC curves for mine at 8cm depth, non-dispersive soil

In Figure 6, we see the ROC curves for the mine at a depth of 12cm, with the same soil parameters. As we expect, the increased distance makes the EMIS sensor perform slightly worse than before. The GPR alone, however,

gets significantly improved performance. This improvement comes from the time delay of the mine signal. While the mine signal is attenuated due to the increased distance, the distance attenuation of the reflection from the rough ground surface is much stronger, resulting in a much smaller interfering signal relative to the mine signal at this time delay. This improvement would be mitigated somewhat by lossy soil. Also, as expected, the fused detector performs better than either sensor alone, despite its simplicity.

Figure 6. ROC curves for mine at 12cm depth, non-dispersive soil

Lastly, in Figure 7, we show the ROCs for the case of a mine buried at a depth of 8cm in lossy, dispersive soil. The EMIS ROC is essentially the same as the first case, but the GPR curve is much different. Here we begin to see problems with model mismatch. Because we have not explicitly modeled clutter statistically, we have found a situation where the GPR clutter signal is much stronger than the mine signal. Thus, despite the differences in the two signals, the clutter signal is detected as a mine more often than the mine is. This poor GPR detector performance suggests that we can do much better if we model the clutter explicitly in our statistics. The AND detection rule again does quite well; in fact it appears to do perfectly. This is an artifact of ROC estimation from discrete, experimental data and the small number of Monte Carlo runs. More Monte Carlo samples, or another approach, such as importance sampling, would help rectify this issue. With more samples, our ROC estimates and confidence in them would improve.

5. CONCLUSIONS

We have developed a framework for studying the system design tradeoffs in sensor fusion for landmine detection applications. We can now conduct controlled experiments that examine the effects that soil or landmine parameters, sensor geometries, clutter, and fusion algorithms have on the landmine detection problem. With this approach, we aim to identify the optimal sensor configurations and fusion algorithms for general, real-world landmine problems.

We have used this framework to study the effect of variations in soil parameters and mine depth on GPR and EMIS data fusion, particularly for the case of plastic A/P mines. We also focused on the issue of model mismatch and the advantages of accurate clutter modeling for detection. We found that even simple detection-level sensor fusion techniques can provide a large improvement in our ability to detect plastic A/P mines.

FDTD Wave Propagation in Dispersive Soil Using a Single Pole Conductivity Model

Carey M. Rappaport, Shuang Wu and Scott C. Winton
Center for Electromagnetics Research, Northeastern University, Boston, MA

Abstract—In FDTD modeling of lossy, dispersive soil for subsurface imaging and detection applications, the electric flux and the current are convolutions of $E(t)$ with $\epsilon(t)$ and $\sigma(t)$ respectively. To avoid these memory-intensive computations, the convolutions can often be accurately and simply modelled as second order difference equations. In particular, by matching the corresponding Z -transform of the E-field/current relation to frequency-dependent conductivity results in a ratio of polynomials in Z^{-1} (where $Z = e^{j\omega\Delta t}$). A good fit to measured soil data over two decades in frequency is possible using only a single pole, two zero conductivity model. Compared to a similarly accurate three-term Debye model, this one-pole model requires one-third the storage of previously computed field values.

Index terms—FDTD, Soil Modeling, Dispersion, Mine Detection

I. BACKGROUND

There is growing interest in simulating wave propagation for underground microwave and RF sensing and imaging applications. Soil is a good candidate for the finite difference methods since it is usually inhomogeneous, lossy, and has an irregular surface boundary. It has been challenging to accurately compute wideband wave behavior in realistically modelled soil because of its dispersive nature, requiring either many individual frequency domain calculations or a robust deconvolution of $E(t)$ from $D(t)$ in the time domain. A simple dispersive variant of the FDTD algorithm which includes the effects of frequency-dependent conductivity and dielectric constant enables the use of this prevalent and efficient modeling method.

The conventional approach to modeling dispersion in soil approximates the frequency domain dispersive complex dielectric constant with rational functions (Debye or Lorentz models) of $j\omega$ [1,2], multiplies the constitutive relation by the denominator and inverse Fourier transforms the result. We improve on this method by modeling solely the conductivity as a simple rational function of the Z -transform [3,4], based on the observation that the frequency variation of the real dielectric constant does not significantly affect either the real propagation constant β or the decay rate α . By modeling σ in terms of powers of the Z -transform variable Z^{-1} (which readily transforms to time delays), the conversion of the generalized dispersive Ohm's Law $\mathbf{J}(Z) = \sigma(Z)\mathbf{E}(Z)$ to the time domain is particularly straightforward.

II. MODEL FORMULATION

To preserve the conceptual elegance and simplicity of the FDTD method, it is important to keep the media model to at worst second-order. In previous reports, a quite satisfactory two-pole, two-zero rational function conductivity model was presented. This current work shows that a model with a single pole can often be just as good. The right hand side of Ampere's Law $\nabla \times \mathbf{H} = \partial \mathbf{D} / \partial t + \mathbf{J}$ Z -transforms to: $[(1-Z^{-1})/\Delta t]\epsilon_0\epsilon_{Av}\mathbf{E} + \sigma(Z)\mathbf{E}$ (where it is assumed that ϵ_{Av} is frequency independent). The time-dependent conductivity may thus be modelled as

$$\sigma(Z) = \frac{J(Z)}{E(Z)} = \frac{b_0 + b_1 Z^{-1} + b_2 Z^{-2}}{1 + a_1 Z^{-1}} \quad (1)$$

Both the real and the imaginary components of $\sigma(Z)$ depend on the frequency sampling interval Δt and the coefficients of the rational function (a_1 , b_0 , b_1 , and b_2). The imaginary component corresponds to an effective permittivity. This model is implemented by fitting $\text{Re}\{\sigma\}$ to measured conductivity and $\text{Im}\{\sigma\}/\omega\epsilon_0$ to measured real dielectric constant less an average value ϵ_{Av} . To simultaneously solve for b_0 , b_1 , and b_2 , an initial guess is made for a_1 . The conductivity and dielectric constant at three representative frequencies for the measured data and the model are equated. Further simple optimization is performed by trial and error, varying either a_1 or one of the three frequencies. Complex wave number $k(\omega)$ is then calculated from both the model and the measured data, and the real propagation constant β and the decay rate α are derived from $k = \omega/c\sqrt{\epsilon_{Av} - j\sigma/\omega\epsilon_0}$.

Once the a and b parameters of σ have been determined, integration into the FDTD algorithm is straightforward. If the temporal average of the current density \mathbf{J} is used, Ampere's law in the Z domain becomes:

$$\nabla \times \mathbf{H}(Z) = \epsilon_{Av} \frac{1 - Z^{-1}}{\Delta t} \mathbf{E}(Z) + \frac{1 + Z^{-1}}{2} \sigma(Z) \mathbf{E}(Z) \quad (2)$$

Using (1) in (2) and noting that Z^{-1} corresponds to the time index shift $n \rightarrow n-1$, the E-field update equation for a 2-D Transverse Magnetic ($\mathbf{E} = \hat{z}E_z$) simulation is:

$$\begin{aligned} E_z^{n+1} &= \frac{1}{e_0} (-e_1 E_z^n - e_2 E_z^{n-1} - e_3 E_z^{n-2} + \Delta H) \\ \Delta H &= \frac{\Delta t}{\epsilon_{Av}} \left(-I_x^{n+\frac{1}{2}} - a_1 I_x^{n-\frac{1}{2}} + I_y^{n+\frac{1}{2}} + a_1 I_y^{n-\frac{1}{2}} \right) \end{aligned} \quad (3)$$

where $e_0 = 1 + b_0 \Delta t / 2\epsilon_{Av}$, $e_1 = a_1 - 1 + (b_0 + b_1) \Delta t / 2\epsilon_{Av}$, $e_2 = -a_1 + (b_1 + b_2) \Delta t / 2\epsilon_{Av}$, $e_3 = b_2 \Delta t / 2\epsilon_{Av}$ and I_x and I_y are the spatial first differences of the H_x and H_y fields with respect to y and x (spatial indices have been suppressed for clarity).

The one-pole model of $\sigma(Z)$ requires storing I_x and I_y (and I_z in a three-dimensional simulation) a single additional time compared with non-dispersive FDTD. For each additional conductivity pole, this same amount of storage space must be additionally allocated. Fig. 1 shows the fit of the model (at $\Delta t = 20$ ps) to the conductivity and dielectric constant data measured from Puerto Rican clay loam (PRCL) with 1.4 g/cm^3 density and 10% moisture [5]. The difference between the imaginary conductivity of the model and the measured ϵ (lower panel) is used to determine the constant real soil permittivity ϵ_{Av} . Fig. 2 shows the fit of the full model to β and α . The maximum amount of error is less than 20%, which is close to the measurement error of the soil sample.

Fig. 1. (a) Measured (circles) versus single pole model (continuous curves) of $\sigma(Z)$: (a) real conductivity and (b) imaginary conductivity (real relative dielectric constant) for Puerto Rican clay loam, 10% moisture, 1.4 g/cm^3 density [5]. The constant real dielectric constant ϵ_{Av} is the average difference between the curve and the measured circles of (b).

The use of the average value of the current density is well established and produces accurate results. However, using only the present value of the current density in the update equation results in the savings of another storage location. To facilitate this savings without sacrificing accuracy, $\sigma(Z)$ is multiplied by $(1 + Z^{-1})/2$ and a new set of model parameters is determined to fit this

product over the frequencies of interest. In this case, (3) is additionally simplified with $e_0 = 1 + b_0 \Delta t / \epsilon_{Av}$, $e_1 = a_1 - 1 + b_1 \Delta t / \epsilon_{Av}$, $e_2 = -a_1 + b_1 \Delta t / \epsilon_{Av}$, and $e_3 = 0$, and this dispersive model requires only one additional storing of each field value compared to non-dispersive FDTD. This compares with two field storings for the (2,2) model and three field storings for the comparably accurate three-term Debye model.

Similar modeling for several different types of soil with widely varying density and moisture [5,6] at $\Delta t = 20$ ps is summarized in Table 1. All models have wave numbers in agreement with measured values within 20%.

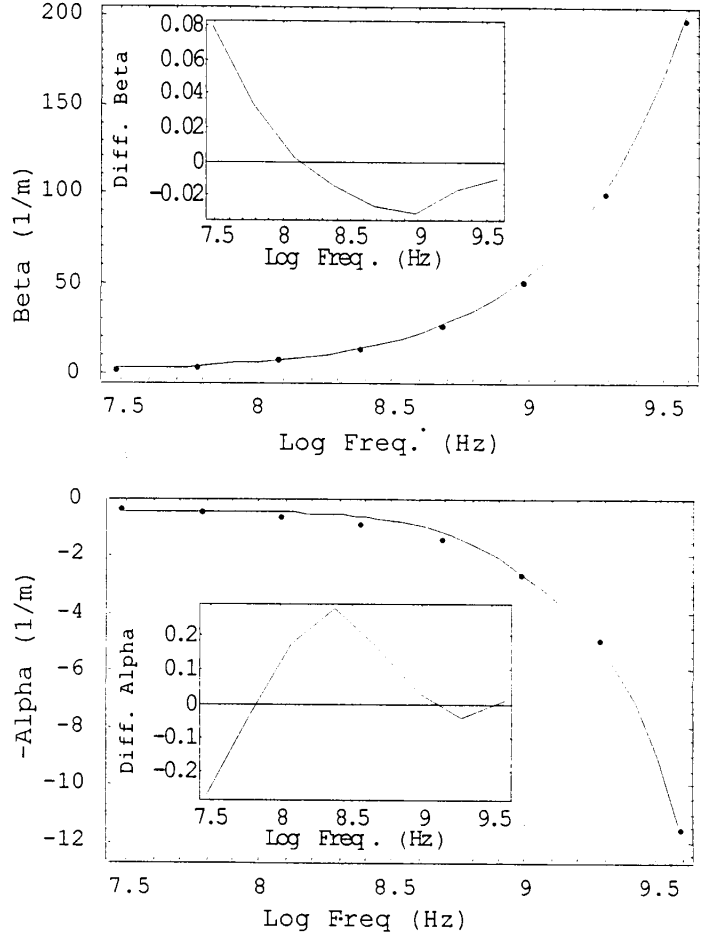

Fig. 2. Measured (circles) versus model for single pole model of $\sigma(Z)$ with constant ϵ_{Av} (continuous curves): (a) Real and (b) imaginary parts of wave number for Puerto Rican clay loam, 10% moisture, 1.4 g/cm^3 density [5] as a function of frequency. Insets show normalized error for this model.

III. STABILITY CONSIDERATIONS

The Courant stability analysis in [3] shows that in a source-free homogeneous medium, the time-space transform of the wave equation for a plane wave ($\Delta x = \Delta y = \Delta z = \Delta$) is:

$$(Z - 1)F(Z) = -4r^2 s^2 \quad (4)$$

where from (2), $F(Z) = \epsilon_{Av}(1 - Z^{-1}) + (\Delta t/2\epsilon_0)(1 + Z^{-1})\sigma(Z)$, and $r = c\Delta t/\sqrt{\epsilon_{Av}}\Delta$, and $s^2 = \sin^2 k_x\Delta + \sin^2 k_y\Delta + \sin^2 k_z\Delta$ with maximum value of s equal to the spatial dimension of the FDTD simulation. Expressing $F(Z)$ in rational form:

$$F(Z) = \epsilon_{Av} \frac{(e_0 + e_1 Z^{-1} + e_2 Z^{-2})}{1 + a_1 Z^{-1}} \quad (5)$$

Using (4), (3) becomes a third order polynomial in Z^{-1} . The solution to this equation yields one real root and two complex roots that are a function of Δ . Stability requires $|Z| < 1$. For Δ within the range of 4.6mm to 120mm, all three roots are within the unit circle.

NUMERICAL TEST CASES

Several numerical experiments were performed to validate this method. The simulations were run in one dimension for simplicity. The choice of Δt is critical since it defines the model, determines the range of usable frequencies and determines the limits on Δ through the Courant condition. For these experiments, the spatial increment was 2.5 mm. The incident field is a modulated gaussian pulse, used to excite many frequencies simultaneously. The modulation frequency is 3 GHz for the Alicia and A.P. Hill soils and 1.5 GHz for the PRCL soil sample.

In order to compare the results of the FDTD simulations with the measured data, the frequency-dependent wave number k must be extracted. Fast Fourier Transforming the time domain fields gives

$$k_{\text{FDTD}} = -\frac{1}{j\ell} \ln \frac{E_z(\omega, \ell)}{E_z(\omega, 0)} \quad (6)$$

Fig. 3 shows the real and imaginary parts of the wave number versus frequency for measured values and either the “Time-Averaged” or “Model-Averaged” k_{FDTD} . These latter “Model-Averaged” simulations use only the current value of the conduction current J^n . The parameters in Fig. 3 correspond to the three separate sites of Table 1. Both the real and imaginary wave numbers agree well for each soil, for both types of models across the entire two decades of bandwidth from 45 MHz to almost 4 GHz. It should be noted that the “Time-Averaged” FDTD computation is more robust, with less sensitivity to excitation function and Courant number.

CONCLUSIONS

A minimal-storage time-domain model for frequency-dispersive soil based on a constant real dielectric constant and a (2,1) rational function of Z^{-1} conductivity function has been developed and tested. By pre-multiplying the measured conductivity data by the Z-transform of the time average function, the resulting model avoids requiring conduction current time averaging in Ampere’s law. Without this time averaging,

TABLE I
ONE-POLE CONDUCTIVITY PARAMETERS

Puerto Rican Clay Loam: $m = 10$, $d = 1.4^\dagger$					
av?	a_1	b_0	b_1	b_2	ϵ_{Av}
no	-0.88	0.91625	-1.67662	0.761072	4.18775
yes	-0.9	0.7983	-1.4695	0.67176	4.282
A.P. Hill, Firing Point 22: $m = 19.3$, $d = 1.527$					
no	-0.975	1.51947	-2.97284	1.45362	5.25834
yes	-0.97868	1.5473	-3.036	1.4888	4.7731
Bosnia, Test site Alicia: $m = 25.3$, $d = 1.263$					
no	-0.925	1.76106	-3.32102	1.56193	5.03815
yes	-0.93	1.6325	-3.0827	1.4521	4.9831

$^\dagger m$ is percent moisture content of the soil, d is soil density (g/cm³).

a one-pole conductivity model requires just one additional store of electric and magnetic field compared to the non-dispersive FDTD algorithm. This is half the required additional storage of the previously reported (2,2) model, and even less than standard Debye and Lorentz models. In addition, fitting parameters to a single, real conductivity function — rather than to both parts of a complex permittivity function — is quite advantageous.

Numerical simulations on measured data show that this simple model is efficient and accurate across a wide frequency band for both real and imaginary parts of wave number, giving good predictions of velocity and decay rate. A stability analysis shows that the model is stable for one, two, and three dimensions, for a wide range of grid spacings.

ABSTRACT

We present an analysis of statistical model based data-level fusion for near-IR polarimetric and thermal data, particularly for the detection of mines and mine-like targets. Typical detection-level data fusion methods, approaches that fuse detections from individual sensors rather than fusing at the level of the raw data, do not account rationally for the relative reliability of different sensors, nor the redundancy often inherent in multiple sensors. Representative examples of such detection-level techniques include logical AND/OR operations on detections from individual sensors and majority vote methods. In this work, we exploit a statistical data model for the detection of mines and mine-like targets to compare and fuse multiple sensor channels.

Our purpose is to quantify the amount of knowledge that each polarimetric or thermal channel supplies to the detection process. With this information, we can make reasonable decisions about the usefulness of each channel. We can use this information to improve the detection process, or we can use it to reduce the number of required channels.

1. INTRODUCTION

The need for mine and unexploded ordnance (UXO) detection and removal is growing in both military and humanitarian applications. In places like Cambodia, the threat of mines to the general populace is overwhelming. Since the end of the Cold War, there has been a growth in smaller, regional conflicts where threats are often not from high-tech weaponry, but from inexpensive ordnance. Bosnia is just one example. Mines are one of the least expensive weapons available, and their threat often far outlasts the conflict for which they are emplaced. Mine detection is therefore necessary in two roles: detecting minefield obstacles for military intelligence and detecting individual mines for eventual removal.

One specific subject of mine detection involves wide-area surveillance. In one case, military forces need to chart possible impediments to ground movement accurately over broad swaths of territory. In humanitarian applications, surveyors examining terrain for mine clearance can limit the area searched with wide-area surveillance. For both situations, it is highly desirable to conduct mine searches from the air to minimize the danger to personnel. Unfortunately, ground penetrating radar and quasistatic electromagnetic approaches are somewhat limited in range.

Optical techniques can meet many of the requirements of wide-area minefield detection. One area of much interest is polarimetric sensing. In the near infrared domain, surface mines have a highly polarizing characteristic. Disturbed soil, indicative of buried objects, may also have such a polarizing nature. In fact, mine detection rates are high using only polarization information, but reducing the false alarm rate is a harder problem, requiring that we apply additional information. While this feature alone is inadequate to detect mines, it can be a powerful tool when combined with multispectral information, such as thermal imaging or imaging spectrometers.

However, fusing information from multiple sources in a rational, statistical way is often neither simple nor obvious. In previous work, we showed that fusing local spatial information with polarization and thermal observations can reduce false alarms, either through a statistical prior model or local adaptivity.¹ In this paper, we focus solely on the

R.A.W.: Email:lorax@bu.edu; WWW: <http://mdsp.bu.edu/lorax.html>

relative advantages of fusing combinations of polarization, reflectance, and thermal data for distinguishing mine-like targets from background. Counterintuitively, we find that fusing only polarization and thermal information gives better results than any other combination, including the combination of all channels together, even under conditions of low thermal contrast. This finding is likely caused by model mismatch, but it clearly points out the complexity of choosing an appropriate fusion method. System designers should not develop sensors, models, and algorithms in isolation. We must develop these technologies together to achieve optimal solutions.

2. SENSOR BACKGROUND

Our data consist of three infrared imagery channels generated by the U.S. Army Engineer Waterways Experiment Station's Remote Minefield Detection System (REMIDS).^{2,3} The system images the first two channels using an active infrared system at the $1.05\ \mu\text{m}$ wavelength. One channel is percent polarization, $(P - S)/(P + S)$, and the other channel is total reflectance, $(P + S)$, where P is reflectance in parallel polarization and S is reflectance in cross polarization. The third channel is a passive thermal infrared channel operating over the $8\text{-}12\ \mu\text{m}$ range. The sensor is mounted on an airborne platform, represented in Figure 1. The data that we use for this study has a resolution

Figure 1. REMIDS Thematic Representation

of 2-3 inches per pixel, depending on altitude, although later system upgrades have increased this resolution.

Several researchers have shown that polarization characteristics are advantageous in the mine detection process.^{2,4,5} Man-made objects such as mines and other unexploded ordnance (UXO) are significant near infrared polarizers compared to natural backgrounds, which tend to be uniformly random polarizers. Disturbed earth can indicate buried objects, and may also be a source of polarization features. REMIDS only uses linear polarization features, but we can extend the same algorithmic techniques to circular polarization as well. Additionally, thermal data alone is sensitive to weather and time of day, especially diurnal thermal crossover.

The active near-IR sensor used in REMIDS is capable of all-weather imaging, but this all-weather capability comes at the price of a laser source, its power supply, and other support equipment. A passive polarization sensor could be implemented cheaply, but would have weather-dependent detection and false alarm rates. An alternative system is a passive hyperspectral polarimetric imager,⁴ but this again increases the system cost. Additionally, the computational requirements of the system increase approximately as the square of the number of channels used in the detection process, so every channel that we can ignore reduces the overall cost of the system. This last cost is the main reason we are fusing different combinations of sensors in this study: to determine if intelligently choosing channels to fuse can provide such savings with little loss in detection capability.

One difficulty with the data set used in this study is that the percent polarization channel had been saturated prior to the signal processing stage to “improve” usage of available dynamic range. Unfortunately, doing so results both in a decrease in signal-to-clutter ratio in the percent polarization channel and an unrealistic decrease in the variance of the mines in this channel. This approach also saturated many background pixels, and thus these pixels cannot be distinguished from mine pixels through the percent polarization channel alone. To distinguish these pixels, we must use data from the other channels or prior information. We will return to this issue in Section 4.

3. METHOD

To analyze and compare the advantages of the various channels and their combinations, we choose to use a simple Maximum Likelihood (ML) approach to detection:

$$\hat{x} = \underset{x}{\operatorname{argmax}} p(y|x) = \underset{x}{\operatorname{argmax}} \ln p(y|x) \quad (1)$$

where y is the multichannel image and x is the hypothesis image of mine locations, each represented as a vector,

$$y = [y_1^T, \dots, y_N^T]^T \quad x = [x_1, \dots, x_N]^T$$

$$y_i = \begin{bmatrix} y_i^p \\ y_i^r \\ y_i^t \end{bmatrix} \in \mathbb{R}^3 \quad x_i = \begin{cases} 1 & \text{if pixel } i \text{ is a mine} \\ 0 & \text{if pixel } i \text{ is not a mine} \end{cases}$$

and N is the total number of pixels. Thus, each element of the observation image, y_i , is a 3-vector where the superscripts p , r , and t denote the three channels, percent Polarization, total Reflectance, and Thermal, respectively. For our channel comparison analysis, we sometimes ignore one or two channels. For these cases, y_i becomes either a 2-vector or a scalar, respectively.

For our observation model, we assume that each pixel of data, y_i , is conditionally independent of all other data pixels, conditioned on knowledge of mine presence at that pixel, x_i . Formally,

$$p(y|x) = p(y_1, \dots, y_N | x_1, \dots, x_N) = \prod_{i=1}^N p(y_i | x_i) \quad (2)$$

This assumption allows us to perform the maximization in Equation 1 individually for each pixel,

$$\hat{x} = \underset{x}{\operatorname{argmax}} \ln p(y|x) = \underset{x}{\operatorname{argmax}} \sum_{i=1}^N \ln p(y_i | x_i)$$

$$\hat{x}_i = \underset{x_i}{\operatorname{argmax}} \ln p(y_i | x_i) \quad (3)$$

Thus, we formulate the problem as a likelihood ratio test,

$$\frac{p(y_i | x_i = 1)}{p(y_i | x_i = 0)} \underset{\hat{x}_i = 0}{\overset{\hat{x}_i = 1}{\geq}} \alpha \quad (4)$$

where α is a threshold chosen by the user.

We also assume that each pixel is a conditionally identically distributed Gaussian, with parameters that are a function mine presence at the pixel of interest,

$$p(y_i|x_i) = \frac{1}{|2\pi\Sigma(x_i)|} \exp \left\{ -\frac{1}{2} (y_i - \mu(x_i))^T \Sigma(x_i)^{-1} (y_i - \mu(x_i)) \right\} \quad (5)$$

where $\mu(x_i)$ and $\Sigma(x_i)$ are the mean and the covariance, respectively, of the observation variable, y_i . For the purposes of this paper, we assume that the mean and covariance are known for both background and mines, and we estimate the mean and a full covariance matrix for both mines and background directly from the data. We make no attempt to model or adapt to nonstationarity of the background in this study. The likelihood ratio test then simplifies as follows,

$$[y_i - \mu(0)]^T \Sigma^{-1}(0) [y_i - \mu(0)] - [y_i - \mu(1)]^T \Sigma^{-1}(1) [y_i - \mu(1)] \underset{\hat{x}_i=0}{\overset{\hat{x}_i=1}{\geq}} \gamma \quad (6)$$

Note that these decision threshold surfaces are quadratic, not linear, because the covariances are not equal.

The simplicity of this model is desirable because it makes the resulting analysis and comparison of the channels easier to understand. One possible drawback, however, is that this very simplicity may not be a good match to reality, and may produce unexpected results.

4. RESULTS

For our test we have access to only two data sets, both from 1991 test flights of REMIDS over Fort Drum, New York. The first flight took place at 9 am on an overcast day, resulting in low thermal contrast between mines and background, but also low thermal variance. The second flight occurred at 3 pm on a clear, sunny day. We show representative segments of all channels of both scenes in Figures 2 and 3. The mines in these images are surface patterned anti-tank mines, but this approach to comparing the relative usefulness of the channels is equally applicable to scattered mines as long as sufficient spatial resolution is available. The applicability to buried mines depends on whether the advantages of polarization information extend to buried mines that disturb the surface of the soil in which they lie. Thermal detection of buried mines is an established technique.

For the purposes of our analysis, we define a detection as any continuously 8-connected region of pixels labeled as a mine by the ML approach. Using an image ground-truthed by hand, we define a correct detection as any single detection that coincides with at least one pixel of any continuously 8-connected region of pixels in the ground-truth image. If two such detection regions coincide with a mine region, we only count one as a correct detection. We define the total number of false alarms as the difference between the total number of detections and the number of correct detections. This definition is imperfect; as the threshold, γ , of Equation 6 increases, an initially continuous detection region can break into multiple disjoint regions, resulting in an increase in the number of false alarms, without a related increase in correct detections. Using a Maximum A Posteriori (MAP) detector with a smoothness prior model can relieve this problem.¹

We show the resulting empirically derived Receiver Operating Characteristic (ROC) curves for the clear and cloudy days in Figures 4 and 5, respectively. Each graph contains multiple curves, one for each possible combination of the three channels: percent polarization, total reflectance, and thermal. We label the graph legends with the same convention used in the superscripts of Section 3: 'p' for percent Polarization, 'r' for total Reflectance, and 't' for Thermal. We denote combinations of channels by multiple letters, e.g. 'rt' represents the combination of the total reflectance and thermal channels. Since these are semilog plots, we assigned a value of 0.99 to any cases of zero false alarms, for display purposes.

There are three unusual features of these ROC curves that we must interpret. We explained the first such feature previously, the occasional increase in false alarms as correct detections decrease, as the breaking of a detection into multiple smaller detections as detection threshold increases. The second is the square ROC curve associated in each graph with the polarization channel alone: a sudden decrease from 1 to 0 in the probability of correct detection as you trace the curve from the right with no change in false alarms, followed by an immediate decrease in the number of false alarms to zero. This odd characteristic is a result of the saturation of the polarization channel described in Section 2. There are a fixed set of false alarms and correct detections that exactly attain the upper limit of the range

of values on which the polarization channel is defined. As the detection threshold approaches this upper limit it rules out all other false alarms. As the threshold crosses the top of the range, both correct detections and false alarms plummet to zero immediately. While the graph we chose to represent this is not unique, it is the closest match to our intuition about the shape and structure of ROC curves.

The third unusual feature involves the order of the ROC curves from lower right to upper left. From a statistical viewpoint, adding channels, and hence adding information, cannot result in a worse detection characteristic unless the model used does not match the data. Yet our ROC curves in both types of weather clearly show an increase in false alarms as the reflectance channel is included with the polarization and thermal channels. Similarly, the reflectance channel alone appears to perform better than the combined thermal and reflectance channels on the overcast data. There are two possible ways that we can explain this counterintuitive result. One is our simplifying assumption of background stationarity, which a cursory perusal of the data will show is clearly inaccurate. Including model adaptivity may fix this problem. Another possibility could be a sensitivity in the reflectance channel to the parameter estimates, particularly its covariance with the thermal channel. Each of the unusual cases involves combining the reflectance channel with the thermal channel.

In the other cases, the ROC curves follow our intuition about fusing channels: fusing one channel with another results in an improvement over either channel separately. The interesting result is the amount of improvement. First, note that the polarization and reflectance false alarm rates, alone and separately, do not change much as a function of the weather conditions. We could anticipate this, since a narrowband active sensor should be influenced little by ambient radiation. The thermal channel and all of its combinations outstandingly improve on a clear, sunny day. Again, we could anticipate this since thermal contrast increases dramatically with input radiation. Surprisingly, even on the overcast day, the thermal channel in conjunction with the polarization channel gives a significant and useful improvement, more than halving the number of false alarms of either channel separately. The reflectance channel, on the other hand, provides a much more limited improvement when used in conjunction with the polarization channel under all conditions.

5. CONCLUSIONS

In this research, we have examined the relative value of polarization, reflectance, and thermal information in the particular context of the mine detection problem. Using a particular simplified model we have shown that polarization and thermal information, when fused in a statistically rational way, can significantly improve the detection process over either alone, primarily through a reduction in false alarm rate. Also the thermal channel provides significant information, even under conditions of low thermal contrast.

The advantages of expending the computational effort to include the reflectance channel appear more dubious. The improvements in false alarm rate that this channel provides are relatively small when compared to the other two channels. Also, it appears from a cursory examination of the results that the reflectance channel may be particularly sensitive to model mismatch. However, a careful analysis of the causes of this difficulty will require further study.

6. ACKNOWLEDGMENTS

We would like to thank Ricky Goodson and Ernesto Cespedes of the US Army Corps of Engineers Waterways Experimental Station's Environmental Laboratory for graciously sharing their REMIDS data. This work is partially supported by the Army Research Office under Grant ARO DAAG55-97-1-0013, the Air Force Office of Scientific Research under Grant F49620-96-1-0028, and the National Institutes of Health under Grant NINDS 1 R01 NS34189.

ABSTRACT

Mechanisms for the production of acoustic energy in soil by pulsed CO₂ laser excitation of the surface are reported. When the laser pulse is unfocused with a spot size about 1 cm in diameter, a single narrow acoustic pulse is observed with a spectral content near the detector limit of 100 kHz and a velocity of 255 m/s, close to the speed of sound in air. When the laser is focused to a spot size on the order of 1 mm diameter, the audible acoustic intensity is greatly increased and we observe a second broad acoustic feature. This feature has a much lower frequency (near 3 kHz) and velocity (75 m/s). We have tentatively identified the fast mode as a normal compressive mode and the slow mode as a Biot slow-wave. A study of visible light emission when the focused CO₂ laser beam strikes the sand surface indicates ionized nitrogen, oxygen, and silicon are present. This implies that the mechanism for sound production with the focused beam involves ionization by the optical electric field, expansion, and subsequent collapse of the air. The mechanism for sound production by the unfocused beam, which produces better imaging of underground objects, appears to be quite different.

Keywords: laser-induced, acoustic, landmine detection, Biot waves, porous media

1. INTRODUCTION

The use of high-frequency (~30kHz) acoustic waves produced by a pulsed CO₂ incident on the surface of dry sand for imaging of shallow buried objects such as anti-personnel landmines has been demonstrated in the laboratory^{1,2}. The mechanisms for the conversion of the optical pulses into sound, however, is poorly understood. Since the optimization of the process of optical to acoustic conversion in a porous media depends on understanding and modeling the physical processes, we have initiated an experimental investigation of the behavior of the acoustic modes created in soil under different laser pulse focusing conditions. For a broad, unfocused laser spot, modeling the soil as a uniform effective medium as in Figure 1a may be appropriate. If the laser is focused to a small spot comparable to the size of the sand grains as in Figure 1b, a more complex calculation may be necessary which takes into account the random position and orientation of the sand grains and the intervening air spaces. In addition, under focused beam conditions the optical field intensity can become very large, leading to different physical effects. We have observed

Figure 1 Conceptual models of optical-to-acoustic conversion in soil. a) An effective medium approximation may be adequate when the laser spot is much larger than the structure of the soil, b) The details of the interaction of the light with the discrete particles of the poro-elastic medium may be critical when the beam size is comparable to the particle size.

Figure 2 Photograph of experimental setup. The pulsed CO₂ is at top left and the experimental sandbox is below. Objects to be detected or hydrophones to study the laser-to-acoustic coupling are buried in the sand.

that focusing the laser beam to a spot size on the order of 1mm in diameter greatly increases the audible acoustic sound associated with the laser pulse and, in addition, can cause the production of a flash of visible light at the point where the infrared CO₂ pulse impinges on the sand. We have studied the time-dependence of the acoustic pulse at various depths and angles in the soil for both focused and unfocused laser pulses. For unfocused pulses we find a single acoustic mode with a velocity slightly less than the speed of sound in air with a directionality perpendicular to the soil surface. With a focused beam we detect two distinct acoustic features in the time trace: a sharp pulse with a velocity and spectral content similar to that achieved with the unfocused beam, and, in addition, a second broad pulse with a much lower frequency content which propagates at a slower velocity. We suggest that these two modes may be related to the two Biot modes allowed in poro-elastic media³.

2. EXPERIMENT

A photograph of the experimental setup is shown in Figure 2. The source laser is a LSI pulsed 10.6 μ CO₂ TEA laser with a pulse length of 100ns, a pulse energy of 150mJ, and a repetition rate less than 20Hz. The laser is incident on a 1 m² surface of dry sand about 60 cm deep in which we would bury detectors or various types of subsurface targets. In the present studies of the optical-acoustic conversion mechanism, the acoustic signal was measured with a wide-band hydrophone (0-100kHz) which was buried at various depths and positions in the sand. This configuration contrasts with the experimental setup that we used to image underground objects. For imaging, our best results were obtained with a narrow-band (30kHz) tuned PZT detector which was suspended in the air above the position of the laser pulse on the surface of the sand.

The laser was used in two configuration: unfocused or with a focusing lens to reduce the spot size. The unfocused laser spot is an oval approximately 1.1 \times 0.7 cm in size. A germanium lens with a focal length of 25cm was used to focus the beam to a spot size less than 1mm in diameter, comparable to the size of the sand grains. 10.6 μ light is very effectively absorbed in soil with a reflection less than 10% and skin depth of approximately 5 μ . The sound produced by both the focused and the unfocused beams was audible across the room. With the focused beam the sound was considerably louder and there were flashes of visible light emitted and some movement of sand grains at the spot where the laser hit the surface.

The acoustic signal detected by the buried hydrophone for the focused and unfocused beams is shown in Figure 3 and Figure 4.

Figure 3 The time trace of the acoustic signal measured by a buried hydrophone as a result of a pulse from the unfocused laser on the sand surface.

Figure 4 The time trace of the acoustic signal measured by a buried hydrophone as a result of a pulse from the focused laser on the sand surface.

Figure 5 Experiment to measure the velocity in sand of the acoustic features in Figure 3 and 4.

Figure 6 The arrival time vs. distance for the features indicated by the arrows in the inset. The propagation velocity in sand of the two features is determined as indicated from the slope of the lines.

The initial spike is electrical noise caused by the laser discharge. The acoustic pulse is dominated by a sharp peak with a width (about $10\mu\text{s}$) that is probably limited by the bandwidth of the 100kHz detector. For the focused beam only, there is a second, much broader feature with a peak-to-peak width of about $300\mu\text{s}$.

To determine the propagation speed of these two different acoustic features observed with a focused laser beam, we measured the change in the acoustic signal as a function of distance from the laser spot to the detector using the configuration in Figure 5. The time trace of the acoustic signal measured by a buried hydrophone as a result of a pulse from the focused laser at two different positions on the sand surface are shown on the left in Figure 6. Identifying the sharp feature by the initial spike, and the broad feature by the dip between the two broader peaks, in Figure 6 we plot the time delay after the laser fires of these two features as a function of distance from the laser spot to the detector. By taking the slope of these two curves, we find the velocities of the two features are dramatically different. The sharp feature propagates with a velocity around 255 m/s, while the broad feature propagates with a velocity of about 75 m/s.

The observation of acoustic modes with two different velocities in porous media is a well-known phenomena. In the theory of Biot, the solution for acoustic propagation in a random porous elastic media gives rise to two modes: a mode in which the frame and the fluid move in phase (compressional wave) and an additional mode in which the motion of the frame is out of phase with the motion of the fluid. Typically the in-phase mode has a velocity which is close to the velocity of sound in the fluid, while the out-of-phase mode, the "Biot slow wave" has a lower velocity. If we tentatively make an identification of the features we observe with the Biot modes, the sharp feature which travels at 255 m/s, close to the velocity of sound in air, could be the Biot in-phase mode, while it is natural to identify the broader feature, low-velocity feature with the Biot slow wave. Note that we only observe this second, slower wave under excitation with a focused laser beam.

To measure the angular dependence of the magnitude of the acoustic signal from the focused beam, we positioned hydrophones at different angles along an arch buried in the sand centered on the position of the laser spot, as shown in Figure 7. In Figure 8 and 9, we plot the peak amplitude of the sharp "fast-wave" signal and the

Figure 9 Angular dependence the amplitude of the “slow wave” feature produced with a focused laser beam.

broad “slow-wave” signal as a function of angle from the normal. The two modes show a dramatic difference in angular distribution, with the slow wave signal propagation peaked at angles perpendicular to the surface, while the fast-wave signal strength is peaked along the surface of the sand. The angular dependence of the fast-wave mode is hard to understand, since when the beam is unfocused we observe only a single mode with a shape and velocity similar to the fast-wave signal, but with an angular distribution sharply peaked at a direction normal to the surface, as shown in Figure 10.

The unfocused beam has a Rayleigh length d^2/λ on the order of 1 cm, so for distances into the sand on the order of 1 cm the unfocused beam looks like an extended source. The focused beam, on the other hand, has a Rayleigh length less than a millimeter and is a point source to a good approximation. Since the radius of the detector arch was about 10 cm, it is unlikely, however, the difference between the fast-mode angular dependence seen in Figure 9 and 10 can be accounted for by such physical optics effects. It is more likely that the different acoustic excitation physics between the broad laser beam and the focused beam, such as illustrated in Figure 1, may account for these differences. We will return to this question later.

Table I summarizes the differences between the two acoustic modes that are observed with the focused laser beam. We note that these differences may impact on the utility of the two modes for underground detection and imaging. The fast mode, having a

Table I: Comparison of Fast-Wave and Slow-Wave laser-induced acoustic features produced with a focused laser beam.

Comparison of Fast and Slow Acoustic Waves

	Fast Wave	Slow Wave
Unfocused Beam	Yes	No
Focused Beam	Yes	Yes
Speed	250 m/s	75 m/s
Frequency peak	100 kHz*	3 kHz
Directivity	Along Surface	Perpendicular to Surface
$\alpha(\omega)$	Unknown	Unknown

* Band-width of detector=100kHz ($1/\Delta t_{\text{laser}} = 10 \text{ MHz}$)

higher spectral frequency content may be more useful for high-resolution imaging where a small wavelength is desired. On the other hand, if we have correctly identified the slow wave as a Biot out-of-phase wave, it will see an exceptionally large contrast between the porous soil where the slow wave is allowed and any subsurface non-porous object where, since there is no longer any differentiation between frame and fluid, its propagation is forbidden. There may also be implications about detection strategies, since to the extent that the energy of the slow-wave is carried in the fluid, techniques that measure the motion of the solid surface, such as laser vibrometry, will be less effective than with an ordinary compressional wave. On the other hand, for the same reason the mismatch between the poro-elastic wave and the wave in the air may be less for the slow-wave than the fast wave, so that detection by means of a microphone above the soil may be more favorable for the slow wave.

It is noteworthy that our attempts so far at subsurface imaging with the focused beam have been less successful than our previous work with the unfocused beam. These imaging studies were carried out with an acoustic detector suspended in the air above the surface. It is not possible to say at present whether the lack of success was due to an inherent effect such as the longer wavelength of the slow wave, less efficient acoustic coupling to or from the soil and air, or some interference effects between the fast and slow acoustic waves, or more incidental effects such as noise from the movement of sand grains and drifting of the laser focus due to heating of the air and movement of the surface.

One clue about the mechanism for acoustic excitation is that a flash of visible light is observed which the CO₂ pulse hit the surface of the sand when the beam is focused, but not for the unfocused beam. Origins of this visible light that we considered were black-body incandescence of the sand surface, photoexcitation and luminescence of the sand material, and electric field ionization and recombination. The energy density of the focused beam is sufficient to heat the sand over 10⁶ °C if the effects of radiant emission and conduction are neglected, but this does not seem likely on the relatively long (0.1 μs) timescale of the pulse. Luminescence of SiO₂-based materials is usually very broad-band and can extend into the ultraviolet.

To gather more information about the light emitted when the focused CO₂ laser pulse strikes the sand surface, we measured the spectrum of the emitted light using a multispectral filter and a photomultiplier detector as in Figure 11. The measured spectrum is reproduced in Figure 12 and Figure 13. The emission peaks are negative, because the electron current of the photomultiplier

Spectral Signature of Laser Flash (Focused beam)

is converted to a negative voltage by a voltage-to-current amplifier. Electron photocurrent resulting from the detected light yields a negative voltage.

We have identified emission lines in the spectrum by comparison with the CRC Handbook of Physics and Chemistry. We note that large emission lines associated with ionized nitrogen, oxygen, and silicon are present in the spectrum which implies that the model for optical field ionization is the best model for the production of the light. The concentration of the electric field of the optical signal near the sharp points of the sand grains is the most likely mechanism for the breakdown and ionization of the air and sand.

Focused Beam Surface Interactions

The acoustic production for the focused beam can then be best explained by the collapse of the air following the rapid expansion associated with the ionization and plasma formation as shown in Figure 14. The intense audible noise associated with the focused beam is analogous to the crack associated with an electrical arc or with thunder. One implication of this model is that the sound production for the focused beam is probably primarily as a compressional wave in the air above the soil. The reduced effectiveness of imaging with the focused beam may be a result of the poor coupling of this acoustic compressional wave in air into the soil.

Figure 14 Model for production of light and sound by focused laser beam impinging on soil surface.

The unusual angular dependence of the compressional fast wave for the focused beam seen in Figure 9 may represent the more effective transport of acoustic energy in the air along the surface of the sand than propagation in the sand. In effect, the sound produced by this ionization and collapse travels through the air to a point close to the high-angle, near-surface sensor and then propagates only a short distance into the soil to the detector. Since the velocity of the fast wave is very near the speed of sound in air, it is very difficult to distinguish this propagation channel from propagation through the soil. The slow wave may not have the same channel available to it because a Biot wave will not propagate in a single component fluid such as the air.

3. CONCLUSIONS

The production of acoustic energy in soil by a pulsed CO₂ laser has been studied. When the laser beam is focused to a spot size comparable to the soil grains, a much louder acoustic sound is observed and two different acoustic modes are detected in the soil. One mode, which we identify with a normal compressional acoustic wave has a velocity (255 m/s) close to the speed of sound in air, and a bandwidth of at least 100kHz. The second mode, which we have tentatively identified as a Biot slow-wave phenomena, has a velocity of only 75 m/s and a spectral peak near 3 kHz. By analyzing the visible light emitted by the focused laser beam, we conclude that for the focused laser pulse the acoustic energy is produced by ionization of the air and soil components, with a rapid expansion and subsequent collapse of the air column. Preliminary investigations have indicated that imaging of subsurface objects with the focused beam laser is not as successful as with a broader unfocused beam. This may be a result of the poor coupling of sound produced in air into the soil. Studies to measure the attenuation and dispersion of the acoustic signals produced by the focused and unfocused laser beams are underway.

Laser-induced acoustic detection of buried objects

ABSTRACT

We have investigated the use of acoustic energy produced by a pulsed CO₂ laser to detect objects underwater or buried in sand. The CO₂ laser produced 150 mJ pulses of duration 100 ns. The resulting acoustic pulses were detected with an audio microphone with a response to 15 kHz or a PZT transducer with a resonant frequency at 28 kHz. With the laser incident on the surface of a water-filled tank, acoustic echos were observed from the tank walls and from objects in the tank. For objects buried in sand, changes in the acoustic lineshape related to the presence of subsurface objects were observed. Analysis of the data to extract clear signatures of the mine are in progress.

Keywords: laser-induced, acoustic, land mine detection, photoacoustic, optoacoustic

1. INTRODUCTION

The large acoustic mismatch between granular soil and solid subsurface objects suggests that acoustic methods have considerable promise for land mine detection. Sound velocities in sand or granular soil can be on the order of or less than the velocity in air (330 m/s)¹ while in metals or plastics characteristic of land mine casing or fillers, sound velocities are typically greater than 2000 m/s. The velocity and/or density mismatch between soil and mine creates a large acoustic reflection from the mine.

In common with other anomaly detection techniques, the challenge of acoustic detection is to distinguish the effect of a buried mine from stones, roots, and other clutter in the ground. Two separate approaches to acoustic discrimination depend on the identification of acoustic resonances of the target object, or the resolution of the target shape. While mine-like objects may have identifiable acoustical resonances from a few kilohertz to hundreds of kilohertz, these resonances are strongly damped when the object is in soil. Target identification through shape resolution, on the other hand, requires multiple acoustic sources or receivers to correlate the received signal with the position or angle of the source. Coupling acoustic energy from the air into the soil or matching of separate movable ground-contact transducers makes spatial resolution with acoustic transducers difficult.

Optical methods for the detection or generation of sound have advantages for remote position-sensitive acoustic detection. Optical laser vibrometry is a commercially available tool for the detection of sound at a solid surface which has been applied for the detection of subsurface objects.² The photoacoustic effect, production of sound by laser pulses, has been applied for ultrasonic material characterization^{3,4} and for the study of liquid droplet dynamics.^{5,6} In addition, microwave detection of surface acoustic vibrations has also been used for land mine detection.⁷ These optoacoustic techniques create a number of options for the acoustic detection of land mines. First, acoustic transducers can be used both to generate the acoustic signal and to detect the scattered acoustic energy. Second, sound generated by acoustic transducers can be detected by optical (or microwave) signals. This is the approach of References 2 and 7. Alternatively, sound produced by laser pulses can be detected by acoustic transducers. This method is described in this paper.

Figure 1 presents a concept of how a laser-induced acoustic system could be used to locate and identify mines. A pulsed laser is scanned over the ground. The acoustic signal generated by the laser

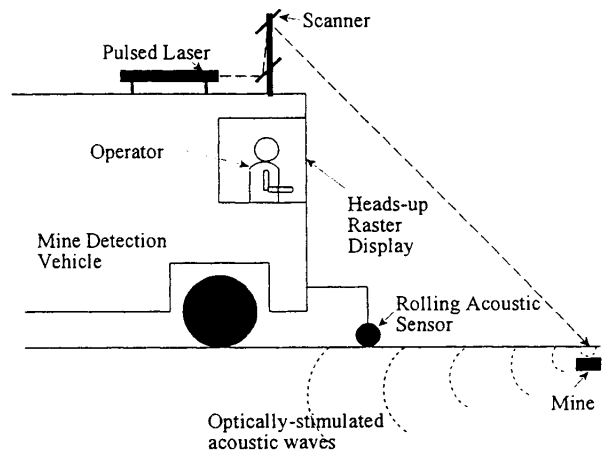

Figure 1. Conceptual laser-induced acoustic land-mine detection technique.

pulses striking the soil is detected by a rolling, ground-contact transducer. Changes in the acoustic signature when the laser pulses are over a subsurface object are encoded into a heads-up display registered with the operator's field-of-view. The correlation of the acoustic signature of an underground object with the position of the laser pulse allows an identification of the location and possibly the shape of the buried object. In concept, this method is similar to location of a structure behind a wall by the change in sound when a percussion source is struck near the target.

It is also possible that sound could be both produced and detected by optical means. This could make possible a remote, non-contact, scanning probe system that could be effective for underground object location and identification. The results of the present investigation will clarify prospects for such a system.

Optical to Acoustic Conversion

Figure 2. Model for conversion of optical to acoustic energy.

2. EXPERIMENTAL RESULTS

A Laser Science LS150 pulsed CO₂ laser was used to create acoustic pulses on striking a surface. The laser was operating at a wavelength of 10.6 μm and pulse length was 100 ns with an energy per pulse of 150 mJ. Although the pulse repetition rate could be as high as 50 Hz, the data here were taken at a repetition rate of 8 Hz. Acoustic pulses when the laser struck a solid surface were audible at distances of a few meters.

Optical radiation at 10.6 μm is typically over 90% absorbed in soil. Our model for the generation of acoustic energy is that the rapid heating and expansion of the soil in the skin depth of the optical radiation leads to a pressure wave in the solid. This process is illustrated in Figure 2. The thermal expansion is also coupled into an acoustic wave in the air above the surface.

Acoustic energy was detected by two transducers: an audio microphone with a high-frequency cut-off near 15 kHz, and a PZT transducer with a resonant frequency of 28 kHz. Experiments in soil were conducted in a 28x32 cm box filled to a depth of about 7 cm with dry sand. Some experiments were also conducted in a 50x30 cm tank filled to a depth of 30 cm with water. Simulated mine targets were metal disks between 3-10 cm in diameter and 1.5-3 cm in height. While metal targets were chosen for convenience, the acoustic mismatch between soil and plastic is nearly as great, and we expect that equivalent results would be achieved with plastic targets.

Figure 3 shows a typical geometry for experiments in the sand box. The PZT transducer is half-buried in the sand approximately 10 cm from the target, and the laser pulse is scanned in rows across the position of the target. The target is buried 2 cm under the surface of the sand. The experiment is then repeated with the target removed from the sand box. Figure 4 shows the transducer voltage as a function of time after the initial laser pulse when the laser pulse is directly over the target position (Scan 3, y=13.5cm, x=13.5cm). The dotted lines in the same figure show the response when the laser is at the same position, but the target is removed.

While it is clear from Figure 4 that there are differences in the signal caused by the target, it is not clear how to process the data to display these changes. In Figure 5 we have taken

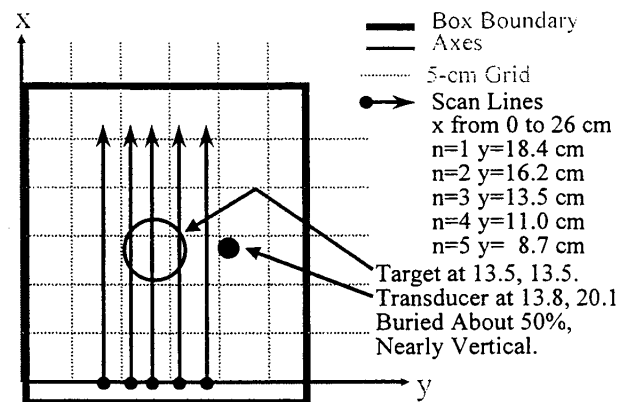

Figure 3. Geometry for experiments in sand.

Figure 4. PZT transducer response as a function of time delay following the laser pulse for the geometry of Figure 3 with the laser pulse incident at $y=13.5$ cm, $x=13.8$ cm. The solid line is with the target present and the dotted line is with no target.

Figure 5. Fourier transform of the data of Figure 4. Solid line is with the target present and the dotted line is with no target.

a Fourier transform of the data in Figure 4. The dominant feature in the plot here is the 28 kHz response peak of the PZT transducer. While there are consistent differences from run to run between the data with the target and without the target, there is no obvious unique identifying feature of the target.

In Figure 6 the difference between the transducer signal with and without the target present is plotted in gray-scale intensity as a function of time delay and laser position for scan number 3 in Figure 3. The effect of the target at $x=13.8$ cm is obscured by the increase in signal strength as the laser excitation approaches and recedes from the point closest to the fixed detector position at $x=13.8$ cm, $y=20.1$ cm. In addition, the difference signal is dominated by changes in the phase of the received signal that may be caused by increased propagation velocity through the target or by slight repositioning error between the data with and without the target.

The arrival time of the initial acoustic pulse is consistent with a propagation velocity near 350 m/s. While as noted above the velocity of sound in sand is highly variable, this is close enough to the velocity of sound in air to leave doubt whether the acoustic signal is propagating primarily through the air or through the sand.

In order to demonstrate conclusively transfer of acoustic energy from the laser pulse into the medium and to improve the chances for detection of a target, we performed experiments on underwater targets in an experimental water tank as illustrated in Figure 7. CO_2 radiation is absorbed very efficiently in water with a reflection coefficient of less than 1% and an absorption length of a few microns. The response of a completely submerged detector was measured as the laser beam was scanned toward an aluminum target extending nearly to the surface of the water.

Figure 6. Difference signal for transducer voltage with target present minus voltage with no target present as a function of time delay and laser position x for scan with $y=13.5$ cm (see Figure 3). The grayscale calibration is in microvolts.

Figure 7. Experimental setup for laser-induced acoustic detection in water tank. As indicated, the time delay between the reflection from the target and the direct reception from the excitation pulse will be expected to decrease as the laser moves closer to the target.

Figure 8. Transducer voltage as function of time delay and laser position for detection of a target in water. The reflection of the target is indicated. The grayscale calibration is in volts.

The target reflection is clearly visible in Figure 8 as the acoustic reflection feature that approaches the direct acoustic reception time delay as the laser excitation approaches the target. From the slope of the target track the propagation velocity can be determined to be consistent with the known speed of sound in water ($v_s = 1500$ m/s). In contrast to the situation in sand or soil, sound propagation in water is only weakly attenuated. The significance of this experiment is that it conclusively demonstrates that laser-induced acoustic signals are transmitted through the target medium (and not just through the air), and that under ideal circumstances reflections from a target can be directly observed.

Acoustic reflections from the enclosure walls have also been observed in experiments in sand. Figure 9 and 10 show the

Figure 9. Experimental setup for detection of target in dry sand with acoustic microphone detector.

Figure 10. Acoustic microphone signal as function of time delay and laser position. Calculated acoustic arrival times are shown for direct transmission from the laser to the detector (+), for reflection from sides of box (\times , \diamond , \square , \circ), and for reflection from the box bottom (∇). The calculated arrival time for reflections from the target is indicated by the triangles (Δ).

experimental setup and data taken with the acoustic microphone in sand. Reflections from the sides of the box are observed in the diagonal bands in Figure 10. The calculated arrival times for direct transmission from the laser spot to the detector and for reflections from the four sides and bottom of the box are indicated by lines in Figure 10. The calculated lines agree well with the features observed in the data using an acoustic propagation velocity of 260 m/s in dry sand under the soil packing conditions of the experiment, about 75% of the velocity of sound in air. There is no obvious feature at the expected arrival time for reflection from the target, indicated in the figure by the triangles. While there are modifications in the acoustic line shape when the target is removed as shown in Figure 11, it is not easy to identify these subtle changes from the data in the absence of a control data set without a target. What is needed is a way to process the data to extract out the differences in the signal with and without the target present.

One possible processing technique is to use the acoustic signal when the laser spot is far from the target as a control to compare to the signal when the laser spot is near the target. In this way the signal received when the laser is over clear ground could be used as a background to detect the anomaly when the laser is over a buried object. Unfortunately, if the separation between the laser spot and the detector position is changing as the laser is scanned, as in Figure 10, changes in the signal as the laser excitation is over the target are difficult to extract from the changes caused by the spot moving closer to or farther from the detector.

A solution to this problem may be found if the separation between the laser excitation source and the detector can be fixed as the laser spot is scanned. This may be achieved in a practical mine detection system if the detection system as well as the excitation system is laser-based. For example, the CO₂ laser excitation system could be maintained in registration with a laser vibrometer acoustic detector as the two are scanned across the ground.

Figure 12. Experimental setup for the acoustic difference experiment. To simulate the registered motion of the laser and detector, the sand box with the mine-simulant target is moved with respect to the laser and detector. The target is buried about 1 cm below the surface of dry sand.

Figure 11. Microphone signal received with and without buried target between laser spot and detector. Experimental configuration is illustrated in inset.

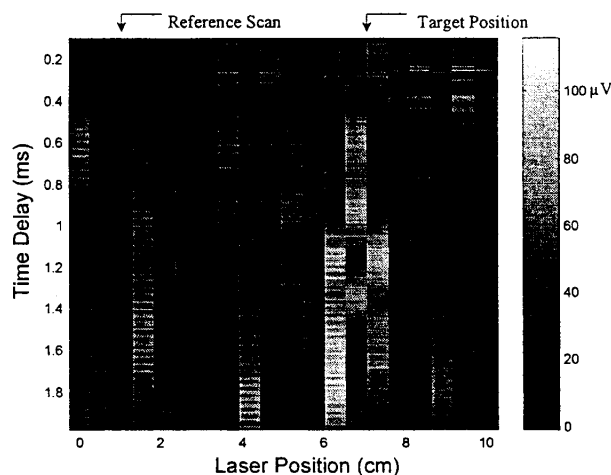

Figure 13. Acoustic anomaly detection as a function of time delay and laser position. The gray scale represents the absolute value of the difference between the time record of the microphone voltage at any laser position and that measured at $x=1$ cm when the laser is far from the target. A clear anomaly is observed near the target position at $x=7$ cm.

As a test of acoustic anomaly detection when the source and detector are maintained in registration, we mounted a microphone in the air over the sand and simulated the coordinated movement of the source and detector by moving the sand container with the detector and laser spot fixed. This experimental configuration is shown in Figure 12. The mine-simulant target was a metal cylinder about 3 cm in diameter and 2 cm high buried with its top about 1 cm under the surface of dry sand. While the acoustic signal will be received in the air above the soil in this configuration, it is reasonable to assume that there will be modification in the sound when the excitation over a near-surface buried object due to changes in the acoustic resonant structure of the soil. In fact, this is the method by which percussion is used to detect objects behind a wall. It is also notable that the configuration in Figure 12 is a non-contact measurement, a considerable advantage in detection of mines.

We processed the data by subtracting the detector signal when the excitation was far from the target from the intensity vs. the time scan at each position. The result of this difference signal is shown in Figure 13, where the data from the third distance bin is subtracted from each of the other data sets and the absolute value of the difference is plotted vs. position and time delay. A clear anomaly is observed at $x=7$ cm when the laser spot is over the position of the mine. Localized anomalies with strong contrast as seen in Figure 12 were not observed in scans taken with no target present. We have not completed experiments to determine if the time delay where the largest difference is observed is correlated to target depth.

3. CONCLUSIONS

Pulsed CO_2 laser-induced acoustic excitation has been shown to be an effective way to get localized acoustic excitation in soil without directly contacting the ground. The acoustic signal detected by a PZT transducer or by an audio microphone has been shown to be sensitive to the presence of near-surface buried objects. While direct target echos have been observed in experiments with laser-induced sound in water, the modification of the acoustic signal by objects under dry sand is complex and not easy to interpret. In experiments with a fixed acoustic receiver in contact with or under the sand, the changes in the acoustic signal when the laser excitation is close to the target position are difficult to distinguish from the changes that result from the change in separation between the scanned laser pulse and the receiver. By maintaining a fixed separation between the laser spot and the acoustic receiver, we have been able to identify acoustic anomalies by taking a difference of the response when the laser is near the target and the response when the laser is far from the target.

These experiments indicate that laser-induced acoustic detection of land mines is a promising area for further study. Our results indicate significant modification of the acoustic signal when the laser is directly over a buried object, so shape discrimination of man-made objects from natural underground objects is possible. Processing of the acoustic signals to identify anomalies from buried objects is complex. Background subtraction has been shown to be feasible, but it is necessary to take account of the changing distance between the scanned laser spot and the microphone. Optical detection by laser vibrometry may be particularly effective in conjunction with laser excitation since the excitation and detection positions can be kept in registration without ground contact or mechanical detector movement.

Additional experiments are required to determine if target depth can be correlated with the time delay associated with the anomaly. In addition, the application of the technique in different types of soils needs to be established. The experiments in dry sand reported here may represent one of the more difficult mine detection scenarios since acoustic propagation in sand is strongly attenuated and depends in a complex way on the packing of the sand grains. Clay soils may allow acoustic detection at greater distances. More sensitive acoustic detectors or accelerometers may improve prospects as well.

Imaging of Buried Objects by Laser-Induced Acoustic Detection

S. W. McKnight*, W. Li, and C. A. DiMarzio

Center for Electromagnetics Research, Northeastern University, Boston, MA 02115

ABSTRACT

We report here on the use of acoustic pulses generated by a pulsed-laser incident on the ground surface for the depth- and shape-resolution of buried objects. The laser-induced acoustic wave has considerable advantages over other acoustic wave generation techniques for landmine detection applications. (1) It is efficient because the sound is generated directly in the ground. (2) The acoustic source can be precisely positioned or scanned by optical redirection of the laser spot. (3) Remote, non-ground-contact detection can be accomplished with a receiving microphone in the air or by using optical vibrometry of the soil surface for detection. Research has been focused on the data acquisition and signal processing applicable to de-mining scenarios. A de-convolution method using a Wiener filter is introduced to the processing of data. By scanning the laser position and filtering the time-trace of the reflected acoustic pulse, we have obtained 3D images of the underground objects. The images give us the clear discrimination of the shapes of underground objects. The quality of the images depends on the mismatch of acoustic impedance of buried objects, the bandwidth of acoustic sensor, and the selection of filter function.

Keywords: Laser-induced acoustic imaging, buried-object detection, landmine detection, photoacoustic, optoacoustic

1. INTRODUCTION

Current de-mining techniques are limited in their ability to resolve sufficient detail to allow the land mine to be identified and differentiated from stones, roots, or stray metal particles. Standard inductive techniques can find low-metal-content mines, but over 300 false alarms must often be investigated for every mine found. These false-alarm rates are unacceptable, even for non-time-critical humanitarian de-mining efforts, due to the enormous areas that need to be cleared as well as the risk of carelessness and inattention caused by a large number of false alarms. A technique that would allow imaging of the shape of a buried object would enable an enormous reduction in the number of underground clutter objects that would need to be investigated. Unfortunately, electromagnetic or acoustic wavelengths that easily penetrate the ground are too long to adequately resolve the shape of scattering objects in the far-field. However, near-field resolution on a sub-wavelength scale is possible with long-wavelength probes in attenuating media if sources can be localized within a few absorption lengths of the object.

Acoustic probes of buried objects are attractive because of the large impedance contrast between solid underground objects and granular soil even for non-metallic targets. Since coupling of sound into and out of the soil is difficult because of the mismatch at the air-ground interface, previous work has used optical¹ or microwave² vibrometry to directly detect the motion of the ground surface. Others have proposed the use of ultrasonic vibrometers to identify landmines by the discrimination of characteristic acoustic non-linear effects.³ We have reported on the use of a short-pulse CO₂ laser to generate acoustic pulses directly in the ground.⁴ Detection was by means of a PZT transducer either buried in the ground or suspended in the air above the laser pulse spot. The acoustic signal was dominated by detector ringing at the 30 kHz resonant frequency, but we were able to detect acoustic anomalies by background subtraction when the laser source was incident on the surface directly over the position of a buried object. In this paper we report on the application of a Wiener filter deconvolution to recover the acoustic pulse echo from our resonant PZT detector and demonstrate that depth resolution can be obtained by time-sampling the filtered signal. Scanning the laser source in registration with the transducer suspended above the ground allows us to map out the shape of a buried object. We demonstrate the application of this technique in determining the shape of a shallow buried non-metallic target, and in differentiating two closely buried objects.

2. EXPERIMENT

The experimental configuration is indicated in Figure 1. The laser source is a Laser Science CO₂ laser with a pulse width of 100 ns and a pulse energy of 150 mJ. Our experiments were carried out with a laser pulse repetition rate of 8 Hz, corresponding to an average power less than 1.2 W. The laser spot is about 1 cm in diameter without focusing.

Our target is a hard rubber hockey puck buried between 0.1 and 2.0 cm under the surface in a box of dry sand. The velocity of sound in hard rubber, about 1600-1800 m/s, creates a good contrast with the velocity in dry sand which we have measured to be 300 m/s, in good agreement with the literature.⁵ The sound velocity in plastic landmine materials are likely to be in the range 1600-2800 m/s.⁶

The laser pulse is strongly absorbed within the first 1 μm of the surface, instantaneously heating the sand about 3°C, and the accompanying pressure wave creates an acoustic pulse. The surface displacement of the sand was measured by a laser vibrometer at about 2 nm, and although we have not measured the energy of the sound pulse, it is clearly audible across a 5 m room.

The detector is a PZT transducer with a resonant frequency of 30 kHz suspended 10 cm over the surface of the sand. Since ambient room noise is small at 30 kHz, the data could be taken without averaging. Data with a lower-frequency ($f \leq 15$ kHz) broad-band microphone were typically averaged over eight laser pulses. The microphone data were not as successful for imaging purposes, either because of the lower signal-to-noise or possibly because of the longer acoustic wavelength. During the experiment the laser spot and the detector are traversed in tandem across the sand box, with the laser spot/detector distance kept as nearly fixed as possible. In some cases the surface of the sand was not level, and that caused the distance to vary as we scanned over the mine location.

Figure 1. Experimental configuration for laser-induced acoustic experiment with background subtraction or Fourier filtering.

3. RESULTS

In Figure 2 we show a time trace of the detector voltage as a function of time for two single laser pulses—one when the laser and detector are over our target, and one when they are far from the target. The dominant feature in both of these traces is the detector ringing at 30 kHz. While the difference between the traces with and without the target is well above the noise, it is difficult to distinguish characteristics of the target from this data. We have processed this data by using a background subtraction method. In this method, as the laser and detector are scanned across the target we take the acoustic signal as a function of time at each laser position, $y(t, x)$, and subtract the acoustic signal at some reference position where we know there is no mine, $y(t, x_0)$.

An example of the application of this technique is shown in Figure 3. The top panel illustrates on a gray scale the detector signal as a function of time for 25 different positions x as the laser and detector are scanned across the position of a target. The target in this case is a hockey puck buried vertically (with

Figure 2. Unprocessed detector signal for a single laser pulse when the laser is over the target (solid) and when it is not over the target (dotted).

its curved side up) with its center at $x=6$ cm. Since the initial acoustic pulse arrives at the detector at the same time for each trace, subtraction of data from the second position ($x=0.5$ cm) from each of the traces reveals the presence of the buried object as illustrated in the bottom panel.

For this technique to be successful, it is necessary that the $t=0$ point be perfectly correlated for each trace. Since the beginning of each time trace is triggered by the laser pulse, this requires the surface of the ground to be perfectly level. If the distance between the laser spot on the ground and the detector changes as the laser beam is scanned, the phase difference between the signals will cause large spurious differences. In addition, as seen in Figure 3 this subtraction does not remove the 28 kHz detector ringing.

To remove the background, including the detector response, in all cases, we have implemented a normalization procedure on the Fourier-transformed data. The justification of this processing is as follows. We assume that the received signal $y(t,x)$ is a convolution of the actual acoustic signal $s(t,x)$ and an unknown time-dependent detector response $h_d(t-t')$, with an added noise term $n(t)$, as shown below in Equation 1.

$$y(t,x) = \int s(t',x) h_d(t-t') dt' + n(t) \quad (1)$$

The Fourier transform of this equation is:

$$Y(\omega,x) = H(\omega)S(\omega,x) + N(\omega) \quad (2)$$

Since we assume that the detector response $H(\omega)$ is independent of position, we can use the data when there is no target $Y(\omega,x_o)$ to get an estimate of $H(\omega)$. Assuming that $S(\omega,x_o)$ is an impulse function, since the laser pulse width is instantaneous on the acoustic timescales, we find that $H(\omega) = Y(\omega,x_o)$. In the absence of noise, we can then recover the real acoustic signal $S(\omega,x)$, assumed to be an impulse plus one or more echo signals, from the unknown data $Y(\omega,x)$ by dividing by $Y(\omega,x_o)$.

This process gives rise to singularities at frequencies where there is little amplitude in the Fourier spectra of the reference signal ($Y(\omega,x_o) \approx 0$). To allow for these cases we add a small real constant ϵ to the Fourier spectrum that we use for a reference. This process is implemented to get an estimation of the acoustic signal $\hat{S}(\omega,x)$ as shown in Equation 3.

$$\hat{S}(\omega,x) = Y(\omega,x) F(\omega) = Y(\omega,x) \left[\frac{Y^*(\omega,x_o)}{|Y(\omega,x_o)|^2 + \epsilon} \right] \quad (3)$$

The filter function $F(\omega)$ defined in Equation 3 is a variation of a Wiener filter⁷. At frequencies where $Y(\omega,x_o)$ is large compared to ϵ , $F(\omega)$ achieves a deconvolution of $Y(\omega,x)$. At frequencies where $Y(\omega,x_o)$ is small compared to ϵ , $F(\omega)$ reduces to a matched filter.

The selection of the constant ϵ and the maximum spectral frequency included in the filtering process, f_{max} , is illustrated in Figure 4. The values in the Figure, $f_{max} = 52.3$ kHz and $\epsilon = 1.75$, were chosen empirically, based on the consideration that almost all of the signal strength is concentrated below 50 kHz. In fact, the results of the filtering process are not drastically affected by the

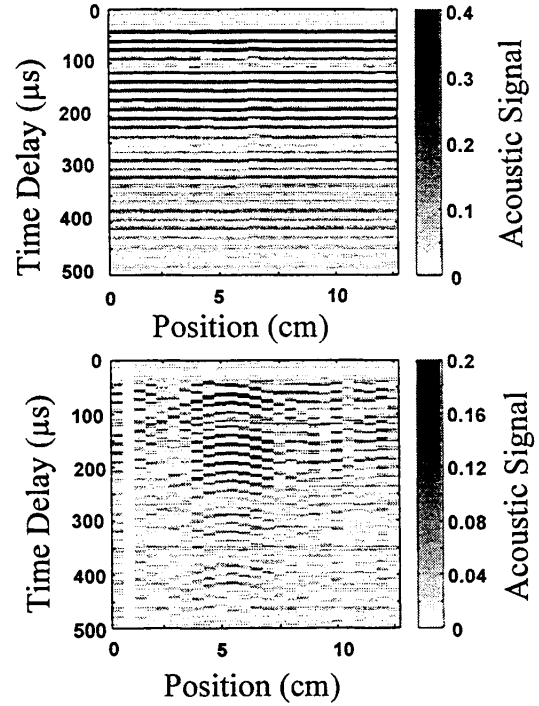

Figure 3. Example of background subtraction technique. Top: A series of time traces of the detector signal a function of time delay after the laser pulse, taken at different positions as the laser/detector are scanned over a target (vertical hockey puck). Bottom: same data with the data in the second horizontal position subtracted from each time trace.

Figure 4. Fourier transform of reference laser-induced acoustic pulse received by PZT transducer, illustrating the selection of the frequency cut-off f_{max} and the constant ϵ .

choice of f_{max} and small variations in ϵ do not have a significant effect. The result of the application of the filtering process in Equation 3 to the data in Figure 3 is shown in Figure 5. The filter has removed the detector ringing and the surface of the puck is clearly indicated by the echo pulses.

The effectiveness of this Fourier filtering technique under conditions where the ground surface is not level is shown in Figure 6 where the top surface of a hockey puck that was deliberately placed under the ground in a tilted position. In this Figure, the strong return from the ground surface is shown as well as the weaker return from the puck surface. The variation in the time delay of the surface return with laser position indicates that the ground surface is uneven in this experiment, so an intensity subtraction as performed in Figure 3 would be impossible. Nevertheless, the Fourier filtered signal effectively images the puck

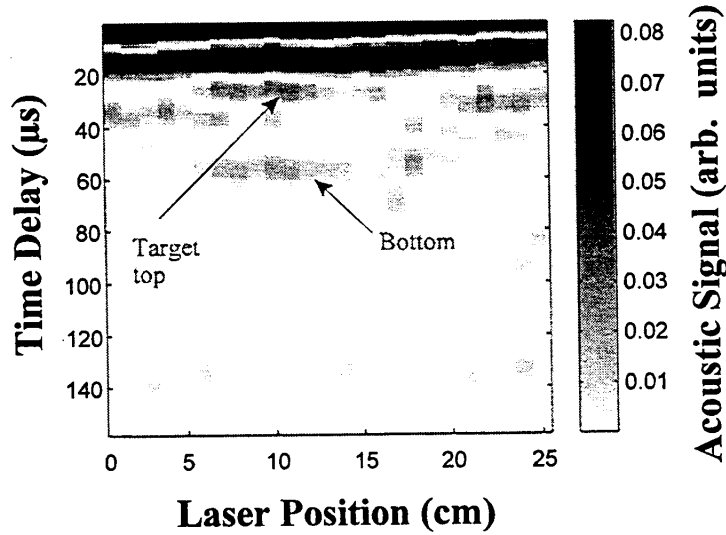

Figure 7. Fourier-filtered acoustic data for hockey puck buried horizontally under surface of dry sand. Echoes from the top and the bottom of the puck are visible.

surface underground. Using a velocity $v_s=300$ m/s that we have measured for the speed of sound in dry sand, we can convert the time difference between the surface return and the return from the puck into a distance under the surface: $d=v_s \Delta t/2$. (The factor of 2 here corresponds to the round trip of the sound from the surface to the puck and then back to the surface.) The data indicate the surface of the puck slopes from about 1mm under the surface to 1.2cm under the surface, in good agreement with the actual puck placement.

Figure 7 shows the Fourier-filtered return from a hockey puck buried horizontally with its top surface 4mm under the surface of the sand. In this Figure, not only is the top surface of the puck well imaged, but the return from the bottom of the puck is also

Figure 8. Experimental configuration for laser-induced two-dimensional scanning. The detector and laser are scanned in registration in the x- and y-directions. The time delay Δt identifies the depth of the object.

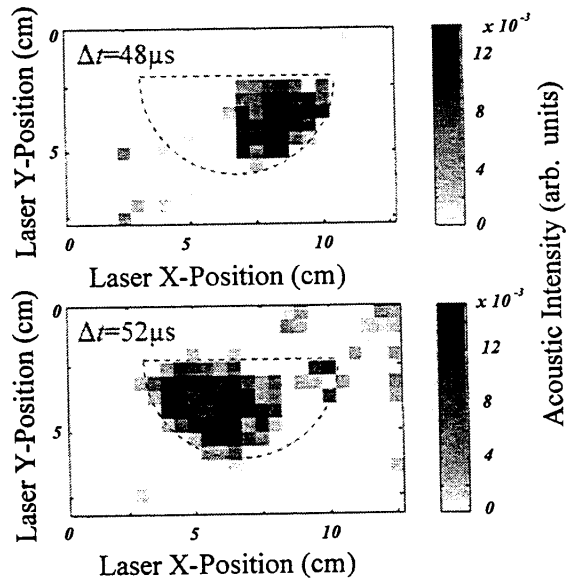

Figure 9. Results of two-dimensional scanning of underground target. The return signal strength is indicated at two different delay times shown, as a function of x- and y-position. The position of the target, a half-hockey puck, is indicated by the dotted lines. The shift of the signal from the left half of the target the right half at longer Δt is due to a slight tilt of the puck.

Figure 10. Sum of acoustic return from $\Delta t=45$ to $60\mu s$ along with shape of actual buried object, showing imaging of object shape in horizontal plane.

apparent near a time delay of $60\mu s$. The time delay between the return from the top surface and bottom surface of the 2.5cm thick puck is consistent with a velocity of sound in the hard rubber of 1600 m/s, within the range expected for this material. The ability illustrated in Figure 7 to image both surfaces of an object may be a powerful tool for object identification.

Three-dimensional imaging of object shape can be accomplished by combining a two-dimensional horizontal scan with the information on depth gained by the time delay measurements. This is illustrated in Figure 8. The laser spot is moved across the surface over the position of the underground object in registration with the suspended acoustic receiver. When the spot is over an underground object, an acoustic return will be detected at a time delay characteristic of the depth of the surface of the object. The results of applying this technique to a buried test target consisting of a hockey puck cut in half are shown in Figure 9. The actual position of the target is indicated by the dotted lines on the figure, and the acoustic return at two different delay times, $\Delta t=48$ and $52\mu s$ are shown in the upper and lower part of the figure. The shape of the target is well indicated and the approximately 1 mm tilt of the surface results in the right half of the surface being imaged at the earlier time delay and the left half of the surface selected at the later time delay. By summing up the returns over all time delays, the composite object shape is determined in Figure 10.

Figure 11. Experimental configuration for determining horizontal resolution of scanning laser-induced acoustic detection. The targets are half-hockey pucks set vertically in sand with flat edge up.

Figure 12. Sum of Fourier-filtered acoustic returns for all time delays vs x- and y-position for two targets as in Figure 11 with a separation $d=2$ cm.

To determine the horizontal resolution limit of the scanning technique, we used as a target two half hockey pucks buried vertically so their horizontal cross sections were rectangular as shown in Figure 11. We then varied the separation between the two pucks to see when we could not distinguish them as two separate objects. An x-y scan across the two half pucks when they were separated by 2cm is shown in Figure 12, and the acoustic signal vs. time delay and horizontal position for a single scan perpendicular to the two pucks is shown in Figure 13. It is clear that the two objects are well resolved and imaged at a separation of $d=2\text{cm}$, and even at a separation of $d=0.5\text{ cm}$ it is apparent that there are two objects. This resolution might be improved by focusing down the size of the laser spot which was about 1 cm in diameter for these experiments.

4. CONCLUSION

We have shown that sound pulses induced by a pulsed CO_2 laser incident on the surface of dry sand and detected with an acoustic transducer suspended over the surface can be used to determine the shape of buried objects. The ringing of the acoustic transducer was removed by a Fourier filtering technique similar to a Wiener filter. The technique is able to image the vertical dimensions of the underground object with a resolution of better than 2mm and the horizontal resolution is better than 0.5 cm. This ability to do three-dimensional acoustic imaging of underground objects has great potential for reducing the false alarm rate in de-mining operations by discriminating target from clutter on the basis of shape. The technique does not require any ground contact and the laser acoustic source can be easily redirected by scanning mirrors. A promising extension of the technique would be to use a laser Doppler vibrometer to measure the vibration of the ground surface in conjunction with the laser source, so that both source and receiver could be remotely located and scanned either together or independently. Experiments along this line are underway.

ABSTRACT

The use for subsurface buried object detection of high-frequency (15-30 kHz) acoustic waves generated by CO₂ laser pulses incident on the surface of dry sand has been demonstrated previously. In this work, field tests of the technique have demonstrated imaging of landmine simulants buried 2.5 cm below the surface in an outdoor test track. Acoustic finite-difference time-domain calculations have given insight into the observed acoustic lineshapes and verified that the over-estimate of the target dimensions in the outdoor field trials may be related to the lower frequency detector used in these measurements. The models also suggest that a large increase in detected signal may potentially be gained by the use of a Laser Doppler Vibrometer interfacial velocity detector in the place of the present airborne microphone.

Keywords: Laser-acoustic, underground imaging, land mines

INTRODUCTION

Acoustic sensing is a promising technique for the detection of low-metal-content buried land mines due to the large impedance mismatch between the porous soil and the solid non-metallic mine case. As in most mine detection strategies, however, the key is reducing false alarms by distinguishing the buried mines from clutter objects (rocks, roots, etc.). Most of the work in acoustic detection has focused on relatively low acoustic frequencies (<1kHz) where resonant oscillations of the soil above the compliant mine cover plate have been observed in both frequency-domain detection of ground motion above the insonified soil¹ and in the time-domain response to surface wave pulses.² In addition, acoustic non-linearities in the mine casing have been exploited to distinguish mines from other underground objects.³

In contrast to these low-frequency techniques, we have reported previously on a technique to probe buried objects with high-frequency ($f > 20$ kHz) acoustic waves generated by directing a pulsed CO₂ laser at the ground surface.⁴⁻⁶ At these frequencies acoustic waves are attenuated within a fraction of a meter in soil, but with the laser source it is possible to create an acoustic wave in close proximity to the buried mine, even at a safe stand-off distance. We have demonstrated that it is possible to detect the echoes from a buried object with a non-contact microphone in the air above the laser source. Since the acoustic wavelength in soil at these frequencies is about a centimeter, it is possible to probe the shape of the buried object by scanning the laser spot. In experiments in a laboratory sand box, we have demonstrated shape resolution in the horizontal plane of 0.5cm, with depth resolution of a few millimeters.⁵ Shape and depth resolution of this order could provide a powerful discriminator for clutter objects, drastically reducing the false-alarm rate.

In this work we report on the application of our technique to image mine simulants in an outdoor field trial. We also report on computational simulations of the laser-induced acoustic effect which have enabled us to identify the source of image features and make predictions of the sensitivity limits of the technique.

EXPERIMENTAL RESULTS

CO₂ radiation is efficiently absorbed in the first few microns of soil. With a sufficiently energetic pulsed source, the rapid heating and thermal expansion caused by the absorption creates a broad-band acoustic pulse. Our laser source is a pulsed laser manufactured by LSI, Inc. with a 100mJ pulse energy, 100ns pulse length, and 20 Hz repetition rate for a modest 5W average

Figure 1. Laser-generated acoustic pulse measured by wideband hydrophone located a few millimeters under the surface of dry sand.

Figure 2. Amplitude of Fourier transform of laser-generated acoustic pulse in Figure 1, indicated bandwidth of laser-generated acoustic source.

power. It creates an acoustic “snap” which is audible at in air a distance of several meters from the approximately 1cm-diameter laser spot. The acoustic pulse as detected with a wide-band B&K, Inc. 100kHz hydrophone 8 mm under the surface of dry sand is shown in Figure 1. The magnitude of the Fourier transform of this pulse, shown in Figure 2, indicates a peak energy intensity between 15 and 25 kHz with significant amplitude from DC to 60 kHz. Note that the data in Figures 1 and 2 have not been corrected for the frequency-dependent attenuation in the propagation path. The wide-band nature of this source contrasts sharply with the low-frequency sources employed in other acoustic detection schemes.

In our previously reported imaging results, we used a narrow-band 30kHz PZT detector suspended in the air over the laser spot to detect the sound reflected from buried objects. This detector had the advantage of removing the omnipresent low-frequency acoustic noise from our signal, but required a Fourier-domain filtering technique to deconvolve the echo pulse from the detector ringing. It also exploited the bandwidth of our acoustic source and permitted high-resolution shape- and depth-imaging of buried non-metallic objects.

To test this technique under more realistic field conditions, we took our laser source to the Northeastern University Dedham test track facility, where nine mine simulants are buried along with several clutter objects in a 2.3m x 21m track filled with screened loam and spanned by a concrete and metal track that carries an instrument cart. A photograph of the laser source on the instrument cart is shown in Figure 3. The acoustic detector for this experiment was an Radio Shack 33-1073A unidirectional acoustic microphone with a nearly flat audio response below 15kHz. This relatively low frequency detector proved to be overly sensitive to low-frequency noise and degraded the resolution of the detector as shown below.

The target we concentrated on was an M-14 antipersonnel land mine simulant with the charge removed and replaced with silicone filler, buried with its top plate 2.5cm below ground surface. This mine is small in size (56mm diameter x

Figure 3. Field test of laser acoustic detection at the Northeastern University Dedham test track. The laser, power supply, and data acquisition computer are mounted on the cart, and the microphone detector is suspended just above the ground over the focused laser spot.

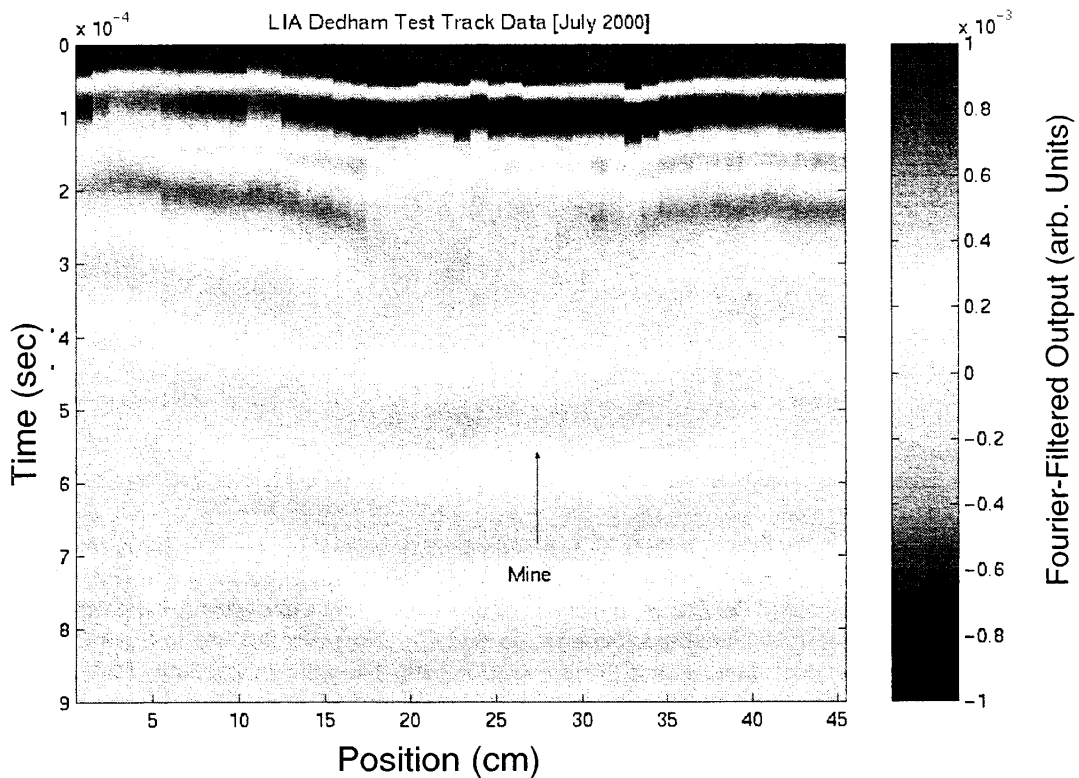

Figure 4. Processed acoustic signal as a function of position as the laser source is moved across a buried M-14 land mine simulant. The detector was an acoustic microphone with bandwidth 0-15kHz and the mine simulant was located near the 25 cm point.

40mm high) and has almost no metallic content. It is considered very difficult to detect by convention means. We moved the laser cart over the centerline of the mine, stopping to take a series of eight shots every 1.2 cm. The laser was focused to a spot about 0.5cm in diameter and the microphone was suspended about 4cm over the laser spot. We processed the microphone data first by normalizing the peak amplitude of the signal to correct for different acoustic intensity created when the laser pulse struck different parts of the soil surface (embedded pebbles, etc.). Then we applied the Weiner Fourier filter as described in Reference 6. The data is shown in Figure 4. The Weiner filter was not as successful in removing detector characteristics as in our experiments in the lab with the PZT detector, and the uncanceled detector ringing is the dominant feature of the processed data. Nevertheless, there is a clear anomaly at the position of the M-14. The size of the anomalous region exceeds the 5.6cm diameter of the mine by a factor of two, but is still considerably less than the region of soil disturbed during mine emplacement (~20 cm diameter). We will demonstrate in the next section that the most likely cause of this is the reduced resolution caused by the lower frequency detector.

ACOUSTIC MODELING

To understand the line shapes and acoustic effects in the laser-induced acoustic detection technique, we have applied a two-dimensional acoustic Finite-Difference-Time-Domain (FDTD) computation to model the problem. The soil was modeled as a linear and lossless effective media—no attempt was made to simulate the porous nature of the medium. The laser source was assumed to be a point source excitation at the surface of the soil and we did not model the surface roughness or the noise environment. The calculation was second-order in space and time on a two-dimensional Cartesian grid with a march in time. The density and sound speed were taken from empirical data, and an absorbing boundary was placed at the edge of the domain. The parameters for the calculation are indicated in Figure 5, which also indicates the alternative positions of the acoustic point source and three modeled detectors: a microphone in the air above the source, a hydrophone in the soil under the pulse, and a surface motion sensor such as a laser Doppler vibrometer. The goals of this calculation were: 1) to understand the time-domain acoustic

Numerical Set-Up

Source: 1 cycle, 100 kHz, Wavelength = 2.55 mm (sand); 3.4 mm (air)

Figure 5. Parameters for acoustic modeling of laboratory experiment in dry sand. The position of the laser source, airborne microphone, buried hydrophone, and an interfacial velocity sensor (LDV) are indicated.

waveform we measure in the experiment, 2) to compare the effects of different detection bandwidths, and 3) to predict relative detection performance from different detector types, airborne or buried pressure sensors and interfacial velocity sensors. The sensitivities of the three receivers were selected to mimic the following commercial sensors: a Radio Shack Model 330-1052 Electret Condenser Microphone, with a nominal sensitivity = 2.5 nV/ Pa (airborne microphone), a B&K 8103 Hydrophone with a nominal sensitivity = 12.6 pV/ Pa (buried sensor), and a Polytec Model OVD-02 Laser Doppler Vibrometer with a nominal sensitivity = 0.2 V/(mm/sec) (interfacial velocity sensor). The frequency dependencies of the detectors are not considered in the calculation, and they were all taken as point receivers.

With the target modeled as a 25mm x 60mm hard rubber disk to simulate the laboratory hockey puck targets, we calculated the response at the airborne sensor as the acoustic source was moved from a horizontal offset of -20mm from the target edge to +5mm from the target edge (over the target). The airborne receiver is maintained at a constant offset of +15mm from the source. (The target edge is taken as the zero point of the distance scale.) The data for several positions of the source and receiver as they approach and overlap the target position are shown in Figure 6.

The direct reception from the source to the receiver is the first feature in each trace. This is reduced from the signal in the ground by a factor of over 100 due to the impedance mismatch at the air-ground interface. The small feature following the direct pulse that appears in every trace is an artifact due to incompletely absorbing boundary conditions. When the source is -10mm away from the target edge (and the receiver is at +5mm over the target), a second feature appears in the traces at a later time. This feature grows in size as the source approaches closer to the target. By observing the time evolution of the pressure waves in two-dimensional movies, the source of this second feature becomes apparent: it is a second bounce from the top surface of the target by the acoustic pulse which reflects from the top of the target, then off the air-ground interface, reflects off the target again, and transmits across the interface to the receiver. While this signal will certainly be reduced from the model calculation by the actual acoustic attenuation of the soil (which is not modeled), we have observed this second signal in our data. Figure 7 shows previously

Microphone Response in Air (Probe-3)

Figure 6. Predicted signal from the acoustic model as measured at an airborne microphone when the laser source is moved closer to the edge of the mine simulant. D_{s-t} is the horizontal distance from the laser source to the edge of the target. D_{r-t} is the horizontal distance from the microphone receiver to the edge of the target.

published data showing the time signal as a function of position as the laser is moved over a rubber hockey puck buried 4mm below the surface. The direct signal between 0 and 20 μ s, the return from the top of the target near 30 μ s, and the second bounce at 60 μ s (previously misidentified as a reflection from the bottom of the puck) are all clearly visible.

A second question that can be addressed by the model calculations is to what extent the apparent increased size of the target in Figure 4 can be attributed to the lower resolution caused by the lower frequency of the microphone detector (<15kHz as opposed to ~30kHz for the PZT detector used in Figure 7). We modeled this by observing the response at an airborne detector as the laser point-source is moved across the top of a 56mm dia x 40 mm target buried 25mm below the surface, as in the acoustic field tests. The positions of the source and receiver with respect to the target are as in Figure 6. The acoustic source is taken to be a single cycle at 30kHz, a signal which has significant intensity across the frequency spectrum from DC to above 50 kHz. The signal received at the detector position is Fourier transformed and the magnitude of the Fourier component at three frequencies, 7, 14, and 28kHz are compared with the actual target extent in Figure 8. The decrease in target resolution is apparent in the figure, and the signal extent at 7kHz, in the midband of the microphone used in the experiment, is approximately twice the true target extent. This suggests that bandwidth considerations may well explain the larger extent of the image in the experiment of Figure 4, and emphasizes the resolution advantage of utilizing the entire bandwidth of the laser-acoustic source.

Figure 7. Laboratory data image of target (hockey puck) buried under 4mm of dry sand, showing the second return predicted by the acoustic model in Figure 6.

Figure 8. Predicted acoustic signal vs. laser position compared with actual target extent for different receiver frequencies, showing effect of detector frequency on target resolution.

A major loss mechanism for laser-acoustic detection is the impedance mismatch at the air-ground interface which causes a reflection of about 99% of the signal reflected off the target. While the laser source produces acoustic signal directly in the ground, thereby bypassing this loss in transmission, the received signal has to be transmitted to the airborne detector above. The solution suggests itself to use a Laser Doppler Vibrometer (LDV) to detect the motion of the free surface of the ground instead

Comparison of Microphone, Hydrophone & LDV Signals

Figure 9. Predicted signal received at detector positions as shown in Figure 5 for airborne microphone sensor (top), buried, hydrophone (bottom), and LDV interfacial velocity sensor (middle). Note that the voltage scale for the LDV is approximately 100 times that for the microphone. (The extra returns in the hydrophone trace result from the detection of both the outgoing and returning wave at the buried sensor location.)

of the weak transmitted pressure signal. This configuration could not only result in increased sensitivity, but would permit look-ahead, stand-off detection which is very desirable from a counter-mine operations point of view.

Using the configuration of Figure 5, and the detector sensitivities as given above, we modeled the received detector voltages as a function of time when the laser excitation was directly over the target. No attempt was made to estimate the different noise floors of the detectors. Nevertheless, as shown in Figure 9, the predicted detector voltage output from the LDV is a factor of 100 greater than that predicted at either the airborne microphone or the buried hydrophone. The potential signal-to-noise gain of this detector configuration would be an enormous step toward making laser-acoustic detection a reality. Tests of LDV detection with laser-acoustic excitation are underway to confirm the advantage suggested by the model.

CONCLUSION

Laser-acoustic imaging of underground objects has been shown in the laboratory to allow detailed imaging of the shapes of buried objects. The shape and depth resolution could contribute to a drastic reduction in the false-alarm rate for underground clutter. We have demonstrated the practicality of the technique in tests using realistic antipersonnel mine simulants at an outdoor test track. The images obtained with laser-acoustic excitation and a low-frequency (<15kHz) microphone detector indicate anomalies associated with the position of the mine simulant, but the size and depth of the simulant are not as clearly defined as in the laboratory measurements in dry sand with a higher frequency (30 kHz) detector.

Acoustic modeling has been performed using a two-dimensional FDTD code, assuming linear and lossless propagation in a single-phase effective media. The results of the simulation accurately predict lineshape features observed in the data, and indicate that the excessive size of the image in the field trials at the test track may be a result of the lower frequency of the detector, compared with the detector used in the laboratory experiments. The acoustic model predicts a factor of 100 gain in the signal voltage may be obtained by using a LDV interfacial velocity sensor to avoid the acoustic loss at the air-ground interface.

Distinguishing shape details of buried non-metallic mine-like objects with GPR

Carey M. Rappaport, Shuang Wu, Misha Kilmer, and Eric Miller

Center for Electromagnetics Research, Northeastern University
235 Forsyth Building, Boston, MA 02115

Abstract

The finite difference frequency domain is used to study the scattering of buried non-metallic mine-like targets to determine the feasibility of identifying mines from shape features. It is shown that for constant cross-sectional target area -- approximately 100 cm^2 -- the scattered fields of targets with roughly the same height-to-width aspect ratio at 500 MHz are virtually indistinguishable regardless of burial depth. A comparison of the field obtained for mine-like targets of different aspect ratios, but with constant area, buried at a depth of 5 cm, shows marked differences, as does scattered field for GPR frequencies above 700 MHz.

The conclusion of this study is that while low GPR sensing frequencies may help to detect shallow anomalies, they do not supply any useful information about the shape details -- particularly the edges -- of the buried non-metallic mine-like targets.

Keywords:

GPR, mine detection, dielectric target imaging.

1. Introduction and Computational Electromagnetic Background

For many underground detection problems, it is important to know what target features are characteristic and most easily detectable. For metallic targets in free space, edges provide strong scattering centers and are often used for scattering signature analysis. For buried non-metallic objects, however, edges do not provide as strong a scattered signal.

To determine the importance of edges -- and shape in general -- as discriminating features, the scattered signal from two-dimensional objects buried in a lossy, dispersive soil medium can be simulated using finite difference computational methods. Both the finite difference time domain (FDTD) and the finite difference frequency domain (FDFD) algorithms discretize the scatterer and its surrounding space, and hence can model any target shape, soil inhomogeneities, and rough surface boundaries [1,2].

The FDFD method is preferable to the time domain algorithm in the present analysis, because it computes the scattering response at a single frequency, giving the field distribution throughout the problem space. Since knowledge of the frequency dependence of the scattered signal is an important sensing parameter, and since there is no need to iterate until transients have died out, FDFD is the method of choice. An additional advantage of FDFD is that there is no need to rely on special methods to handle frequency-dependent soil media in the time domain [3-5].

Contrary to common perception, the FDFD method is relatively fast. For a 100 by 100 point grid, terminated on each side by a Perfectly Matched Layer (PML) absorbing boundary condition [6,7], the entire evaluation on a 233MHz Pentium Pro running the Matlab 5.0 sparse matrix solver is about one minute. Using a preconditioned QMR iterative solution method [8], the CPU time for large two dimensional grids of N unknown field values grows as $N \ln N$.

One important requirement for efficient FDFD code is the PML material absorber ABC. Since the PML is composed of just layers of propagation media with particular values of electric and magnetic conductivity, the sparse, symmetric structure of the simultaneous equation matrix is unaffected by the ABC.

Care must be used to tune the PML to the air/soil interface. With the usual PML boundary, it is assumed that this ABC terminates a region of free space. The electric and corresponding magnetic conductivity of the PML sub-layers build up from zero to the maximum value at its termination. For the PML termination to a uniform conductive scattering space, the conductivity of the first sublayer must be slightly greater than that of the scattering space. Subsequent sublayer permittivity and conductivity increase according to the anisotropic space mapping principle[9], with corresponding magnetic conductivity increasing to keep the impedance of each PML sublayer constant.

To compute the scattered fields due to plane wave incidence on a target in a lossy half-space, the incident field in the half-space is first determined analytically, using the standard transmission coefficient, and then this field across the support of the target is used as the excitation. That is, the source-free Helmholtz equation for total field:

$$[\nabla^2 + k^2(x,y)] E_z^{tot} = 0 \quad (1)$$

is rewritten in terms of material variations from the constant soil background, $k(x,y) = k_0 + k_{target}$, and incident (in the soil background) and scattered electric field, $E_z^{tot} = E_z^{inc} + E_z^{scat}$. Since E_z^{inc} solves the Helmholtz equation with background k_0 , Equation (1) becomes:

$$\begin{aligned} [\nabla^2 + k^2(x,y)] E_z^{scat} &= - [\nabla^2 + k^2(x,y)] E_z^{inc} \quad (2) \\ &= - k_{target}^2 E_z^{inc} \end{aligned}$$

Note that this formulation is exact, unlike the Born approximation. Approximation is unnecessary since FDFD calculates field values across the grid for all types of materials in any shape or form.

2. Target Shape Scattering Characteristics

The effects of scattering by corners of a dielectric target, typical of buried mine-like objects, can be studied by examining the scattered fields throughout space, and in particular above the surface of a lossy dispersive soil model half-space. Figure 1 shows the geometries of two representative scattering cases. In both cases a target with material characteristics of TNT (dielectric constant, $\epsilon' = 2.9$, loss tangent $\tan \delta = 0.001$) is embedded in a half space of material with electrical characteristics of dry sand ($\epsilon' = 2.5$, loss tangent $\tan \delta = 0.01$) [10]. The targets have the same cross-sectional area of 100 cm^2 , and are buried at a nominal depth of 5 cm. In the first case the target is circular, obviously with no corners, while the second target case has a square cross-section.

Geometry of buried non-metallic mines

Dry Sand: $\epsilon_s = 2.5$, $\tan \delta_s = 0.01$

TNT mine: $\epsilon_m = 2.9$, $\tan \delta_m = 0.001$

Figure 1: Nominal geometry of buried targets, 5 cm below ground surface. Soil assumed to be dry sand, targets modeled with electrical characteristics of TNT.

A normally incident time harmonic plane wave excites each target case. The scattered fields, as determined by the FDFD discretization of Equation (2), are presented in the top row of Figure 2. The excitation frequency is 500MHz, corresponding to a wavelength of about 40 cm in dry sand. The targets are roughly one-quarter of one wavelength in extent, so it is not surprising that the resolving power of the scattered field is limited.

Scattered Field - Aspect Ratio Dependence

Figure 2: Real parts of scattered fields from mine-like targets with circular (top left), square (top right), and rectangular cross-sections: progressively taller (middle row), and progressively wider (bottom row). All shapes have the same cross-section, 100 cm^2 .

Surface Field - Cross Section Area Dependence

Dry Sand, $\epsilon = 2.5$, $\tan\delta = 0.01$
frequency = 500 MHz, $d = 5 \text{ cm}$

Figure 3: Magnitude of scattered field on the ground surface for circular and square target shapes, each with 100 (left), 225 (middle), and 400 cm^2 (right) cross-sectional area.

While the corners do not appear to be a detectable scattering feature at 500 MHz, the width-to-height aspect ratio does affect the scattered fields. The second row in Figure 2 shows the scattered fields from rectangles that are taller than wide with aspect ratios: 9/16, 1/4, and 1/16; while the third row shows wider rectangles, with aspect ratios: 16/9, 4, and 16. Despite all targets having the same area, the taller rectangles have an upward shattered field with roughly semi-circular contours with greater curvature than that of wider targets.

Figure 3 shows the dependence of scattered field for circular and square targets of various sizes. As expected, both the magnitude of the scattered signal and the differences between target shapes become more apparent with increasing size. In addition, the horizontal variation of scattered field is greater for the larger targets.

Several additional target shapes are presented in Figure 4, including a square tilted 45 degrees, an asterisk, and an asymmetric, irregular shape. The real part of the scattered fields for these shapes are given in Figure 5 for 500 MHz incident field. Note again that it is very difficult to ascertain any shape information from these scattered fields.

Different Buried Test Target Shapes

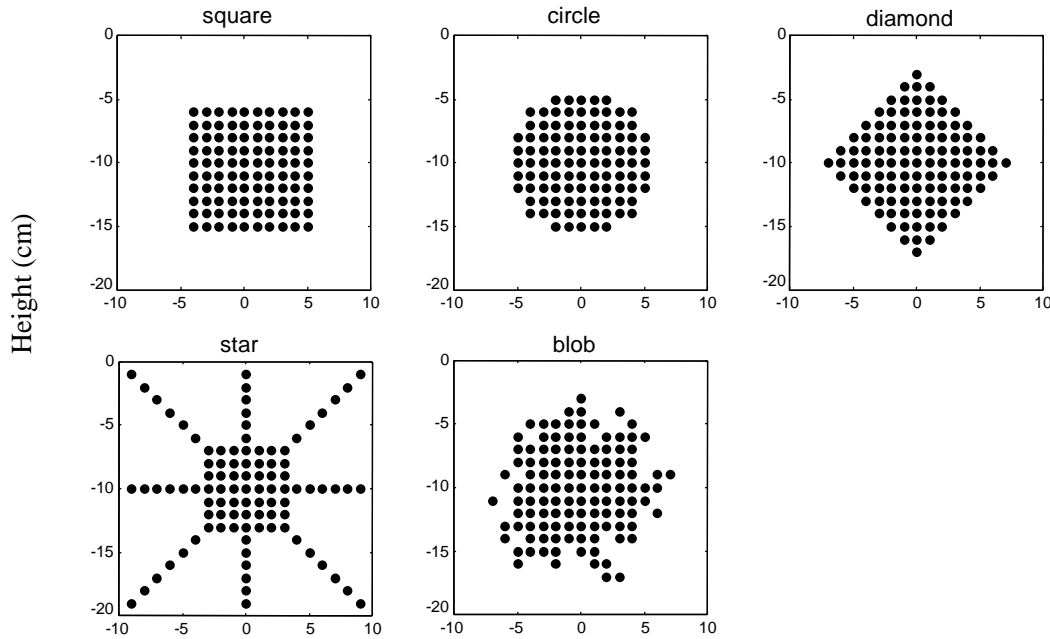

Figure 4: Various target shapes, each with 100 cm² cross-sectional area.

Figure 6 shows the scattered fields for the same target shapes of Figure 4, but for 1 GHz incident field. At this higher frequency, the differences in the scattered fields are visible. In particular, the scattered signal due to the finned structure in the lower right is weaker under ground, and that of the diamond target in the upper right is weaker above the ground.

Scattered Field - Real Part

Figure 5: Real parts of fields scattered from the target shapes of Fig. 4 for 500 MHz excitation.

Scattered Field - Real Part

Figure 6: Real parts of fields scattered from the target shapes of Fig. 4 for 1 GHz excitation.

The surface scattered fields for the two excitation frequencies are shown in Figure 7. These would be the signals measured by radar near the surface of the ground across the target from 40 cm to one side to 40 cm to the other. Although slight differences are visible for 500MHz scattering, these would be difficult to detect in practice. However, for 1 GHz, there are quite visible differences due to shape. For example, a tilted square has almost an order of magnitude lower scattered signal than the level square.

Surface Field - Magnitude

Figure 7: Magnitude of scattered field at the ground surface for the target shapes of Fig. 4: 500 MHz excitation (left) and 1 GHz (right).

Clearly, between 500 MHz and 1 GHz, the appearance of shape features becomes apparent. Figure 8 shows this effect along with burial depth dependence for the 100 cm² cross-section circle and square. At 750 MHz there are several slight differences between the scattered signals for each target depth: 1 cm, 5 cm, and 10 cm below the surface. However, these differences are not nearly as prominent as those for 1 GHz incident waves.

Finally, Figure 9 shows that the angle of incidence of the exciting wave does not help to distinguish target shape. Once again, 100 cm² cross-sectional targets are illuminated with 500 MHz plane waves. While the pattern of scattered field is indeed different for incidence angles of 30 or 45 degrees, there is no noticeable difference between scattering from the circle as oppose to the square target.

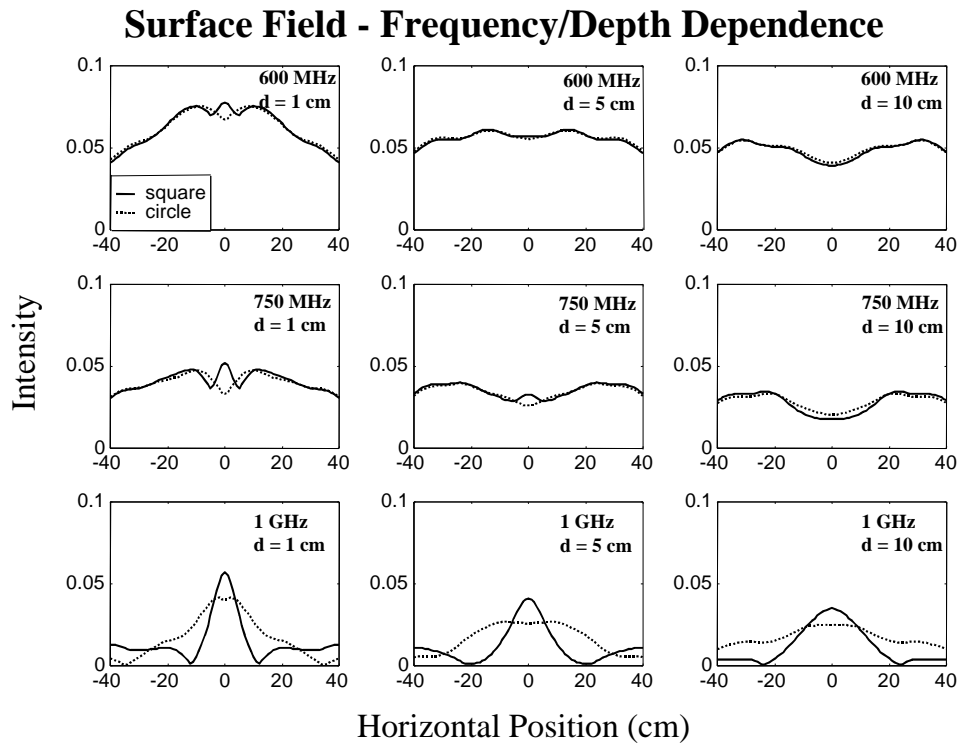

Figure 8: Surface field magnitude at the ground surface for circular and square targets for 600 MHz (top row), 750 MHz (middle row), and 1 GHz (bottom row); and burial depths 1 cm (left), 5 cm (middle), and 10 cm (right).

Figure 9: Real part of scattered field from circular (left) and square (right) targets at 500 MHz for inclined incidence angle excitation.

3. Conclusions

The scattered fields from various two-dimensional non-metallic mine-like target shapes have been calculated and compared. Although the target models are relatively simple, analysis of these fields indicates that for typical antipersonnel mine sizes of 10 cm, there is very little shape-distinguishing feature information available when the incident wave is at frequency 600 MHz or below. Aspect ratio appears to be the dominant discriminator of target shape, while corners, rotational symmetry, tilting, depth of burial, even concavity of target boundary do not seem to contribute much information to the scattered signal. At 1 GHz, shape features of 10 cm targets are quite evident, but a wide aperture of multiple sensors across the ground surface are needed to measure the variations of scattered field.

Clearly, for non-metallic antipersonnel mine detection, frequencies above 600 MHz must be employed if there is to be any hope of distinguishing mines in terms of the shape of target anomalies in soil.

COMPARISON OF A RECURSIVE T MATRIX METHOD AND THE FDTD METHOD FOR SCATTERING PROBLEMS IN LOSSY DISPERSIVE SOIL*

Scott C. Winton, Adnan Şahin, Carey M. Rappaport and Eric Miller

Center for Electromagnetics Research

Northeastern University

Boston, MA 02115

Abstract A comparison between two forward solving methods, recursive T-matrix and FDTD, is presented. The strengths and weaknesses of both methods are discussed. The recursive T-matrix method is a fast solver that is well suited to solutions in homogeneous media where the scatterers are bodies of rotation. The FDTD method is best suited to complicated and realistic problems involving inhomogeneities, rough surface interfaces and irregular shaped scatterers. Numeric results from both methods are presented.

I. INTRODUCTION

Interest in land mine remediation has helped to initiate development of techniques to accurately simulate electromagnetic waves propagating in a lossy dispersive medium, such as soil. Development of different techniques has indicated that the 'best' method to be used may depend greatly on the specific problem to be solved. With this in mind we discuss two such methods, the Recursive T Matrix method and the Finite Difference Time Domain method in order to compare and contrast the two methods to illustrate their respective strengths and weaknesses and therefore give an indication as to which types of problems each is best suited.

We begin with a brief description of each method, including a general overview as well as identification of the parameters required for comparison. This will be followed by a comparison of results from several numeric experiments. Then a detailed discussion is given which cites specific difference between the methods and how changing the problem to be solve effects each method.

II. THE RECURSIVE T MATRIX METHOD

For a single scatterer, the T-matrix method involves finding the coefficients to describe the scattered field as an expansion of basis functions(e.g. Bessel functions for 2-D problems). The elements of the T-matrix are found by using a Greens function and applying Poincaré-Huygens principle. For multiple scatterer, the T-matrices from individual scatterers are incorporated into a single T-matrix through a recurrence relation. This single T-matrix will include all multiple scattering effects. For a detailed analysis of single and recursive T-matrix algorithms, the interested reader is referred to [1-3].

* This work was supported by MURI Grant DAAG55-97-1-0013

Unlike finite difference techniques, the T-matrix methods do not require an absorbing boundary condition and substitutes the discretization of space with harmonic expansions of the fields thereby reducing the number of unknowns for a wide range of problems. Chew and co-workers have pioneered development of a number of fast, recursive T-matrix algorithms for determining the scattered fields in a variety of scenarios [4-6]. These methods basically function by tessellating electrically large objects into small sub-scatterers whose individual T matrices can be well represented using low-order harmonic expansions. A recursive formula then is used to aggregate the effects of all the sub-scatterers to compute the fields.

In [7], Şahin and Miller have extended the results of recursive T-matrix techniques to near field scattering problem using high-order harmonic expansion while keeping the computational cost at reasonable levels. This is an important extension since ground penetrating radar problems often require looking at near field solutions. The shortcoming of these recursive T-matrix methods is that they require a homogeneous background, since the Green's function needs to be expanded in cylindrical (or spherical in 3-D) harmonics in closed form. There has been some work on T-matrix techniques with inhomogeneous medium, but a computationally effective, and accurate technique is required for inhomogeneous background.

In order to use the T-matrix method for wide band excitation, the technique must be run several times at different frequencies. This may be seen as a disadvantage, but it allows dispersion to be dealt with in a straightforward manner, since electrical parameters may be defined for each frequency.

Before continuing, we must identify the parameters of the T-matrix method that will be important in the subsequent discussions. If Bessel functions (of spherical Bessel functions) are to be used as the basis functions, then clearly cylinders (or spheres) are the elemental type of scatterer. The previously mentioned tessellation of large or irregular shaped objects would be into small cylinders. For the single scatterer matrix the infinite series of basis functions will be truncated to M harmonics. It can be shown that for accurate representation of the fields due to this single scatterer, M must be increased as the radius of the scatterer is increased. In order to relate the T-matrices of the single scatterers for the multiple scatterer case, there must be a common reference point called the scattering origin, which is different from the global origin of the problem geometry. In [7] it is stated that a circle around the scattering origin must include all scatterers and none of the observation points. Furthermore, for accurate results, it is required that N harmonics are used to relate the individual T-matrices together. It can be shown that N must be increased as the distance from the scatterers to the scattering origin is increased.

III. THE FINITE DIFFERENCE TIME DOMAIN METHOD

The Finite Difference Time Domain method addresses the forward solving problem by discretizing the entire problem space and time stepping through spatial updates based on nearest neighbors. The use and development of the FDTD method has seen exponential growth over the last decade [8]. One of the primary reasons for this growth is that the technique is basically quite simple and so readily adaptable to a wide variety of problems.

Unlike the T-Matrix method, inhomogeneity is trivially modeled in FDTD since all that is required is to define the electrical parameters at each grid point. Scatterers are defined in the same way. For ground penetration radar applications, an air-ground interface is easily incorporated.

The use of the time domain allows wide band excitations, such as gaussian pulses or Ricker wavelets to be easily implemented. However, the inclusion of dispersion is problematic since multiplication in the frequency domain

becomes convolution in the time domain. Considerable effort has been expended on this problem with impressive success [9-11]. The obvious disadvantage is that to include these techniques greatly increases the complexity of the algorithm.

An important consideration with FDTD is the requirement of an Absorbing Boundary Condition(ABC) to eliminate reflections that would otherwise be caused by the abrupt termination of the discretized problem space. Great advancement in ABCs have been made over the last few years. Most notably the introduction of Berenger's Perfectly Matched Layer [12], which has helped to greatly increase the usefulness of the FDTD method. Unfortunately, as the complexity of the medium is increased, the problem of finding an effective ABC becomes more difficult. Once again, considerable work has been done on this problem and has led to the introduction of ABCs for lossy and dispersive material. However, in general, the performance of these ABCs tends to fall well short of their dielectric counterparts.

IV. NUMERICAL EXPERIMENTS

In order to facilitate a comparison between the two methods and to help illustrate the relative advantages of the methods. Four numerical experiments have been performed. In each case, a Transverse Magnetic continuous wave (CW) uniform plane wave at 1Ghz is incident on the scatterer(s) in a homogeneous medium typical of soil with dielectric constant, $\epsilon_r = 6.0$ and a conductivity $\sigma = .05S/m$.

For the FDTD method, it will be shown that the two critical parameters are the spatial increment Δ and the Courant number R . The Courant number is the ratio of the distance moved by the wave in one time increment to the spatial increment, i.e. $R = v\Delta t/\Delta$. Stability analysis reveals that for a simulation on a cubical grid to remain stable, $R \leq 1/\sqrt{d}$, where d is the dimension of the simulation.

Figure 1 shows the geometry for the first experiment. A single non-conducting dielectric scatterer is 15cm away from the array of receivers. The radius r of the scatterer is 3.75cm. For the FDTD, $R = 0.5$ and $\Delta = 5mm$ which translates to a sampling of about 25 points per wavelength in the soil and about 38 points per wavelength in the dielectric scatterer, which should be more than adequate. However, using $\Delta = 5mm$ means that there are only about 7 points along the radius of the scatterer. If Δ were any larger, the outer surface of the scatterer would not be smooth, affecting the scattered field. For the T-matrix, $M = 20$. Figure 2 shows the magnitude of the solutions obtained from both the T-matrix method and the FDTD method.

Figure 3 shows the geometry of the second experiment. Here the dielectric scatterer has been replaced with a perfect electric conductor $\sigma \rightarrow \infty$. As with the dielectric scatterer, the radius $r = 3.75cm$. As with the previous experiment, $M = 20$ for the T-matrix solution. Figure 4 shows both the T-matrix and FDTD solutions for this geometry.

For these first two experiments, the agreement between the two methods is excellent. Clearly both methods are capable of producing accurate results for these simple cases. For the T-matrix method, no recursion is required to find the scattered field. And since the scatterer is a cylinder, no tessellation is required.

Figure 5 shows the geometry for the third experiment. Here there are two PEC scatterers of radius $r = 30cm$. The separation is 1m. Because the radius of these scatterers is considerably larger than the previous case the spatial increment of the FDTD method has been increased to no more than 2cm. For the T-matrix, $M = 25$ and $N = 110$.

Figure 6 shows the T-matrix solution as well as two FDTD solutions.

Figure 1: Geometry of experiment #1.

Figure 2: Magnitude of scattered electric field due to single dielectric scatterer of T-matrix and FDTD

Figure 3: Geometry of experiment #2.

Figure 4: Magnitude of scattered electric field due to single PEC scatterer of T-matrix and FDTD

Figure 6 shows that the FDTD solution with $\Delta = 2\text{cm}$ is noticeably different than that of the T-matrix solution. At 1GHz , $\Delta = 2\text{cm}$ represents a sampling of only 6 points per wavelength, which is clearly inadequate. By decreasing Δ to 1cm , the sampling becomes about 12 points per wavelength and the solutions achieved good agreement.

Figure 7 shows the geometry for the fourth and final comparison. Here there are two dielectric scatterers with $r = 3.75\text{cm}$, the separation is 25cm . For the T-matrix solution, $M = 12$ and $N = 120$. Figure 8 shows the T-matrix solution and the FDTD solutions for this case.

Figure 8 shows that although there are three different levels of spatial resolution, there is still a discrepancy, mostly to the left and right of the scatterers, between the two methods. Since there is no analytic solution available, it is difficult to determine which method is inaccurate. Resolution of this discrepancy is the focus of continuing

Figure 5: Geometry of experiment #3.

Figure 6: Magnitude of scattered electric field due to two PEC scatterers of T-matrix and FDTD

investigation. However, there is good agreement in the region between the scatterers, where most of the interaction between the scatterers takes place.

IV. COMPARISON

As part of the comparison between the two methods, the issue of 'speed' should be addressed. A comparison of execution speed is, unfortunately, not easily accomplished. If FDTD were a matrix problem, like T-matrix, we could just compare the number of computer program flops. However, the FDTD code used in these experiments was written in Fortran and executed on a PC using the Linux operating system. As it turns out, a high resolution comparison is not required because for every case considered here, the T-matrix method has a shorter execution time. For the cases of high spatial resolution, i.e. $\Delta \ll 1$, the execution time for the T-matrix method is significantly shorter than that of the FDTD method. To include some approximate numbers, all of the T-matrix solutions may be obtained using Matlab and a PC in less than 10 minutes. Comparable speed may be obtained with FDTD using the largest Δ possible and a suitable ABC. For example, for the geometry of Figure 7, with $\Delta = 5mm$ and using an 8-layer Perfectly Matched Layer [12] ABC, the simulation can be completed in less than 8 minutes. However, in order to decrease the programming complexity, the grid can be enlarged and the ABC omitted. This was done for each of the experiments. For the geometry of Figure 7 with $\Delta = 5mm$, the run time was about 20 minutes, for $\Delta = 2.5mm$ the run time was about 70 minutes and for $\Delta = 1.25mm$ the run time was over 7 hours. These numbers are clearly not representative of all FDTD or T-matrix solutions, since specific problems, requirements, hardware and software can vary widely. It can, however, be said with confidence, that for case where there is homogeneity and simple scatterers, the T-matrix method will be faster, and in many cases, considerably faster.

The effect that changes in the problem have on the execution time should not be understated and it is worthwhile to examine these effects for both methods. Changing the medium from homogeneous to inhomogeneous requires minimal effort for the FDTD method. However, since the T-matrix method for inhomogeneous material is still under development. Changing to an inhomogeneous material is quite difficult. Changes in the size of the problem can effect both methods in different, sometimes opposite ways. For example, increasing the size of scatterers may actually decrease the computational cost of the FDTD method, since Δ may be larger to achieve the same number of points per wavelength. However, an increase in the size of the scatterers requires an increase in the number of harmonics M for the single scatterer matrices. In other words, FDTD is better suited to electrically large curved scatterers while T-matrix is better suited to electrically small curved scatterers. If the scatterers are held at the same size

but moved apart, this would probably most adversely effect the FDTD method since more spatial points would be necessary. This not only effects the size of the grid, but the amount of time required to propagate the waves between the scatterers. This amount of time may be decreased by increasing the temporal increment. However, the temporal increment cannot be increased without bound since the Courant condition would not be satisfied and the simulation would become unstable. For T-matrix, if a suitable scattering origin can be found, moving the scatterers further apart simply requires increasing the number of harmonics N which are required to relate the matrices together. Adding dispersion to the problem will increase the execution for both methods, but the relative increase between the methods will require further investigation. For the T-matrix method, the solution must be set up and solved for each desired frequency. This will require multiple runs. For FDTD, dispersion can be accomplished in one simulation, but incurs a computational cost in additional difference equations and increased storage space.

Figure 7: Geometry of experiment #3.

Figure 8: Magnitude of scattered electric field due to two dielectric scatterers of T-matrix and FDTD

Although the T-matrix solution for these problems may be obtained more quickly once the problem is set up, the actual creation of the program to solve the problem numerically is more involved. The FDTD method requires less understanding of the physics of the problem and fewer programming skills.

Changes in the problem can also effect the complexity of the program for each of the two methods. Changes in the size of the problem are very easily dealt with in FDTD, usually only requiring changing a few variable. For T-matrix, if the size of the problem is changed, it may require locating a new scattering origin. Changes in the shape of the scatterer are also relatively easy for FDTD. The scatterers can be determined by changing the electrical parameters point by point. For the T-matrix, changes in the shape of the scatterers can have *drastic* effects of the complexity of the problem. If a scatterer is tessellated, the final T-matrix must incorporate the T-matrices of all of the smaller scatterers. Furthermore, care must be taken to ensure that the small scatterers make an accurate representation of the larger scatterer. For example, if many small cylinders are to make up a large irregular shaped scatterer, there will be gaps in between the cylinders that represent errors. Special algorithms must be incorporated to minimize these gaps. Also tessellation is not really appropriate for highly lossy metallic scatterers since the fields inside the scatterer are zero (or very small). If a metallic scatterer is irregularly shaped, schemes must be employed to only incorporate the effect of the outside edge of scatterer into the recursive T-matrix. Adding dispersion to the problem has the opposite effects to changing the shape of the scatterers, i.e, it is much more detrimental for FDTD computation. For the T-matrix, the electrical parameters for a given frequency are easily incorporated into the algorithm, the method is simply employed several times. Because dispersion in the time domain requires

convolution, it can be quite problematic to incorporate it into the FDTD method. With the addition of dispersion, the relative simplicity of the FDTD algorithm is lost and much greater complexity is required to insure accurate results.

In order to be useful, a forward solver must be accurate. As mentioned previously the accuracy of the T-matrix method is controlled by the number of harmonics used while for the FDTD method, the accuracy is controlled by the spatial increment. There is also a temporal increment used in FDTD, but if the Courant condition is met, the accuracy can be seen to be controlled by Δ . Ten to twenty spatial points per wavelength are usually considered adequate to obtain sufficient accuracy. However, this also puts a limit on the size of the grids that can be discretized as discussed above. Also, there is another source of error in FDTD known as numerical dispersion. Numerical dispersion arises from the fact that in FDTD, $k \neq \omega/v_p$, where k is the wave number, ω is the radial frequency and v_p is the phase velocity. Solving the dispersion relation for the discretized wave equation reveals that there is another term in the dispersion relation that is directly dependent on Δ and can be shown that numerical dispersion can be reduced by reducing Δ . Numerical dispersion is usually not a problem for short simulation, but can cause inaccuracies in lengthy simulations.

For FDTD, it was mentioned that the Courant condition, $R \leq 1/\sqrt{d}$ must be met to insure stability. It should be seen by now that the Courant number is the *critical* parameter for the method since it effects not only the stability, but the execution time and the complexity of the problem. These facts in turn limit the types of problems that can be solved with FDTD. For the T-matrix method, it was originally found that instability could arise with higher order harmonics, hence the motivation to tessellate larger objects in order to be able to use lower order monopole expansions. However, that problem has been eliminated for many problems of interest [7] and it has been shown that the use of higher order expansions in un-tessellated scatterers can actually reduce the complexity of the problem.

V. CONCLUSIONS

Through numerical experiment and the subsequent discussion, a comparison of the T-matrix and the FDTD method for electromagnetic forward solving problems has been performed, the relative strengths and weaknesses of each method has been discussed. It should be clear that the advantages of the T-matrix solution are speed with accuracy whereas the advantages of FDTD are simplicity and the ability to adapt FDTD to a wide variety of practical problems.

Obviously, these strengths should effect the decision of which method to use for a given situation. For problems with bodies of rotation in a homogeneous environment, T-matrix is a clear choose. But T-matrix may also be used as an approximation to a more realistic problem in order to perform a proof of principle solution. For the situation that requires more unusual geometries, and especially for wide band excitation or where the transient responses are desired, the FDTD is obvious chose. Both methods represent powerful tools in electromagnetic forward solving problems for use in land mine remediation.

Conductivity Profile Optimization for the PML ABC in FDFD

Carey M. Rappaport, Edwin A. Marengo, Eric L. Miller
Center for Electromagnetics Research
Northeastern University
Boston, MA 02115

The Perfectly Matched Layer (PML) proposed by Berenger (Berenger *J. Comp. Phys.*, 1994) is an extremely effective lattice termination condition in both time domain and frequency domain field computation. The ideal, continuous specification of the PML can have arbitrary loss characteristics, which can absorb without reflection waves incident from any angle. In finite difference wave modeling, however, the staggered electric and magnetic field grids prevent the specification of the same medium at a given position for both E-field and H-field, leading to numerical reflections. To minimize these reflections, the value of conductivity in each PML layer must be profiled so that it is smallest next to the free space/PML boundary, and rises for subsequent layers. The optimal specification of this profile is an open question of much interest to the computational electromagnetic community.

Unlike the in time domain case (Gedney, *ACES* 1997, and Fang and Wu, *IEEE Micro. Guided Wave Let.* 1996), the FDFD formulation of a multilayer PML can be stated explicitly and exactly. One way of doing this is to use the discretized impedance of one layer relative to that of the subsequent layer to iteratively determine the impedance “looking into” the PML at its boundary, relative to the PML termination. For normalized impedance of the i -th layer of width Δ , $\eta_i = (E_i/H_{i+\frac{1}{2}})/\eta_0$, for a plane wave incident with angle θ on a planar layer boundary normal to \hat{x} , the recursive relation is:

$$\eta_i = jk\Delta \cos^2 \theta + \frac{S_{i+\frac{1}{2}} + S_i}{2} \cos^2 \theta + \frac{1}{jk\Delta + (S_{i-\frac{1}{2}} + S_i)/2 + 1/\eta_{i+1}}$$

where $k = \omega\sqrt{\mu\epsilon}$ and $S_i = k\Delta\sigma_i/\omega\epsilon_0$ ($= \sigma_i\eta_0\Delta$ when all PML layer dielectric constants are 1). Note that this formula allows the specification of conductivity values at every half layer, doubling the number of layer parameters from the original. Also, the effects of a tuned PML termination, given by η_{max} (Rappaport, *IEEE Trans. Mag.*, 1996) can be carefully examined.

To find the best conductivity coefficients for a wide range of angles and frequencies, numerical optimization is performed to minimize a cost function based on the error between the free-space transverse wave impedance, $\cos \theta e^{jk\Delta \cos \theta/2}$, and the impedance looking into the PML, η_1 . The goal is to find a set of σ_i and a termination η_{max} that keeps the weighted error small for all frequencies of interest (0 to 75°, say) and all frequencies of interest. The solution to this problem also applies to the coefficients for the FDTD PML layer.

Advanced Land Mine Detection Using a Synthesis of Conventional Technologies

Carey M. Rappaport
Center for Electromagnetics Research
Northeastern University
Boston, MA 02115
United States

The humanitarian need for new, technologically advanced yet cost-effective approaches to demining has recently become critical. First, the proliferation of mines has increased to the extent that not only are there more than 100 million mines buried throughout the world, but new mines are being placed faster than they can be cleared. And second, newer types of mines with inexpensive plastic and non-ferrous metal casings—which are difficult to detect with conventional methods—are becoming more prevalent.

Developing the next generation of demining technology requires using multiple sensors and signal processing algorithms which take into account the way in which the sensor data is gathered rather than treating the data as generically-derived information. We at Northeastern University are leading a team to develop and optimize land mine detection based on ground-penetrating radar (GPR), infrared thermography (IRT), electromagnetic induction (EI), and high frequency acoustic (HFA) sensors. We are implementing sophisticated, physics-based mathematical models to describe the interaction of EM or acoustic waves with mines buried in realistic (electromagnetically lossy, inhomogeneous) soil and as a result are developing “smart” signal processing algorithms to identify and classify mines. These mathematical models are derived from actual soil and land mine measurements, and include detection statistics of the sensors. In addition, we are building prototype land mine detection systems using currently available industrial hardware configured in novel ways based on the physical models under development. This approach allows us to utilize cheap, off-the-shelf components and “smart” algorithms with the hope of providing developing countries with reliable and cost-effective sensor systems. Finally, we are working to integrate these components into a set of scenario-tunable systems for person-portable, vehicle-mounted, and/or airborne use that will be effective for demining operations in both hostile and peaceful areas.

To achieve these goals requires a research program based on a first-principles understanding of the technical challenges posed by the demining problem and the development of an integrated framework for addressing these issues. At its root, the demining problem is particularly challenging because it is an *inverse* problem. That is, one can often obtain information regarding the presence of mines *only* through indirect measurements using electromagnetic, chemical or thermal sensors. Most sensing systems operate by transmitting energy into the earth and measuring the scattered fields arising from the interaction of the energy with sub-surface structures. All mine-related information to be extracted from the data is encoded by the complex scattering processes underlying these non-invasive detection methods.

Non-ferrous mines are undetectable with magnetometry, while quick mobile deployment precludes particle beam and spectrometry methods. Shallow wave penetration in soil limits millimeter and visible frequency techniques, while resolution limitations create difficulties for seismic and gravity sensing. Although olfactory, chemical, and biological sensing may offer advantages for detecting older mines (and hence be useful for humanitarian purposes), they have limited sensitivity, especially in battlefield situations where pervasive explosive residues may be widely scattered across the ground. Newer mines do not give off significant chemical vapors and there is no direct means of continuously sampling soil.

By concentrating our efforts on EI, GPR, IRT, and HFA sensors, we feel that we have the best opportunity for making significant advances in demining. These technologies have been available for many years, and have individually met with limited success. Most importantly, all four technologies are easily integrated since they possess similar modalities, involve similar wave propagation, can be addressed with unified mathematical models, and can be mounted on a variety of demining platforms. We are performing experiments to determine the optimal platforms, sensors, and frequency ranges for specific demining situations and plan to exploit

the capability of multiple sensors and physically-based signal processing algorithms to generate substantial improvements over currently available land mine detection schemes.

Ultrawideband Array-Based Ground-Penetrating Radar

As with standard radar, GPR is useful for the remote sensing of submerged targets. It is an important tool for determining the locations of unexploded ordnance, land mines, underground installations, and hidden arms caches, but also offers many dual-use applications, including precisely identifying the positions of buried waste drums (for environmental clean-up), finding pipes or cables (of interest to utilities), and identifying cavities or obstacles (for construction applications). Ground penetrating radar has been available for many years, and has been fairly successful at the remote identification of buried objects. However, by making use of short pulse and shaped pulse signals, several important advantages become apparent. First, for wet, lossy soils, the wave penetration depth is severely limited for high frequency signals, while the detector resolution is limited at low frequencies; short pulse signals can be tailored to optimize the trade-off between penetration and resolution. Second, since most of the targets are in the nearfield of the radar source, the signal phase effects are unusually important. By mixing the phases of a wide bandwidth of frequencies appropriately, the signals scattered by the target can be more sharply analyzed, and the targets more accurately identified.

Soil is inhomogeneous and dispersive, with dielectric and electrical conductivity parameters depending on the soil composition, density, and excitation frequency. One research effort at Northeastern University uses measured soil data to form a simple clutter model appropriate for both time- and frequency-domain computational wave propagation simulations. In addition, we will include the effects of dielectric constant and conductivity variations as well as rock inclusions as perturbations of the propagation medium. Instead of having to guess soil characteristics or use a look-up table, this model will provide high-accuracy predictions of the penetration depth, resolving capability, and sensitivity to noise and clutter of the EM signals.

It is only through use of the entire RF frequency band and the largest possible aperture that sufficient sensing information becomes available for sophisticated inversion processing. While monostatic data from various locations can be combined for rudimentary imaging, collecting the scattered response with multiple receivers simultaneously provides the extra dimension of information necessary to detect low contrast mine targets. We are developing strategies for optimizing element positioning in one- and two-dimensional arrays, considering synthetic aperture radar (SAR) antenna optimization, and testing trade-offs between array size and platform geometry for synthesizing the best practical sensing aperture.

For the ultra-wideband radar systems we will be developing, it is essential to make use of antenna elements which are compact, efficient, inexpensive, and can faithfully radiate all of the frequency components in the generated radar signal. Geo-Centers, Inc., an industrial partner of Northeastern University, has developed a novel wideband antenna based on a transverse electromagnetic horn with rhombic taper, folded back into itself and terminated with a 50 ohm resistive load used for both transmitting and receiving. The measured performance of this transverse electromagnetic rhombus (TEMR) indicates a very uniform radiation pattern in the plane of curling flare, perpendicular to the metal plates. It is also a wide-band antenna; throughout the 200 MHz to 2.0 GHz range, the radiated signal faithfully duplicates the input signal shape *for all angles*. Thus, the TEMR appears to be close to an optimum antenna element for a time-domain radar array. This wideband antenna has been incorporated into a time domain array as part of a vehicle-mounted GPR countermine system. The detection results for this system have been very encouraging, with 100% of all metal mines and over 90% of plastic mines detected in realistic simulations.

Microwave Enhanced Infrared Thermography

In addition to using individual microwave and infrared sensing systems, we propose a hybrid sensor in which a high-power microwave transmitter is combined with an infrared camera. The transmitter introduces energy into the ground which is absorbed at different rates by buried objects and the surrounding soil. The resulting differential heating is sensed by the infrared camera thereby leading to an image of the underground object.

While careful modeling will be required to evaluate performance and optimize the transmitting antenna design, the basic soundness of the approach has been demonstrated with simulated differential sunlight heating. We are examining the selection of a microwave wavelength to penetrate to the desired mine depth making use of the dielectric contrast of the mine as well the contrast in its thermal parameters. Microwave energy can be focused and directed into the ground at the pseudo-Brewster angle to minimize reflection and thus maximize coupling. For the common variations in soil characteristics, an elliptical reflector-type antenna could be positioned so that its major axis aligns with the Brewster angle far in front of a detector. The converging rays from all parts of the elliptical reflector will arrive at the target focal point with a range of angles. Finally, by taking IR images before and after energy is delivered, difference images can be constructed which will reduce the masking.

Acoustic Phenomena

Although the acoustic mismatch between particulate soils and solid mines makes acoustic sensing a promising area of research for mine detection, previous studies have demonstrated the difficulty of coupling sufficient acoustic energy from air into the ground. Contact sensors, on the other hand, are slow and awkward for use by moving troops, and dangerous in applications where pressure must be minimized.

One alternative is laser-induced acoustic-wave generation. CO₂ laser pulses are strongly absorbed in the surface of most solids. Modulating the laser power at acoustic frequencies produces audible and trans-audible sound vibrations. The dominant frequencies have been identified with dimensional resonances in a 300 cm³ irregular sample. Applied to a mine detection system, the laser could be raster-scanned across the area under investigation with detection through a remote ground contact or rolling sensor array. Acoustic resonance when excitation is near a mine could be correlated with the mine position by knowing the laser excitation position.

Acoustic array signal processing will benefit from the concurrent work in electromagnetic signal processing. Multistatic processing of acoustic signals will closely parallel the work on multistatic EI and GPR. Algorithms for multistatic GPR and EI will be tested with simulated or experimental HFA data to measure the enhanced probability of acoustic detection from array processing.

Summary

Although there undoubtedly exist more exotic sensors which could be used for detecting land mines, we expect that clever use of mature technologies will ultimately prove to be efficient, cost effective, reliable, and with a shorter development horizon since we will utilize commercial, off-the-shelf components which already exist. The novel aspects of Northeastern University's approach are: (1) to combine multiple sensors synergistically, yielding more information than would be available to any single sensor technology operating alone, and (2) to use "smart" signal-processing algorithms derived from physics-based models which take into account the actual sensor parameters as well as material and electrical characteristics of the soil and land mines. By processing data in an intelligent manner, rather than simply treating it as a generic bit stream, we hope to utilize information that would otherwise be discarded, and which will make mine detection much more successful.

Abstract

In this paper we consider a wavelet based edge-preserving regularization scheme for use in linear image restoration problems. Our efforts build on a collection of mathematical results indicating that wavelets are especially useful for representing functions that contain discontinuities (i.e. edges in two dimensions or jumps in 1-D). We interpret the resulting theory in a statistical signal processing framework and obtain a highly flexible framework for adapting the degree of regularization to the local structure of the underlying image. In particular, we are able to adapt quite easily to scale-varying and orientation-varying features in the image while simultaneously retaining the edge preservation properties of the regularizer. We demonstrate a half-quadratic algorithm for obtaining the restorations from observed data.

1 Introduction

In many applications recorded images represent a degraded version of the original scene. For example, the images of extraterrestrial objects observed by ground based telescopes are distorted by atmospheric turbulence [1] while motion of a camera can result in an undesired blur in a recorded image. Despite the different origins, these two cases along with others from a variety of fields, share a common structure where the exact image undergoes a “forward transformation” and is corrupted by observation noise. The source of this noise is the disturbance caused by the random fluctuations in the imaging system and the environment. The goal of image restoration is to recover the original image from these degraded measurements.

Often the forward transformation acts as a smoothing agent so that the resulting restoration problem is ill-posed in the sense that small perturbations in the data can result in large, non-physical artifacts in the recovered image [1, 2]. Such instability is typically addressed through the use of a regularization procedure which introduces *a priori* information about the original image into the restoration process. The prior information underlying the most commonly used regularization schemes is that the image is basically smooth [2]. While the regularized restorations are less sensitive to noise it is well known that the smoothness assumption impedes the accurate recovery of important features, especially edges.

In response to this problem, there has recently been considerable work in the formulation of “edge-preserving” regularization methods which result in less smoothing to areas with large intensity changes in the restored image. These methods necessarily require non-quadratic regularization functions and therefore result in nonlinear image restoration algorithms. Along these lines, Yang and Geman [3] introduced the concept of “half quadratic regularization” which addresses the nonlinear optimization problem that results from using such functions. Later, Charbonnier-Aubert-Blanc Feraud-Barlaud [4] built upon the results of this work by providing the conditions for edge preserv-

ing regularization functions. Another recent advance in this area is the Total Variation (TV) based image restoration algorithms [5]. In this approach, images are modeled as functions of bounded variation which need not be continuous. Therefore, formations of edges are encouraged and the restorations obtained by the TV based algorithms look sharper than those obtained by conventional techniques, especially if the exact image is piecewise continuous.

In this work, we consider a statistically based, wavelet-domain approach to edge-enhanced image restoration in which we employ a stochastic interpretation of the regularization process [6–8]. We note that most all of the work to date on wavelet-based, statistical regularization methods has concentrated on the use of multi-scale smoothness priors [9–12]. While Wang *et. al.* did consider issues of edge preservation in [12], their method was based on the processing of the output of an edge detector applied to the noisy data to alter the degree of regularization in a multiscale smoothness constraint. As described below and in subsequent sections, our approach is significantly different as the edge preservation is built directly into the regularization scheme itself.

Specifically, we regard the image as a realization of a random field for which the wavelet coefficients are independently distributed according to generalized Gaussian (GG) distribution laws. This model is motivated by two factors. First, recent work [6, 7, 13, 14] suggests that these models, which have heavier tails than a straight Gaussian distribution, provide accurate descriptions of the statistical distribution of wavelet coefficients in image data. Second, in addition to being a basis for $L^2(R)$, wavelets also are unconditional bases for more exotic function spaces whose members include functions with sharp discontinuities and thus serve as natural function spaces in which to analyze images [8, 15–17]. Because the norms in these Besov spaces are nothing more than weighted l_p , $0 < p$, norms of the wavelet coefficients, it is shown easily that deterministic regularization with a Besov norm constraint is equivalent to the specification of an appropriately parameterized GG wavelet prior model. From this perspective, our work can be viewed as an extension of the research

done mostly in the area of image denoising. Specifically, the wavelet domain image model of interest in this paper and the resulting nonlinear restoration algorithm are related to the large body of work originating from the *wavelet shrinkage estimators* first proposed by Donoho and Johnstone [18]. In a series of papers, Donoho and Johnstone have shown that wavelet shrinkage estimators achieve near optimal estimation performance when the unknown signal belongs to Besov spaces. Later, several authors contributed to the advancements in the area. The notion of Besov regularization has been introduced by Amato and Vuza [17] and Chambolle-DeVore-Lee-Lucier [8] and the resulting theory was interpreted in a function space setting. On the other hand, Simoncelli and Adelson [6] developed a similar denoising scheme, which they called *Bayesian wavelet coring*, by stochastically modeling the image subbands.

In this work, we make use of GG wavelet priors in a number of ways. We show that their use in an image restoration problem does in fact significantly improve the quality of edge information relative to more common smoothness priors. Inspired by the “lagged diffusivity” fixed point iteration proposed by Vogel and Oman [19] for the solution of the TV problem, we also provide an efficient algorithm for solving the non-linear optimization problem defining the restoration. By appropriately structuring the weighting pattern on the wavelet l_p norm, we demonstrate that these models provide an easy and flexible framework for adaptively determining the appropriate level of regularization as a function of the underlying structure in the image; in particular, scale-to-scale or orientation based features. This adaptation is achieved through a data-driven choice of a vector of regularization parameters. For this task, we introduce and make use of a multi-variate generalization of the L-curve method developed in [20] for choosing a single regularization parameter. We verify the performance of this restoration scheme on a variety of images, comparing the results both to smoothness constrained methods and the TV restorations.

We recognize that there are asymptotic results which state that the L-curve does not provide

consistent estimates of the regularization parameters either as the noise level goes to zero or the data length goes to infinity [21, 22]. In the non-asymptotic regime however, empirical results do point to the practical utility of this method. Moreover, as described in [20], the L-curve framework is easily adapted to handle multiple regularization parameters, a feature required for the work here.

The remainder of this paper is organized as follows. In Section 2 we give the wavelet domain formulation of the image restoration problem. In Section 3 we introduce a multiscale prior model for images and use this model in Section 4 to develop an image restoration algorithm. In Section 5 we apply the “L-hypersurface” method to the simultaneous multiple parameter selection problem posed by our image restoration algorithm. In Section 6 we demonstrate the effectiveness of our algorithm by comparing our results with existing image restoration schemes. Finally, in Section 7, conclusions and future work are discussed.

2 Regularized Image Restoration

A grey-scale image, f , can be considered as a collection of pixels obtained by digitizing a continuous scene. The image is indexed by (m, n) , $1 \leq m, n \leq 2^J$, and the intensity at the position (m, n) is denoted by $f(m, n)$. In image reconstruction and restoration problems, the objective is to estimate the image $f(m, n)$ from its degraded measurements. Mathematically, such a scenario can be adequately represented by the following linear formulation

$$\mathbf{g} = \mathbf{H}\mathbf{f} + \mathbf{u} \tag{1}$$

where the vectors \mathbf{g} , \mathbf{f} and \mathbf{u} represent, respectively, the lexicographically ordered degraded image, the original image, and the disturbance. The known square matrix \mathbf{H} represents the linear distortion. \mathbf{H} is typically ill-conditioned. This implies that the exact solution, $\mathbf{f} = \mathbf{H}^{-1}\mathbf{g}$, to (1) is extremely contaminated by noise. Rather, a unique and stable estimate \mathbf{f}^* is sought by incorporating prior information on the original image. This has the effect of replacing the origi-

nal ill-conditioned problem with a well-conditioned one whose solution approximates that of the original. Such a technique is called a regularization method [23–26].

In the Bayesian image restoration method of interest here the prior information is quantified by specifying a probability density on \mathbf{f} and combining this with the information contained in \mathbf{g} to produce an estimate of the unknown image. We assume here a linear, additive white Gaussian noise model so that the probability density for \mathbf{g} is $P(\mathbf{g}|\mathbf{f}, \sigma) = \frac{1}{(2\pi\sigma^2)^{N^2/2}} \exp \left\{ -\frac{1}{2\sigma^2} \|\mathbf{g} - \mathbf{H}\mathbf{f}\|_2^2 \right\}$ where $N^2 = 2^{2J}$ is the number of pixels in the image and σ^2 is the noise variance. If it so happens that the probability distribution for \mathbf{f} is in the form $P(\mathbf{f}|\boldsymbol{\theta}) \propto \exp \{ -\Phi(\mathbf{f}, \boldsymbol{\theta}) \}$ then by Bayes's rule, the MAP estimate, \mathbf{f}^* , is obtained by minimizing the following log-posterior density with respect to \mathbf{f} [27, 28]

$$L(\mathbf{f}, \sigma, \boldsymbol{\theta}) = \frac{1}{2\sigma^2} \|\mathbf{g} - \mathbf{H}\mathbf{f}\|_2^2 + \Phi(\mathbf{f}, \boldsymbol{\theta}). \quad (2)$$

The function $\Phi(\mathbf{f}, \boldsymbol{\theta})$, called the *energy* function in the context of Bayesian estimation, is the energy attributed to the image \mathbf{f} , and $\boldsymbol{\theta}$ is the vector of possibly unknown model parameters. We give low energy to the images which coincide with our prior conceptions and high energy to those which do not. Thus, if our prior belief about the image is that the original image is smooth, then the energy is a measure of the *roughness*.

2.1 Wavelet Representation of Image Restoration Problem

In this paper, we adopt a wavelet domain approach to the image restoration problem. A comprehensive introduction to the wavelet theory can be found in [14, 15, 29]. It is possible to obtain the wavelet transform of images through a separable representation. This decomposition can be implemented by 1-D filtering of rows and columns of images. In Fig. 1, we have schematically illustrated a 1-level wavelet decomposition of an image $f(n, m)$ with $f_J^{(0)}(n, m)$ denoting the finest scale scaling coefficients. The 1-level wavelet decomposition of the image $f_J^{(0)}(n, m)$ produces four sub-images of size $2^{J-1} \times 2^{J-1}$, $f_{J-1}^{(k)}$, $k = 0, \dots, 3$. $f_{J-1}^{(0)}$ represents the scaling coefficients at scale

$J-1$ and $f_{J-1}^{(k)}$, $k = 1, \dots, 3$ are the wavelet coefficients at scale $J-1$ corresponding to the vertical, horizontal and diagonal orientations in the image plane. Multi-level wavelet decompositions of the image $f(n, m)$ can be obtained by applying the 1-level wavelet decomposition scheme, outlined above, recursively to the scaling coefficients $f_{J-1}^{(0)}(n, m)$. For an l -level wavelet decomposition, $j_0 = J - l$ denotes the lowest resolution at which the image is represented. We will use $\mathbf{f}_j^{(k)}$ to denote the vector of wavelet (scaling) coefficients obtained by lexicographically ordering the elements of the 2-D array $f_j^{(k)}(m, n)$ and $\hat{\mathbf{f}}$ to denote a lexicographically ordered version of all wavelet coefficients $\hat{f}(n, m)$.

With the conventions above, we can represent the problem in (1) in the wavelet domain as

$$\begin{aligned}\mathcal{W}\mathbf{g} &= (\mathcal{W}\mathbf{H}\mathcal{W}^T)\mathcal{W}\mathbf{f} + \mathcal{W}\mathbf{u} \\ \hat{\mathbf{g}} &= \hat{\mathbf{H}}\hat{\mathbf{f}} + \hat{\mathbf{u}},\end{aligned}\tag{3}$$

where \mathcal{W} is the 2-D wavelet transform matrix, $\hat{\mathbf{g}}$, $\hat{\mathbf{f}}$ and $\hat{\mathbf{u}}$ are the vectors holding the scaling and wavelet coefficients of the data, the original image, and the disturbance, $\hat{\mathbf{H}}$ is the wavelet domain representation of our linear degradation operator \mathbf{H} , and $\mathcal{W}^T\mathcal{W} = \mathbf{I}$ follows from the orthogonality of the wavelet transform. Note that since the wavelet transform is orthonormal \hat{u} is again Gaussian with zero mean and variance σ^2 .

3 A Multiscale Image Model

A key component of our image restoration algorithm is the use of a multiscale stochastic prior model for f . To motivate the particular choice of prior model used here, consider the wavelet coefficients of a typical image at a particular resolution. Wavelet coefficients are obtained by differentiation-like operations. Since the spatial structure of many images typically consists of smooth areas dispersed with occasional edges, the distribution of wavelet coefficients should be sharply peaked around zero, due to the contribution of smooth areas, and have broad tails repre-

senting the contribution of the edges [6].

Following the work in [6, 7] on image coding and denoising, we model the distribution of wavelet coefficients of images by a Generalized-Gaussian (GG) density [13, 14]

$$P\left(f_j^{(k)}(m, n) | p, \kappa_j^{(k)}\right) \propto \exp\left\{-\frac{1}{p} \left|\frac{f_j^{(k)}(m, n)}{\kappa_j^{(k)}}\right|^p\right\}, \quad (4)$$

where $0 \leq p \leq 2$ is a parameter which determines the tail behavior of the density function and $\kappa_j^{(k)}$ is a *scale parameter* similar to the standard deviation of a Gaussian density. We will refer to the zero mean density in (4) as $GG(0, \kappa_j^{(k)}, p)$. For $p = 1$ we have the Laplacian density and for $p = 2$ we have the familiar Gaussian density. The tails of the GG distribution becomes increasingly heavier as p approaches zero. We assume that the mean of the image is subtracted from the image and that the scaling coefficients $f_{j_0}^{(0)}(m, n)$, are i.i.d. $GG(0, \kappa_{j_0}^{(0)}, p)$.

The specification of one κ parameter for each scale and orientation results in an image model far too complex to be of use in a restoration procedure. Nonetheless, the structure of the model in (4) coupled with the specification of the problem in the wavelet domain does suggest a variety of simplifications which are of use for the restoration problem. In this work, we consider the following three models:

1. **Model 1:** The scaling coefficients $f_{j_0}^{(0)}(m, n)$, are i. i. d. with $GG(0, \kappa_{j_0}^{(0)}, p)$ and the wavelet coefficients are i. i. d. with exponentially decreasing variances, i.e. $f_j^{(k)}(m, n) \sim GG(0, \kappa 2^{-\alpha(j-j_0)}, p)$, $i = 1, 2, 3$, $j_0 \leq j \leq J - 1$ with j_0 the coarsest scale, κ the scale parameter corresponding to j_0 and $\alpha \geq 0$. The rationale behind this model is that it is equivalent to a deterministic modeling of the image as a member of a Besov space [15].
2. **Model 2:** The scaling coefficients $f_{j_0}^{(0)}(m, n)$, are i. i. d. with $GG(0, \kappa_{j_0}^{(0)}, p)$ and the wavelet coefficients at a particular scale are i. i. d. with $GG(0, \kappa_j, p)$, $j = j_0, \dots, J - 1$. This model is useful in cases where the variance of the wavelet coefficients at different scales cannot be

well-approximated by a simple exponential law.

3. **Model 3:** The scaling coefficients $f_{j_0}^{(0)}(m, n)$, are i. i. d. with $GG(0, \kappa_{j_0}^{(0)}, p)$ and the wavelet coefficients at different orientations (horizontal, vertical or diagonal) are distributed with $GG(0, \kappa^{(k)} 2^{-\alpha(j-j_0)}, p)$, $i = 1, 2, 3$, $j_0 \leq j \leq J - 1$. Such a model is most suitable for images with significantly different characteristics in different orientations as might arise in geophysical restoration problems involving layered structures.

We make several observations regarding these models. First, they are indeed of low dimensionality. In addition to the α and p parameters, Model 1 is characterized by two κ coefficients: one for the coarsest scale scaling coefficients and one multiplying the exponential for the wavelet coefficients. There are a total of $J - j_0 + 1$ κ 's for Model 2 and four κ values required to characterize Model 3. In subsequent sections, we shall see that the number of regularization parameters to be determined in the restoration algorithm is equal to the number of κ 's characterizing the prior model being used. Moreover, an appropriate on-line choice of the model parameters provides a mechanism for adapting the level of regularization in an image to the underlying scale-to-scale structure (Models 1 and 2) or to orientation-dependent structure (Model 3). While, the above three models certainly do not represent an exhaustive enumeration of all possible multiscale regularization approaches, as seen in Section 6, they do provide a strong indication as to the utility of this type of modeling technique for image restoration.

Finally, we comment on the estimation of the hyper-parameters, p , α , and $\kappa_j^{(k)}$. In a restoration algorithm, these parameters could be estimated from the data by assigning appropriate priors to each and maximizing the resulting log-posterior function with respect to the hyper-parameters and the image. However, such an approach presents many computational difficulties and unnecessarily complicates the problem. Instead, for the remainder of this paper we choose to simplify the problem

by fixing the p and α *a priori*. Generally, the performance of the regularizer is impacted to a greater extent by the on-line identification of the κ parameters [30] (or as explained in subsequent sections, quantities closely related to κ) so we concentrate our effort on identifying good choices of κ .

The issue of selecting an appropriate p is extensively discussed in Section 4.1. As for the selection of α , we propose using a fixed *a priori* choice obtained from the empirical study of a number of images. According to our findings, for most images representing natural scenes the α value which produced the best fit to the image data under the Model 2 scheme (for $p = 1$) fell between 0.6 and 1.6 with mean $\alpha \approx 1.2$. We evaluated the effects of varying the α value on a number of restoration problems and saw that the results were relatively insensitive to variations in α in the range suggested by the observations. The first example in Section 6 supports this. Note also that past research reveals similar conclusions [30] indicating that the performance of the estimator is degraded little by the error in α . Therefore, for all experiments performed we used $\alpha = 1.2$ as our fixed *a priori* choice.

4 A Multiscale Image Restoration Algorithm

The MAP estimate of the wavelet coefficients of the original image is found by maximizing the log-posterior function in (2). Substituting the prior probability density developed in Section 3 into (2), the MAP estimate of $\hat{\mathbf{f}}$ is seen to be the minimum of the following cost function with respect to $\hat{\mathbf{f}}$ (assuming for the time being that $\lambda_j^{(k)}$ is known)

$$J(\hat{\mathbf{f}}, \boldsymbol{\lambda}) = \|\hat{\mathbf{g}} - \hat{\mathbf{H}}\hat{\mathbf{f}}\|_2^2 + \lambda_{j_0}^{(0)} \|\mathbf{f}_{j_0}^{(0)}\|_p^p + \sum_{j=j_0}^{J-1} \sum_{i=1}^3 \lambda_j^{(k)} \|\mathbf{f}_j^{(k)}\|_p^p \quad (5)$$

where $\lambda_j^{(k)} = \frac{2\sigma^2}{p(\kappa_j^{(k)})^p}$ are weighting parameters and $\boldsymbol{\lambda} = [\lambda_{j_0}^{(0)}, \lambda_{j_0}^{(1)}, \dots, \lambda_{J-1}^{(3)}]^T$. The formulation in (5) easily accommodates the Model 1-3 regularization schemes discussed in Section 3 by defining the appropriate relationships for $\lambda_j^{(k)}$. For example, putting $\lambda_{j_0}^{(0)} = \lambda_1$ and $\lambda_j^{(k)} = \lambda_2 2^{\alpha(j-j_0)}$ results in the Model 1 regularization scheme while assigning a different λ_j to each scale in the wavelet

domain without regarding the orientation we obtain the Model 2 regularization scheme. Suppose that $J(\hat{\mathbf{f}}, \boldsymbol{\lambda})$ has a minimum in $\hat{\mathbf{f}}$, then at a stationary point $\hat{\mathbf{f}}^s$, the gradient of $J(\hat{\mathbf{f}}, \boldsymbol{\lambda})$ must vanish. Unfortunately, the l_p norm terms appearing in (5) is not differentiable for $p \leq 1$. Hence, we propose the following *smooth* approximation to the l_p norm, raised to the power p , as in [19]

$$\|\mathbf{x}\|_p^p \approx \sum_i \left((|x_i|^2 + \beta)^{p/2} - \beta^{p/2} \right) \quad (6)$$

where $\beta \geq 0$ is a stabilization constant and x_i denotes the i -th element of the vector \mathbf{x} . Substituting (6) into (5) and taking the gradient of the cost function we arrive at the following equation

$$\mathbf{D}^* = \text{diag} \left[\frac{\lambda_i}{(|\hat{f}_i^*|^2 + \beta)^{1-p/2}} \right]_{i=1}^{N^2} \quad (7)$$

$$\left(\hat{\mathbf{H}}^T \hat{\mathbf{H}} + \frac{p}{2} \mathbf{D}^* \right) \hat{\mathbf{f}}^* = \hat{\mathbf{H}}^T \hat{\mathbf{g}}, \quad (8)$$

where $\hat{\mathbf{f}}^*$ is the minimum of $J(\hat{\mathbf{f}}, \boldsymbol{\lambda})$ with the approximation in (6), \hat{f}_i^* is the i -th element of $\hat{\mathbf{f}}^*$ and λ_i is the associated regularization parameter. The above equation gives the first order conditions that must be satisfied by $\hat{\mathbf{f}}^*$. By direct analogy with the lagged diffusivity method of Vogel and Oman [19], we can develop a fixed point iteration to solve for $\hat{\mathbf{f}}^*$. Starting with an initial point $\hat{\mathbf{f}}^0$, we solve the following equation for $\hat{\mathbf{f}}^{k+1}$

$$\left(\hat{\mathbf{H}}^T \hat{\mathbf{H}} + \frac{p}{2} \mathbf{D}^k \right) \hat{\mathbf{f}}^{k+1} = \hat{\mathbf{H}}^T \hat{\mathbf{g}}, \quad (9)$$

where \mathbf{D}^k is obtained by replacing \hat{f}_i^* by \hat{f}_i^k in (7)¹. The iteration is terminated whenever $\frac{\|\hat{\mathbf{f}}^{k+1} - \hat{\mathbf{f}}^k\|}{\|\hat{\mathbf{f}}^k\|} < \gamma$, with γ being a small positive constant. We use 10^{-5} in our simulations. The fixed point iteration in (9) is a special case of the “half quadratic regularization” scheme introduced by Geman *et. al.* [3] and the ARTUR scheme due to Charbonnier *et. al.* [4]. Adopting the notation in [4] we define the following function

$$\phi(t) = (t^2 + \beta)^{\frac{p}{2}} - \beta^{\frac{p}{2}}. \quad (10)$$

¹The iteration index for the iterative optimization, k should not be confused here with the index (k) used to describe the orientations of the wavelet/scaling coefficients.

Then, the approximated cost function can be expressed in terms of the function $\phi(t)$. Furthermore, $\phi(t)$ satisfies the conditions (a)-(i) presented in [4](page 300, equation (12)). Roughly speaking, these conditions ensure that the $\phi(t)$ function applies less and less penalty as the magnitude of the wavelet coefficients increase (so that the large-magnitude wavelet coefficients, primarily associated with edges, are well-preserved) and that the restoration algorithm is convergent in the sense that the sequence $J(\hat{\mathbf{f}}^k, \boldsymbol{\lambda})$ is convergent and that $(\hat{\mathbf{f}}^{k+1} - \hat{\mathbf{f}}^k) \xrightarrow{k \rightarrow +\infty} \mathbf{0}$. In the special case where $\phi(t)$ is convex (which occurs if $p \geq 1$) and $\hat{\mathbf{H}}$ is full-rank, the iterates $\hat{\mathbf{f}}^k$ converge and the computed solution is the unique minimum of (5). However, when $p < 1$, $\phi(t)$ is concave and the algorithm computes a local minimum of (5) [4].

The iterative algorithm in (9) requires the solution of a very large linear matrix equation. Note that the matrix appearing on the right hand side of (9) is symmetric and positive definite. Therefore, the conjugate gradient (CG) algorithm [31] can be conveniently used to compute the solution $\hat{\mathbf{f}}^{k+1}$ in (9) at each step. In this way, the algorithm given in (9) is doubly iterative in that an outer iteration is used to update the solution $\hat{\mathbf{f}}^k$ and an inner iteration is used to solve the system of equations in (9) by the CG method. The special structure of the matrices $\hat{\mathbf{H}}$ and \mathbf{D}^k could be used to decrease the computational cost substantially. The first matrix, $\hat{\mathbf{H}}$ is merely the wavelet domain representation of our degradation operator. If the kernel is convolutional, it has been shown by Zervakis *et. al.* [32] that this matrix can be diagonalized by a special Fourier transform matrix by invoking the circulant assumption. On the other hand, the second matrix \mathbf{D} is diagonal in the wavelet domain. Therefore, the vector matrix multiplications required for the implementation of the CG algorithm can be computed in an efficient way by going back and forth between the wavelet and the Fourier transform domains. In this case, the cost of multiplying a vector with the matrix $\hat{\mathbf{H}}^T \hat{\mathbf{H}} + \frac{p}{2} \mathbf{D}^k$ is dominated by the cost of the FFT which is $O(N^2 \log N)$.

We note that the iterative algorithm in (9) can be efficient even in the case where $\hat{\mathbf{H}}$ is not convo-

lutional since the wavelet domain representation of a wide range of operators is sparse [18]. In those cases, standard techniques for sparse matrices can be used to reduce computational complexity.

4.1 Selection of Appropriate p and β values

The possibility that multiple local minima of (5) may exist for $p < 1$ presents an interesting trade-off. From a computational viewpoint, it is highly desirable to use $p \geq 1$, since in this case the cost function is convex and global convergence is guaranteed. However, based on empirical studies of the wavelet coefficients of images it has been shown that the GG model for the distribution of the wavelet coefficients usually corresponds to $p < 1$ and a typically recognized value is $p = 0.7$ [13]. Analysis of the use of GG priors in the context of image denoising has been performed by Moulin and Liu [33]. The results in [33] suggest that only modest improvement can be achieved by using $p < 1$ as compared with $p = 1$. In our experiments, we essentially arrived at the same conclusion. That is, the restored images obtained by using the best value of p (in terms of model fit) were visually almost the same as the results obtained by using $p = 1$, although slightly lower estimation errors were observed for $p < 1$. Therefore, we propose using $p = 1$ as the fixed *a priori* choice for the shape parameter of the GG distribution. Note that we do not claim that $p = 1$ is the right value for all types of images. Rather, we are saying that the estimation of p directly from the data is a complicated problem and in the absence of accurate prior information on p , $p = 1$ provides strong restoration results with guaranteed global convergence properties.

The role of the parameter β is two-fold. First it controls how close the approximation in (6) is to the original l_p norm. Using a relatively small β provides better restoration of edges in the image since a smaller β value provides better approximation to the l_p norm. Second, it essentially determines the convergence speed of the algorithm. While we do not intend to carry out a numerical analysis of the fixed point iteration in (9), the basic reason is that for $\beta = 0$, $\phi(t)$ in (10) is not differentiable at $t = 0$ and instability in the numerical computations may arise. If β

is relatively large, the algorithm is fast, and the convergence speed deteriorates as β gets smaller. Therefore, β should be set so as to achieve a compromise between the convergence speed and the edge preservation. Based on our experience on natural scenes, we found that restorations obtained for $\beta \approx 1$ were visually indistinguishable from the restorations obtained for $\beta \ll 1$. We note that a similar value is recommended for the TV algorithm [19].

5 Regularization Parameter Selection

In this paper, we use a multi-dimensional extension of the L-curve method [20], called the L-hypersurface method [34], to determine $\boldsymbol{\lambda}$ in (5). In order to describe the method thoroughly, we consider the following generalized image restoration scheme where the estimate of the original image f is obtained by minimizing the following cost function

$$J(\mathbf{f}, \boldsymbol{\lambda}) = \|\mathbf{g} - \mathbf{H}\mathbf{f}\|_2^2 + \sum_{j=1}^M \lambda_j \|\mathbf{R}_j \mathbf{f}\|_p^p \quad (11)$$

where λ_j , $j = 1, \dots, M$ are the regularization parameters and \mathbf{R}_j are the corresponding regularization operators. The cost function in (11) represents a multiply constrained least squares problem and includes many popular image restoration schemes as its special cases. Our wavelet domain image restoration algorithm is obtained if \mathbf{g} , \mathbf{H} and \mathbf{f} are in the wavelet domain and \mathbf{R}_j , $j = 1, \dots, M$ are the operators which extract desired portions of the wavelet transform of \mathbf{f} . For example, we can take \mathbf{R}_1 as the operator extracting the coarsest scale scaling coefficients and \mathbf{R}_2 as the operator extracting the wavelet coefficients for a doubly constrained, Model 1-type problem.

To extend the L-curve, we first introduce the following quantities

$$\mathbf{f}^*(\boldsymbol{\lambda}) = \arg \min_{\mathbf{f}} J(\mathbf{f}, \boldsymbol{\lambda}) \quad (12)$$

$$z(\boldsymbol{\lambda}) = \log \|\mathbf{g} - \mathbf{H}\mathbf{f}^*(\boldsymbol{\lambda})\|_2^2, \quad x_j(\boldsymbol{\lambda}) = \log \|\mathbf{R}_j \mathbf{f}^*(\boldsymbol{\lambda})\|_p^p, \quad j = 1, \dots, M \quad (13)$$

With the above definitions, the “L-hypersurface” [34] is defined as a subset of \mathcal{R}^{M+1} associated

with the map $s(\boldsymbol{\lambda}) : \mathcal{R}_+^M \rightarrow \mathcal{R}^{M+1}$, such that

$$s(\boldsymbol{\lambda}) = (x_1(\boldsymbol{\lambda}), \dots, x_M(\boldsymbol{\lambda}), z(\boldsymbol{\lambda})) \quad (14)$$

For a single constraint, the L-hypersurface reduces to the conventional L-curve which is simply a plot of the residual norm versus the norm of the restored image in a doubly logarithmic scale for a set of admissible regularization parameters. In this way, the L-curve displays the compromise between the minimization of these two quantities. It has been argued and numerically shown that the so called “corner” of the L-curve corresponds to a point where regularization and perturbation errors are approximately balanced [20].

Analogous to the one dimensional case, the L-hypersurface is a plot of the residual norm $z(\boldsymbol{\lambda})$ against the constraint norms $x_j(\boldsymbol{\lambda})$, $1 \leq j \leq M$. Intuitively, the “generalized corner” of the L-hypersurface should correspond to a point where regularization errors and perturbation errors are approximately balanced. By a generalized corner, we mean a point on the surface around which the surface is maximally warped. We can measure how much a surface is warped around a point by computing the Gaussian curvature [34]. In Fig. 2 we plot a typical L-hypersurface along with its Gaussian curvature and the error between the original and the restored images for a range of regularization parameters. The experiment for which the L-hypersurface was computed was the restoration of a 32×32 image degraded by a Gaussian blur of variance 1 pixel and corrupted by white Gaussian noise at 30dB SNR. We used our multiscale algorithm with $p = 2.0$ and Model 1 regularization scheme as shown in Fig. 3(a). Figure 2(b) shows the curvature of the L-hypersurface shown in Fig. 2(a) with λ_1 (resp. λ_2) being the regularization parameter for the scaling (resp. wavelet) coefficients. Figure 2(b)-(c) clearly indicate the usefulness of the Gaussian curvature plot in assessing the goodness of regularization parameters. It is observed that the curvature is significant along an extended maxima which is very close to a region in the error norm, $\|\mathbf{f} - \mathbf{f}^*(\boldsymbol{\lambda})\|_2^2$, plot in Fig. 2(c) where the error between the actual and the restored images is minimized. Moreover, the

curvature plot indicates that there is in fact more than one good regularization parameter for the scaling coefficients, and as long as we choose the correct value for the regularization parameter corresponding to the wavelet coefficients the restorations should have approximately the same quality. The error norm plot in Fig. 2(c) supports this point of view.

For the numerical experiments described in the following section, the regularization parameters are selected by searching over a grid of parameter values in λ space and choosing that point whose curvature is maximum. The computational complexity of this technique is clearly quite high. The major difficulty here is that the curvature of the L-hypersurface possesses many maxima/minima as seen in Figure 5(c) and therefore the use of well-known optimization techniques such as the Gauss-Newton method would fail. As the primary issue of interest here is in demonstrating that there is utility to the L-hypersurface method, we leave the considerable effort of finding a more efficient implementation to future work.

6 Experimental Results

In this section, we illustrate the performance of our proposed multiscale image restoration algorithm. All computations were carried out by using the Matlab commercial software package with double precision arithmetic. We used the routines in Donoho's Wavelab toolbox [35] for the computation of forward and inverse wavelet transforms with Daubechies' eight tap most symmetrical wavelets [29]. In all cases below, we limited the number of levels of wavelet decomposition to 3. In the first example, we used a Gaussian convolutional kernel, $h(x, y) = \frac{1}{4\sigma_x\sigma_y} \exp\{-\frac{x^2+y^2}{2\sigma_x\sigma_y}\}$, with $\sigma_x = \sigma_y = 2.0$ to blur the 256×256 Mandrill image. Zero mean white Gaussian noise was added to set the SNR to 30dB. In Fig. 4 (a)-(b) we display the original and the blurred, noisy images.

We restored the degraded Mandrill image using three regularization techniques: our proposed multiscale regularization scheme, the Constrained Least Squares (CLS) algorithm with a 2-D Lapla-

cian regularizer [2], and the TV algorithm. The CLS and the TV algorithms are special cases of the generalized image restoration scheme in (11) for $j = 1$ in which taking $p = 2$, and $\mathbf{R}_1 = \Delta$ (i.e. 2-D Laplacian) results in the CLS cost function and $p = 1$ and $\mathbf{R}_1 = \nabla$ gives the cost function corresponding to the TV algorithm. The action of the 2-D Laplacian operator Δf at the pixel (m, n) is $\Delta f(m, n) = -4f(m, n) + f(m, n + 1) + f(m + 1, n) + f(m, n - 1) + f(m - 1, n)$ and the action of the gradient operator ∇f is given by $\nabla f(m, n) = [\nabla_x f(m, n), \nabla_y f(m, n)]^T$ with $\nabla_x f(m, n) = -f(m, n) + f(m + 1, n)$ and $\nabla_y f(m, n) = -f(m, n) + f(m, n + 1)$. Both operators are implemented by circularly wrapping the image at the boundaries. The relevant regularization parameters were determined using the L-curve or the L-hypersurface method. For the TV algorithm and our algorithm we used $\beta = 1.0$. Experimental results obtained for $\beta = 10^{-10}$ indicate that smaller choices of β do not improve the visual quality of the restorations (see Fig. 4(g)-(h) and Fig. 7(e)-(f)).

In Fig. 4(c)-(h) we display the restored Mandrill images corresponding to the CLS, the TV and the multiscale algorithm. For our multiscale image restoration method we computed four restorations, displayed in Fig. 4(e)-(h), according to the Model 1 and Model 2 regularization schemes described in Section 3. Figure 4 shows that both the TV algorithm and our algorithm produce restored images visually superior to the CLS algorithm. We also observe that the images restored by our algorithm are a little sharper than the image restored by the TV algorithm and that the texture-like regions abundant in the Mandrill image (e.g. the hairs around the mouth of the Mandrill) are better recovered by our algorithm. The Root Mean Square Error (RMSE), $\sqrt{\frac{1}{N^2} \|\mathbf{f} - \mathbf{f}^*(\boldsymbol{\lambda})\|_2^2}$, between the original and restored images are listed in Table 1.

For the Model 1 restoration in Fig. 4(e) the L-hypersurface was used to determine two parameters, λ_1 and λ_2 corresponding to the coarsest scale scaling coefficients and the wavelet coefficients respectively as shown in Fig. 3(a). In this case, the curvature of the L-hypersurface is a 2-D function

of the regularization parameters as seen in Fig. 5(a). Also shown in Fig. 5(b) is a plot of RMSE as a function of these regularization parameters. Examining these plots shows that the curvature surface has a distinct extended maxima along which the norm of the error is very close to being a minimum. Thus, we see that the restoration algorithm is not overly sensitive to the scaling coefficient regularization parameter and locating the correct regularization parameter for the wavelet coefficients is more important.

In the Model 2 restoration in Fig. 4(f), each scale in the wavelet domain is assigned a different regularization parameter as seen in Fig. 3(b). Based on the L-hypersurface obtained for the Model 1 restoration in Fig. 5(a), we set the scaling coefficient regularization parameter to 10^{-5} . Figure 6(a)-(c) shows the curvature of the L-hypersurface obtained for this experiment. Since in this case the curvature is a 3-D function (one parameter for each wavelet scale), each of the 2-D plots in Fig. 6(a)-(c) is actually a slice of the curvature hypersurface with the regularization parameter corresponding to the coarsest scale being constant. Again, the maxima of the curvature of the L-hypersurface track well the minima of the RMSE surface so that we are close to the “optimal” regularization parameters. We see little difference either in terms of the error norm or in terms of visual quality between the Model 1 and Model 2 restorations in Fig. 4(e) and (f). This example verifies the primary assumption of Model 1 scheme where it was assumed that the variance of the wavelet coefficients decrease uniformly across scales according to an exponential law.

Finally, in Fig. 4(g)-(h) we display the Model 1 restorations corresponding to an idealized case where the parameters α and p were estimated directly from the original image. Clearly, this is not a realistic situation since in practice the original image is not available. Nonetheless, this example is interesting since it gives us an idea about how much improvement can be expected when using the optimal α and p values as opposed to fixed *a priori* choices $\alpha = 1.2$ and $p = 1.0$. The optimal p was estimated by using the method proposed in [14] and was found to be $p_{opt} = 0.7280$. The

exponential parameter α_{opt} was estimated by computing the slope of the line fitted to the $\log \kappa_j$ for $j = j_0, \dots, J - 1$. It was found to be $\alpha_{opt} = 0.6117$. Since p_{opt} yields a non-convex optimization task, we computed the restorations for this case in 2 stages. The first stage starts with computing the restoration for $p = 1.0$, which is unique and then the restored image for $p = 1.0$ is fed as the starting point to the restoration algorithm with $p = 0.7280$. There is no guarantee that the restored image for p_{opt} corresponds to the global minimum of the cost function, nevertheless we obtained good results with this scheme. Figure 5(c)-(d) shows the L-surface and the RMSE surface for p_{opt} , respectively. Figure 4(g)-(h) are the restorations obtained for this case. Figure 4(g)-(h) differs only in the value used for β which was set to 1.0 in (g) and 10^{-10} in (h). As already pointed out the two restorations are visually indistinguishable, though the convergence of the algorithm took significantly longer for $\beta = 10^{-10}$. Finally, comparison of Fig. 4(g)-(h) with Fig. 4(e)-(f) reveals that there is visually little difference between the restored images corresponding to p_{opt} and $p = 1.0$ cases. This example shows that using $p < 1$ does not yield a significant improvement in the performance of the multiscale algorithm.

In our second example, we first blurred the original Bridge image in Fig. 7(a) with a 9×9 uniform motion blur and added white Gaussian noise to the degraded image to set the SNR at 40dB. The blurred image obtained by this way is shown in Fig. 7(b). Having established the edge preserving utility of the TV and the proposed algorithm over the conventional CLS method, we only display the restorations obtained by the TV and the proposed algorithm in Fig. 7(c)-(f). For our multiscale algorithm, we applied the Model 1 and Model 2 regularization schemes with the L-hypersurface choice of regularization parameters. As in the previous example, we determined 2 regularization parameters corresponding to the scaling and the wavelet coefficients for Model 1 and 3 parameters corresponding to the wavelet coefficients at each scale for Model 2. In Model 2 restoration, the regularization parameter for the scaling coefficients were set to 10^{-4} from Fig. 8(a).

Figure 7(d) shows the Model 1 restoration and Fig. 7(e) and (f) show the Model 2 restorations. In Fig. 7(e)-(f) all parameters except for β are the same ($\beta = 1.0$ in (e) and $\beta = 10^{-10}$ in (f)).

Although the RMSE values in Table 1 were similar, the restored images in Fig. 7(c)-(d) exhibit vastly different visual characteristics. The TV algorithm fails to recover many of the small features in the image and produces an overly homogenized restoration resembling an “oil painting” of the original scene. The multiscale algorithm is able to reproduce finer detail thereby yielding a more visually appealing restoration. As in the previous example, we see little difference in terms of the visual quality between the Model 1 and Model 2 restorations. Note that we used the same value $\alpha = 1.2$ in both Mandrill and Bridge examples regardless of the image considered.

In our final example, we demonstrate the orientation adaptive nature of our approach. In Fig. 9 (a), we display an artificial 32×32 image which has significant structure in the horizontal direction, but little in the vertical and diagonal directions. This image was blurred by a Gaussian convolutional kernel with $\sigma_x = \sigma_y = 1$, and zero mean white Gaussian noise was added to set the SNR at 30dB. Because of the large differences between the structure in the horizontal and vertical directions, an ideal image restoration algorithm should use different regularization parameters for vertical, horizontal and diagonal directions. With this in mind, in Fig. 9(c)-(d) we display the restorations obtained using Model 1 and Model 3 schemes which require three regularization parameters, λ_1 , λ_2 and λ_3 , as displayed in Fig. 3(b)-(c), respectively. The L-hypersurface was employed to determine the required regularization parameters. For both Model 1 and Model 3 schemes we set the scaling coefficient regularization parameter to 10^{-5} . For the Model 3 restoration, the regularization parameters obtained for the vertical and diagonal orientations (in which the image is constant) were approximately two orders of magnitude larger than the regularization parameter obtained for the horizontal orientation. It is clear from Fig. 9(c)-(d) that the orientation adaptive algorithm produces a much better restoration than the scale adaptive algorithm.

7 Conclusions

In this paper, we introduced a wavelet domain multiscale image restoration algorithm for use in linear image restoration problems. Following the recent results in the area of image denoising and coding, we developed a statistical prior model for the wavelet coefficients of images. Our priors are able to capture spatial, scale and orientational characteristics of images accurately. We developed a half-quadratic algorithm to solve the nonlinear optimization problem resulting from using such priors and utilized the L-hypersurface method for choosing the required regularization parameters. Experimental results show that our algorithm can produce restorations which are visually significantly better than that of the traditional techniques and at least comparable, if not better, than that of the edge-preserving algorithms.

Acknowledgments The authors would like to thank the anonymous reviewers for their comments and suggestions which have greatly improved the quality of this paper.

Tufts University**

IEEE AP-S/URSI, July 11, 2001

Outline

- **Accurate modeling of subsurface wave scattering**
- **Plane wave FDFD computation with rough ground surfaces**
- **Method validation**
- **Computational examples for mine detection**

Supported by CenSSIS, the Center for Subsurface Sensing and Imaging Systems, under the ERC program of the NSF (EEC 9986821)

Frequency Domain Computational Electromagnetic Models

Numerically Modeling EM Wave Propagation in Soil to Aid Sensor Design

- Only with knowledge of the environment surrounding mines can efficient advanced sensors be developed.
- Soil environment is extremely varied and inhomogeneous.
- Propagation is quite different in different soils.
- Numerical modeling is the only viable means of testing candidate sensing concepts on the wide variety of conditions.
- Simple flexible models that capture the essential electrical characteristics are best.
- Visualization of wave propagation assists in sensor synthesis.

Finite Difference Modeling

Time Domain

- Finite Difference Time Domain (**FDTD**) is fast, accurate, easy to implement, and intuitive.
- FDTD is best for wideband (short pulse) scattering in non-uniform media.
- Special means have been developed for **Dispersive Media**, such as soil.

Freq. domain

- Finite Difference Frequency Domain (**FDFD**) is also good for non-uniform media.
- FDFD handles frequency dependent media easily.
- FDFD is particularly useful for signal processing forward models
- Using **Pre-Conditioning**, FDFD is less computationally expensive.

PML Absorbing Boundary Condition is perfectly suited to FDFD half-space problems

- **PML necessary for wide-angle absorption**
- **Frequency independence useful for general use**
- **PML loss profile can be added to lossy material characteristics**
- **Horizontal layering is amenable to sparse storage/computation**

Abstract

The detection of landmines and buried objects requires methods that can cover large areas rapidly while providing the required sensitivity to detect the optical and spectroscopic contrasts in soil properties that can reveal their presence. These conditions on contrast and coverage can be met by capturing images of the soil at wavelengths which are sensitive to the properties modified by the presence of buried objects. In this work we investigate both imaging and scanning methods which may have some utility for the detection problem. In the imaging approach, we capture hyperspectral reflection images using an acousto-optic tunable filter (AOTF) and fluorescence images using a long-pass filter. For the scanning method, we acquire data point-by-point over a two-dimensional grid with a single emitter/detector pair. The results illustrate the potential of these two approaches for detection of landmines and buried objects.

I. Introduction

Indirect methods of detecting buried objects involve looking for differences between undisturbed soil and soil directly above a buried object. The detection of landmines and buried objects requires methods that can cover large areas rapidly while providing the sensitivity to the contrasts in soil properties that can reveal the presence of foreign objects. The conditions on coverage can be met by acquiring images of large areas or rapidly scanning over the ground. The contrast is provided by acquiring the data at specific wavelengths or over continuous spectral bands which are particularly sensitive to the properties affected by the presence of buried objects. In this work we look at both imaging and point-by-point (scanning) methods which can be adapted for use in the detection problem. The images were acquired by a charge-coupled device (CCD). Two types of images were captured: (1) narrowband reflection images using an acousto-optic tunable filter (AOTF) and (2) fluorescence images using a long-pass filter. The scanning method employed a near-infrared (NIR) emitter/detector pair where data were captured point-by-point over a two-dimensional grid.

II. Imaging-Based Methods for Object Detection

IIa. Reflection Imaging with an Acousto-Optic Tunable Filter

By taking two-dimensional images of a target zone, a large area can be spectrally mapped quickly given that the contrast between the background soil and burial sites are sufficiently strong to allow rapid detection. One method of increasing contrast is to image at/over wavelengths where the differences in reflection or fluorescence properties are maximized. These types of images can be captured rapidly by using an acousto-optic tunable filter (AOTF) for wavelength discrimination. The AOTF is

a narrowband optical filter with a electronically-selectable passband and a two-dimensional aperture. It can quickly jump between remote wavelengths or be rapidly scanned across some continuous spectral range. Band-limited (i.e., a spectral range wider than the resolution width of the filter) imaging can be performed by scanning the AOTF across a specific range of

wavelengths while exposing the image-capturing elements (e.g., film or charge-coupled device array (CCD)). Our laboratory has previously reported on the use of AOTF/CCD based systems for hyperspectral imaging[1-3].

The AOTF operates by propagating ultrasonic waves through an anisotropic crystal. The strains induced by the ultrasound act to spatially modulate the indices of refraction of the crystal. The device is essentially a three-dimensional grating whose spacing can be tuned by changing the wavelength of the ultrasound in the crystal. Since the AOTF has no moving parts and can be rapidly moved to the desired wavelength, it is ideal for use in portable instrumentation where spectral selectivity and timely feedback are required. Figure 1 shows the how the

light is discriminated by the TeO₂ AOTF used here.

In this work our imaging system was limited to wavelengths shorter than 700 nm. Thus to demonstrate the capabilities of an AOTF-based system to make wavelength-resolved images, we have examined a landmine casing both above and partially buried in sand (see Figure 2) illuminated by an incandescent lamp and imaged at wavelengths from 525 to 700 nm. A white-light image of the casing is shown in Figure 3. The imaging system is diagrammed in Figure 4 and employs a TeO₂ AOTF (Brimrose, Inc. tunable from 450 to 700 nm), a thermoelectrically cooled CCD (Santa Barbara Instruments, Model ST-6) and a camera lens with adjustable aperture and focus. At each wavelength, in addition to the landmine images, an image of a white card was also recorded along with the landmine casing for use in data normalization. The normalization process is diagrammed in Figure 5.

The normalized images for the exposed casing are displayed in Figure 6. The casing has five indentations on its surface (four around the rim and one arrow-shaped) which were filled with sand in the wavelength-resolved images. The best images in

Figure 4 The wavelength-resolved imaging system built around the AOTF.

terms of clarity and contrast between the sand and casing are the three images taken at 600 nm, 625 nm, and 650 nm respectively. The images of the partially buried casing, as displayed in Figure 8 (Figure 7 gives the orientation of the casing as seen in Figure 8), showed similar results. For these, the 625-nm and 650-nm images display the best contrast. The resulting contrasts in these reflected-light pictures are of course related to the respective colors of the casing and sand. The casing is mostly green and as one moves to longer wavelengths (starting from 525 nm) the casing reflects less light while the background sand reflects more evenly across the spectrum. Thus the contrast between the two increases as one moves from green wavelengths to the red end of the spectrum. Future work will involve investigating local reflection properties of the soil at NIR wavelengths. By performing narrowband or wavelength-resolved imaging, the contrast in soil properties can be maximized.

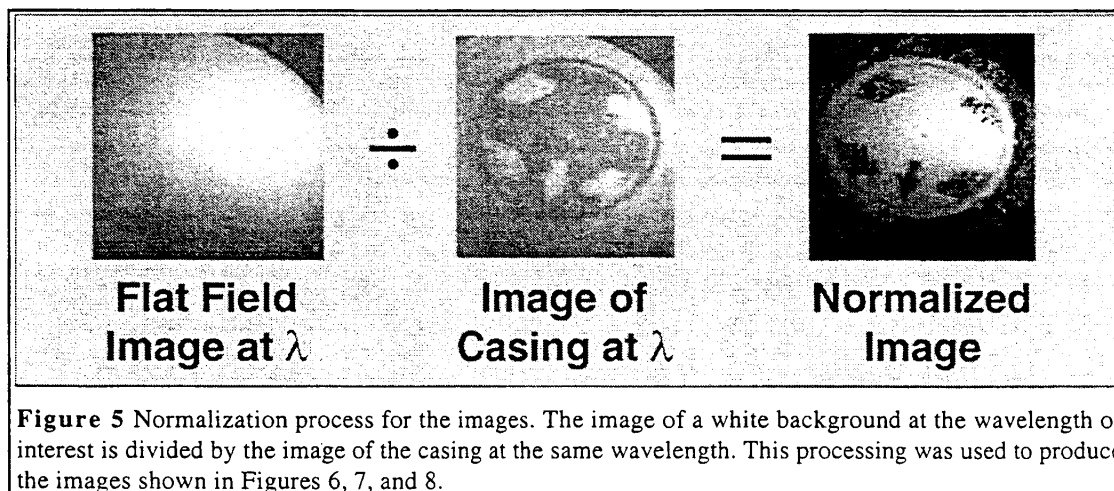

Figure 5 Normalization process for the images. The image of a white background at the wavelength of interest is divided by the image of the casing at the same wavelength. This processing was used to produce the images shown in Figures 6, 7, and 8.

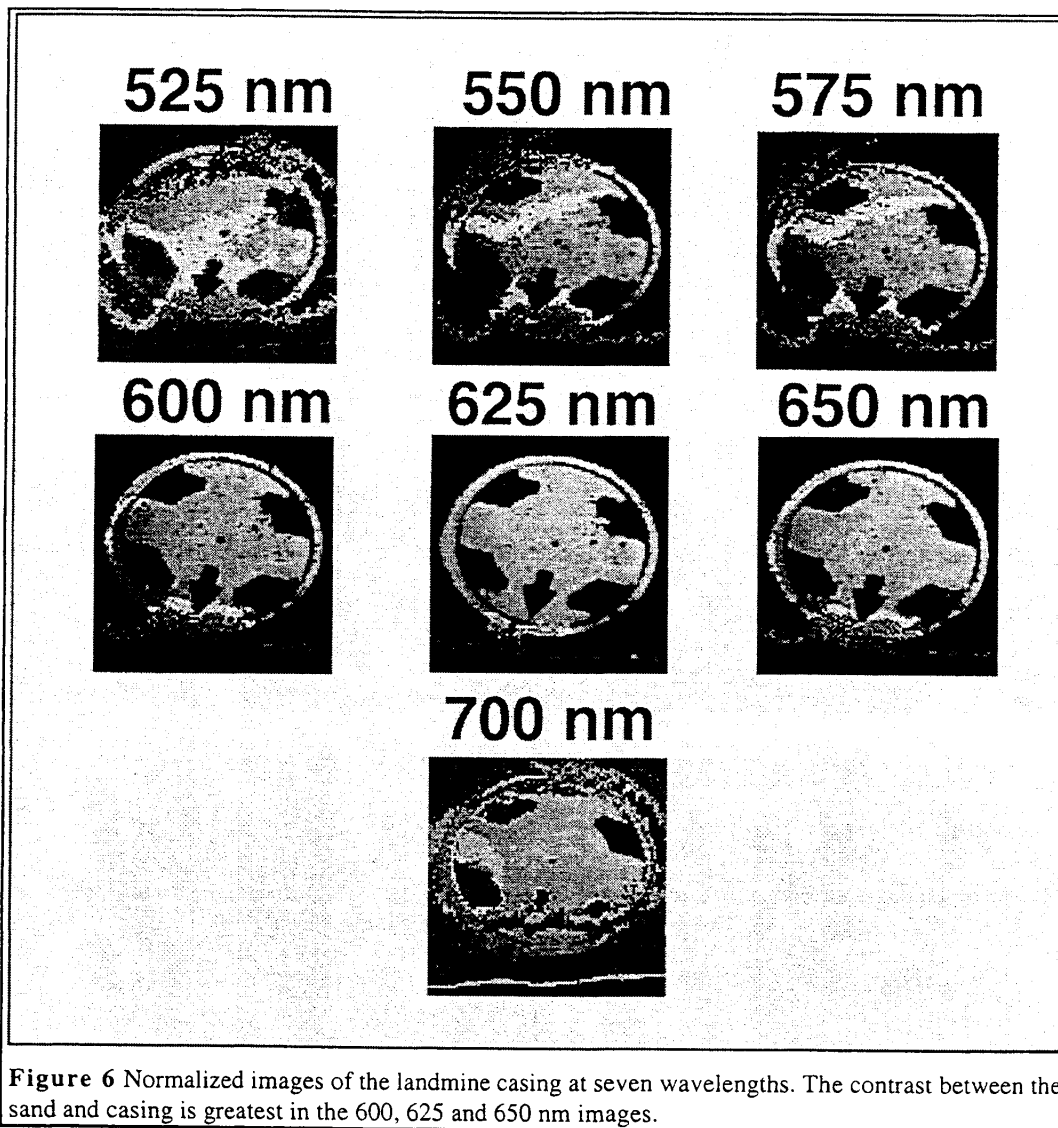

Figure 6 Normalized images of the landmine casing at seven wavelengths. The contrast between the sand and casing is greatest in the 600, 625 and 650 nm images.

IIb. Fluorescence Imaging

In addition to reflected light, we also captured images of the fluorescence emission from the partially-buried object. In this mode, the AOTF was replaced by a 525-nm long pass filter, the focusing lens/camera were axially aligned with the collection lens and the object was illuminated by the 488-nm line of an Argon laser. The captured image is shown in Figure 9. The high contrast between the casing and sand is readily apparent. If a condition of the soil above a buried mine can be detected via fluorescence, this method could be useful in low-light situations where the fluorescence can be measurably detected over ambient reflected light.

Figure 8 Normalized reflection images of the partially-buried landmine casing at seven wavelengths. The degree of contrast between the sand and casing is greatest in the 625 and 650 nm images.

Exposed portion of casing

Figure 9 Fluorescence image of the partially-buried landmine casing. The sample area was illuminated with the 488 nm line of an Argon laser. A 520 nm long pass filter was used to remove the background.

III. Point-by-Point Scanning in the NIR

In contrast to the direct imaging methods, we also performed a point-by-point reflection-mode scan in a 2-D grid pattern at NIR wavelengths over the surface of sand with wet and dry areas. The idea behind this experiment is that the soil above the buried object may contain less moisture - the flow of moisture being drawn up to the surface (due concentration gradients stemming from surface evaporation) may be affected by the presence of the object. A casing for a landmine was buried under 5 mm of material in a tray that measured 30x16x8 mm (LxWxD). In order to simulate the dry and wet areas found in the field, a piece of plastic wrap was used to separate the dry material from the wet. Using an infra-red emitter/detector matched pair operating at 915 nm, a light-

emitting diode (LED) and a photodetector were mounted side-by-side on perforated board and soldered in place. The orientation was chosen to maximize the detection of reflected IR from the infrared LED. The photodetector has a sensitive area of about 1 mm² while the LED has a collimating lens mounted in place and a radiant power of 0.5 mW. The detector and experiment are depicted in Figure 10.

The photodetector was used in the passive mode and voltages were measured with a digital multi-meter. The device was positioned using an optical rail system marked in mm. The LED and photodetector were held about 30 mm above the surface of the soil and a reading was taken, in a darkened

Figure 10 Diagram of the sensor and the experimental arrangement used for the IR scan.

Figure 11 Result for the IR scan of the buried object. The x and y axes are position and the z-axis is the photodiode voltage in linear units.

room, every 20 mm in the x and y direction. The surface scanned in this procedure covers a 12x20 cm area. The resulting image is illustrated in Figure 11.

The experiment provided an image of medium resolution where the wet sand reflected enough radiant energy to produce a signal on the order of 27 - 40 mV and the dry sand that of 50 - 60 mV. The variation of the signal at any given point was about one millivolt. The device was able to differentiate between wet and dry material and produce an image that roughly corresponds with that of the buried landmine. Further work will focus on improving the sensor and more accurately simulating field conditions in the laboratory.

Conclusion

In this paper, we have reported on some preliminary work evaluating methods that could be used in the detection of buried objects. We examined imaging techniques using both reflected and fluorescent light as well as point-by-point scanning with a single infrared emitter-detector pair. Each of the methods shows some promise and will be evaluated under more stringent conditions in the future.

SCATTERING at LOW GRAZING ANGLES from LARGE SCALE TWO DIMENSIONAL RANDOM ROUGH SURFACES USING the STEEPEST DESCENT FAST MULTIPOLE METHOD (SDFMM)

Introduction and Background

The analysis of low grazing angle (LGA) electromagnetic scattering from two dimensional random rough surfaces is a challenging research problem. In spite of several analytical and numerical techniques that have been developed during the last few years, the problem of LGA scattering from practical random rough surfaces remains unsolved. The memory and CPU requirements of classical computational techniques prohibit the analysis of the LGA scattering phenomena, and the accuracy provided by many of these techniques simply is not adequate to solve this problem.

The objective of this work is to analyze LGA electromagnetic scattering for practical random rough surfaces using an enhanced SDFMM. This technique is a hybridization of the Multilevel Fast Multipole Algorithm (MLFMA) and the Steepest Descent Path (SDP) method. It has been successfully used to analyze electromagnetic scattering from two dimensional quasi planar surfaces. Recently, the SDFMM has been enhanced by parameter selection ruler that provides *a priori* error estimates [1]. The SDFMM dramatically accelerates the iterative solution of the method of moments equations for a large class of structures. When using an iterative solver, both the memory and the computational cost for the SDFMM are of $O(N)$ while they are of $O(N^2)$ for the conventional MOM technique.

For the LGA scattering problem, accuracy is an important factor in any numerical technique because of the shadowing effects that occur at these angles. In the SDFMM, there are tradeoffs between accuracy and both the CPU time and the required memory that can be fully controlled by the proper choice of SDFMM parameters. This makes the SDFMM a prime candidate for solving the LGA scattering problem.

Results and Discussion

A random rough surface is modeled as a finite object chosen large enough such that a practical LGA antenna beam does not excite the surface edges. An example considered in this paper is a surface of $115\lambda \times 28\lambda$ which results in a number of MOM current unknowns equal to 617,096 (using eight unknowns per wavelength). A Gaussian beam (with half beam width equal to 4λ) excites the surface at an angle of 80° from the normal direction. The surface is assumed to be perfect conductor with Gaussian statistics. The roughness parameters are 0.5λ for the rms height and 1.0λ for the correlation length. Preliminary results show that the SDFMM is efficient for analyzing LGA scattering problem.

GEM-3: A Monostatic Broadband Electromagnetic Induction Sensor

I.J. Won, Dean A. Keiswetter, David R. Hanson
Elena Novikova and Thomas M. Hall

Geophex, Ltd.

ABSTRACT

We have designed, fabricated, and field-tested a new, unique, monostatic, broadband, electromagnetic sensor for subsurface geophysical investigation. The sensing unit consists of a pair of concentric, circular coils that transmit a continuous, broadband, digitally-controlled, electromagnetic waveform. The two transmitter coils, with precisely computed dimensions and placement, create a zone of magnetic cavity (viz., an area with a vanishing primary magnetic flux) at the center of the two coils. A third receiving coil is placed within this magnetic cavity so that it senses only the weak, secondary field returned from the earth and buried targets.

This monostatic configuration has many advantages including (1) compact sensor head, (2) a large transmitter moment, (3) high spatial resolution, (4) no spatial distortion of an anomaly common to bistatic sensors, (5) circular symmetry that greatly simplifies mathematical description, and, therefore, (6) simplified forward and inverse modeling processes. Three prototype GEM-3 units have been built and tested at various environmental sites, including those containing unexploded ordnance and land mines.

Introduction

Based on the data quality and quantity, portability, and non-intrusiveness, the electromagnetic induction (EMI) method is perhaps the most popular method for shallow geophysical exploration. During the past several years, Geophex has developed a new generation of airborne and man-portable EMI sensors. GEM-2, first debuted in early 1995, is a 9-lb hand-held, bistatic EMI sensor that can operate either in the frequency- or the time-domain mode. In the frequency-domain, GEM-2 is field-programmable to operate at simultaneous, multiple frequencies or in swept-frequency mode between 90 Hz and about 24 kHz. The GEM-2 operating principles and case histories are described in Won et al. (1996).

One of the major motives for GEM-3 was to increase lateral and spatial resolution. A bistatic sensor, because of the long path between the source and receiver, is inherently poor in spatial resolution particularly for small, shallow targets. Figure 1 shows GEM-3 in operation as of August, 1996. For this prototype, the electronic console including the data logger is very similar to that of GEM-2. Figure 2 shows the electronic block diagram of GEM-3.

GEM-3 Operating Principle

The GEM-3 sensor contains a pair of concentric transmitter coils and a small receiver coil at the center. We call this concentric geometry a "monostatic" configuration because all coils are essentially co-located. The GEM-3 is a transmitter-bucked sensor, as will be discussed in a later section. All coils are molded into a single, light, circular disk in a fixed geometry, rendering a very portable package. The disk, along

with a handle boom, is made of a Kevlar-skinned foam board. Attached to the other end of the boom is a removable electronic console (fig. 1).

For a frequency-domain operation, the GEM-3 prompts for a set of desired transmitter frequencies. Built-in software converts these frequencies into a digital "bit-stream," which is used to construct the desired transmitter waveform for a particular survey. This bit-stream represents the instruction on how to control a set of digital switches (called H-bridge) connected across the transmitter coil, and generates a complex waveform that contains all frequencies specified by the operator. This method of constructing an arbitrary waveform from a digital bit-stream is known as the pulse-width modulation (PWM) technique.

The base period of the bit-stream for GEM-3 is set to 1/30th of a second for areas having a 60-Hz power supply, as does the U.S. The period is 1/25th of a second at 50-Hz areas, as in Europe and Japan. The GEM-3 H-bridge switches at a rate of 96 kHz and, therefore, the bit-stream contains 3,200 steps within the 1/30-second base period. Any integral number of the base period may be used for a consecutive transmission in order to enhance the signal-to-noise ratio (SNR). For detailed explanation of how the GEM-2 constructs a transmitter waveform and actual examples, refer to Won et al. (1996).

Bistatic and Monostatic Sensors

The terms "bistatic" and "monostatic" may be new to some readers; hence, a brief discussion is appropriate. As a simple analogy, an underground miner who uses a headlamp operates a monostatic sensor because his light source and eyes are essentially co-located. A camera with a built-in flash

Electromagnetic Induction Spectroscopy

ABSTRACT

An object, made partly or wholly of metals, has a distinct combination of electrical conductivity, magnetic permeability, and geometrical shape and size. When the object is exposed to a low-frequency electromagnetic field, it produces a secondary magnetic field. By measuring the broadband spectrum of the secondary field, we obtain a distinct spectral signature that may uniquely identify the object. Based on the response spectrum, we attempt to "fingerprint" the object. This is the basic concept of *Electromagnetic Induction Spectroscopy (EMIS)*.

EMIS technology can be particularly useful for detecting buried landmines and unexploded ordnance. By fully characterizing and identifying an object without excavation, we should be able to reduce significantly the number of false targets. EMIS is applicable to many other problems where target identification and recognition (without intrusive search) are important. For instance, an advanced EMIS device at an airport security gate may be able to identify a particular weapon according to its maker and type. Other potential applications may include industrial sorting processes and robotics.

Introduction

When an electrically conductive and/or magnetically permeable object is placed in a time-varying electromagnetic field, a system of induced current flows through the object. By observing the small secondary magnetic field emanating from the induced current, we attempt to detect the object; this is the foundation of the time-proven electromagnetic induction (EMI) method. EMI physics is completely described by Maxwell's four equations, although analytical solutions beyond the simplest geometry are rare due to mathematical complexity.

Our main interest in this article is the frequency dependence of the EMI response. By measuring an object's EMI response in a broad frequency band, we attempt to detect and characterize the object's geometry and material composition. We name this potential new technology exploiting the spectral EMI response *Electromagnetic Induction Spectroscopy (EMIS)*.

For low-frequency geophysical applications, the displacement current resulting from the dielectric property may be ignored up to a megahertz and higher. At zero frequency, we observe the induced magnetism from a permeable (i.e., magnetic) object; this is the foundation of the magnetic method. In this sense, the magnetic method is a subset of the EMI method at zero-frequency with the earth's magnetic field as the inducing source.

From numerous surveys that we have conducted using our multifrequency sensors (GEM-2 and GEM-3; Won et al., 1996 and 1997), we have accumulated significant evidence that a metallic object undergoes continuous changes in response as the transmitter frequency changes. For instance, we have commonly noticed that the observed anomalies have

opposite polarities at certain frequencies, depending on whether the target is ferrous or nonferrous. It appears that the phase also depends on the target's geometrical shape. These observations suggest strongly that the EM anomaly measured in a broad band may offer the ability to both detect and identify a target.

Based on elementary EM theory, an object must exhibit different responses at different frequencies. The reason why this fact has not been exploited is due to the lack of practical broadband EMI instruments to study the phenomenon. Most commercial EMI sensors (including common metal detectors) operate at single frequency or, rarely, at a few discrete frequencies. However, with the recent development of the GEM-series sensors, it is now practical to exploit broadband EMI spectra in order to detect and identify the targets.

Because of this spectral limitation, there has been more interest in the "geometrical sounding" method (an expanding transmitter-receiver array at single frequency) than in the "frequency sounding" method (a fixed transmitter-receiver geometry with varying frequencies). We use such sounding methods to obtain enough data to solve for unknown parameters of a preconceived mathematical model. In contrast, EMIS looks for a spectroscopic identity by matching an observed EMI spectrum to a spectrum of known objects.

On the research level, however, there have been many experimental works that studied broadband EMI phenomena. To mention a few, Ryu et al. (1972) measured at 14 discrete frequencies between 200 Hz and 10 kHz with a horizontal loop and measured tilt angle and ellipticity to explore groundwater in California. Ward et al. (1974) tested a similar 14-frequency system between 10.5 Hz and 86 kHz. Won (1980) showed broadband theoretical models and experimental results using a saltwater tank and graphite targets in the labora-

Multifrequency Electromagnetic Signature of the Cloud Chamber, Nevada Test Site

Dean Keiswetter and I.J. Won
Geophex, Ltd.
Raleigh, North Carolina

ABSTRACT

Multifrequency electromagnetic (EM) data acquired over the Cloud Chamber (CC), Nevada Test Site (NTS), clearly delineate the lateral bounds of the facility and detect the line-of-sight pipe - a 0.4-m diameter stainless-steel pipe buried nine meters below ground level. The purpose of the ground-based electromagnetic surveys was to demonstrate that the CC could be detected using the GEM-2, and acquire multi-frequency data for inversion processing and algorithm development. We present herein GEM-2 data acquired at the CC and discuss the importance of wideband EM data.

Introduction

Geophex acquired broadband electromagnetic data over the Cloud Chamber (CC) facility, Nevada Test Site (NTS), during 1995 and 1996 to support a Department of Energy (DOE) funded, multi-year, multi-agency research program to geophysically characterize underground structures. This manuscript presents contoured maps of multifrequency EM data and describes the sensor and acquisition methods. Witten et al. (1997) presents details of multifrequency-based inversion theory, and imaging results of these data.

Cloud Chamber

The CC is located in north central Yucca Flats, an alluvial basin on the NTS that has been used repeatedly for underground nuclear tests (Office of External Affairs, 1988). The shallow geologic strata are composed of Tertiary and Quaternary volcanic and clastic rocks (Dockery et al., 1985).

The CC, built in 1968 as part of a diagnostics experimental program, was used to measure ionized particles from the 7.4-kiloton (KT) HUPMOBILE event (Office of External Affairs, 1988). The quonset hut CC structure is approximately 42 m in length, 10 m wide at its base, and 5 m high at its maximum. Semicircular steel members support a wooden frame as shown in fig. 1. The reinforced-concrete floor of the CC is 9 m below ground surface.

Multifrequency Electromagnetic Approach

The electromagnetic induction method can be used to target different depths of interest by changing either the spacing between transmitter and receiver coils, or the frequency of the transmitted field (Patra and Mallick, 1980; Won, 1980). The first method is known as geometrical sounding and involves recording data using several transmitter-receiver coil spacings centered over fixed location; the depth of exploration increases with the coil spacing. The two coils systems, although typically connected by an umbilical cord, are physically separate and require two or more field operators.

The second method is known as frequency sounding and involves changing the transmitter frequency, but keeping the transmitter-receiver separation constant (fig. 2). The depth of exploration (also called the depth of penetration or skin depth) is mainly determined by the source frequency and ground conductivity (Won, 1980). In simple terms, low frequency signals travel further than high frequencies through conductive media and, thus, detect deep structures. Conversely, high frequencies detect shallow features better than low frequencies. Broadband frequency sounding is therefore analogous to depth sounding and can be used to create a pseudo 3-D subsurface image (Won, 1983) or for 3-D conductivity inversion processing (Lee et al., 1987; Witten et al., 1997).

Frequency sounding possesses inherent advantages over geometric sounding for depth imaging because it is logistically and operationally simple (due to a one-person operation) and improves spatial resolution (by averaging vertically instead of laterally; fig. 2). Theoretical and practical discussions on these methods may be found in Grant and West (1965), Keller and Frischknecht (1966), and Kaufman and Keller (1983).

GEM-2 Sensor and Data Acquisition Methods

We acquired broadband electromagnetic data using the GEM-2, (fig. 3; Won et al., 1996), a multifrequency induction sensor developed at Geophex. The GEM-2 contains a transmitter, receiver, and bucking coil in a single lightweight, portable, and compact package. The signal-processing electronics, analog circuitry (for signal conditioning), and power supply are housed in a removable console.

The primary field generated by the GEM-2 sensor is controlled via a digitally constructed waveform. The transmitted signal can vary from a complex waveform containing any number of frequencies (user-defined) to a simple square wave. Although the design of the GEM-2 allows it to operate in the either the time- or frequency-domain, only frequency domain data were recorded during this project. The maximum current

Comparison of Magnetic and Electromagnetic Anomalies Caused by Underground Structures

I.J. Won and Dean Keiswetter

ABSTRACT

Magnetic and electromagnetic (EM) methods are perhaps the most convenient and popular geophysical survey methods for detecting buried manmade objects, which is due to their non-intrusiveness, light field logistics, high survey speed, and the quality of information. One should always consider the two methods as the precursor to any geophysical survey. Often, the data resulting from the two methods are sufficient for characterizing buried objects.

In this paper, we present magnetic and EM data collected at four sites: (1) Cloud Chamber at the Nevada Test Site, (2) Anacostia Metro Tunnels in Washington, D.C., (3) Cold Test Pit at Idaho National Engineering Laboratory, and (4) Unexploded ordnance site at Jefferson Proving Ground, Indiana. The first two sites may be considered typical underground facilities. The last two sites, however, contain small buried objects (storage tanks, ordnance, etc.) specifically prepared to test various geophysical methods for detection and, possibly, discrimination.

We find through these and numerous other comparisons that broadband EM data are superior to magnetic data in terms of the amount and the quality of information. The monopolar EM anomaly is invariably easier to interpret, and thus can locate a buried target more accurately than the dipolar magnetic anomaly. In addition, the EM method senses both electrically conductive and magnetically permeable targets. In contrast, the magnetic method responds only to permeable, or ferrous, metals. In that sense, the magnetic method should be considered a subset of the EM method, or a special "passive" EM method at zero frequency.

Introduction

From the viewpoints of non-intrusiveness, field logistics, and survey speed, the magnetic and electromagnetic (EM) methods stand far ahead of other geophysical techniques, including gravity, electrical resistivity, seismic refraction or reflection, and ground-probing radar (GPR).

Intrusiveness: Magnetic and EM sensors are commonly man-portable. The methods do not require ground contact (e.g., seismic and electrical resistivity) or demand a stabilized survey platform (e.g., gravity). The GPR is sensitive to ground roughness, particularly at high frequencies.

Field Logistics: Portable magnetic and EM sensors are usually light in weight, simple to operate, and consume relatively little electrical power. The methods do not involve an array of sensors connected by tangled cables and wires, as would be common for seismic, electrical resistivity, and GPR methods.

Survey Speed: Magnetic and EM sensors can operate continuously in time and in motion. With high-capacity data-logging electronics common to modern portable sets, the sensors can collect over tens of thousand survey points per hour. For a typical high-resolution survey, this translates to an areal coverage of one acre (0.4 hectare) or more per hour. The data can be downloaded to a portable computer and the survey results can be viewed, typically in a color contour format, on

site within a few minutes.

Based on these advantages, one should always consider conducting magnetic and EM surveys as the precursor to any ground geophysical surveys for detecting buried objects, including underground facilities. If nothing else, they are quick and easy and provide a first geophysical view of the site. Quite often, the two methods provide enough data to proceed with planned site activities.

Most manmade objects, except for plastics, contain metals that are easy to detect by the magnetic and/or EM method. Quite often, the two methods can be complementary. In this article, we compare the viability of the two methods and present example data collected over known buried objects. We limit our discussions in this article to ground-level geophysical surveys, although similar arguments can be made for airborne geophysical surveys.

Nature of Magnetic Anomalies

Whether induced or permanent, a buried, ferrous object exhibits basically a dipolar magnetic source. Any object may be represented as a sum of magnetic dipoles having various magnetic moments and dipole orientations. The surface manifestation of this source on a survey plane (i.e., the ground) can be varied according to the source distribution, topography, and geomagnetic latitude.

Modeling the effects of non-uniform soil moisture on detection efficacy of mine-like objects with GPR

Carey Rappaport, Scott Winton, Dongping Jin, and Lori Siegel
Center for Electromagnetics Research
Northeastern University
Boston, MA

ABSTRACT

We present dispersive soil finite difference time domain wave propagation simulations to study the effects of realistic multilayered soil moisture on modulated short pulse Ground Penetrating Radar mine detection exciations. Our conclusions suggest the amount of water and application time -- as a function of soil hydraulic conductivity -- that is necessary for modifying the ground to most effectively detect non-metallic anti-personnel mines.

Keywords: GPR, mine detection, dielectric target imaging.

1 INTRODUCTION

There is considerable interest in detecting buried dielectric mines by modifying the electromagnetic characteristics of soil. It has been suggested that since wetting the ground increases its effective dielectric constant and therefore also increases the dielectric contrast relative to non-metallic mines, this modification may improve detectability.

When water is applied to the ground, the soil becomes saturated on the surface, but remains relatively dry below the wetting front. The wetting front descends with continual watering with time. If insufficient water or time is used in the soil environment modification, there is a multi-layer effect to the electromagnetic scattering of incident radar pulses. In particular, with a rough ground surface, a layered soil moisture content profile may make the target detection problem more difficult than for a uniform, dry soil volume.

2 DISPERSIVE MEDIA FDTD

The finite-difference time-domain (FDTD) method [1] is a straightforward means of modeling wide-band wave propagation in inhomogeneous media. For wave propagation in most real materials, the constitutive parameters are frequency dependent. This dispersion -- which is just a multiplication in the frequency domain -- become a convolution operation in the time domain. Dispersion can be modeled in the time domain in three main ways: 1) Discrete convolution of constitutive relation $D(t) = \epsilon(t) * E(t)$ for Debye and Lorentz models of complex permittivity [2]; 2). Discretization of a differential equation approximation relating $D(t)$ to $E(t)$ [3]; and 3) Direct discrete modeling using the Z-transform of either constitutive relation $J(\omega) = \sigma(\omega)E(\omega)$ or $D(\omega) = \epsilon(\omega)E(\omega)$ [4,5].

For soil propagation problems, the third method, modeling conductivity, has been found to be most suitable. By expressing the soil conductivity as a ratio of polynomials in Z-domain, the conversion to discrete time domain is quite straightforward, since factors involving Z^{-1} correspond to sample time delays. We can approximate it using the single pole approximant[6].

$$\frac{J(Z)}{E(Z)} = \sigma(Z) = \frac{b_0 + b_1 \cdot Z^{-1} + b_2 \cdot Z^{-2}}{1 + a_1 \cdot Z^{-1}} \quad (1)$$

By setting $Z = \exp(i\omega t)$, the real part of Eqn. (1) can be fit to experimentally measured soil conductivity values. The imaginary part of Eqn. (1), divided by $\omega\epsilon_0$ added to an average dielectric constant parameter ϵ_{Av} is then fit to measured dielectric constant. This model can be compared to the standard Debye model, which consists of sums of terms with single poles. A two-term Debye model has been fit to Puerto Rican clay loam with 1.2 g/cc density for three typical moisture levels [3]. This soil has measured conductivity that varies by almost one order of magnitude across two decades of frequency 30 to 3840 MHz [7]. A comparison of the modeled dielectric constant and conductivity for the two different models is shown in Figure 1.

Figure 1 Puerto Rican clay loam, density = 1.2g/cc

Although the Debye model fit is better than that of the Z-transform model for the dielectric constant, the latter is a closer match for conductivity. A more important performance metric than these electrical parameters is the complex wave number, k , which specifies wave velocity and decay rate. The real and imaginary parts of k are shown in Figure 2. Note that the agreement between the values corresponding to measured decay rate α and the Z-transform model for α is far superior to that of the Debye model. This is particularly surprising since the former specifies only one pole, while the two-term Debye model has two poles, and thus requires more storage and computation.

Table 1: Puerto Rican clay loam, density = 1.2g/cc

Moisture (%)	2.5	5	10	20
b_0	0.2401	0.6344	0.9162	1.1482
b_1	-0.4336	-1.1647	-1.6766	-2.0672
b_2	0.1937	0.5308	0.7611	0.9218
a_1	-0.88	-0.88	-0.88	-0.88
ϵ_{Av}	2.18	4.39	8.74	11.84

While the measured soil data gives important information at particular moisture levels, it is necessary to interpolate model parameter values between measured levels to accurately represent realistic continuously varying wetting profiles. Using the best fit values for b_0 , b_1 , b_2 , a_1 , and ε_{Av} for the specified moisture levels – presented in Table 1 – a simple set of interpolating functions have been generated. We interpolate using the function: $b_i = p_i \ln m + q_i$, $i=0,1,2$, with the goal to find values for p_i and q_i [6].

Figure 2 Puerto Rico clay loam, density = 1.2g/cc

The interpolating functions are shown in Figure 3.

Figure 3. Continuous moisture variation parameter functions.

To model the effect of non-uniform watering of dry soil, we first determine the wetting profile. Water movement in a vertical column of a medium is described by the advection-dispersion equation in the z -direction, as [8]:

$$\frac{d\Theta}{dt} = \frac{d}{dz} \left(D(\Theta) \frac{d\Theta}{dz} \right) + \frac{d}{dz} K(\Theta) \quad (2)$$

Where z is the depth of the water column, $\nu(z)$ is the moisture content, D is the dispersion coefficient of water, K is the hydraulic conductivity of the soil (a measure of the rate of water to pass through). By numerically solving Eqn. (2) we can plot the moisture profile as a function of depth and time.

Figure 4 shows profiles for 0.1, 1, 2, 3, 4, and 5 minutes of watering for soil with saturation hydraulic conductivity of 0.2. From these profiles and the parameter functions derived above, the material characteristics of the wave simulation can be specified to arbitrary accuracy.

Figure 4. Moisture profile for several watering duration times.

3 SCATTERING SIMULATION

Using the dispersive FDTD code along with the model for continuously varying moisture, we have simulated the two dimensional TE (single longitudinal magnetic field component into the plane of calculation) scattered field from non-metallic mine-like targets for three different cases: 1) constant moisture at 5% (by weight), typical of the residual background moisture in clay loam; 2) constant 20% moisture, representative of clay loam after a long steady rain; and 3) a continually varying moisture profile from 20% down to 5% for the one minute profile as described above. The geometry of the test cases is shown in Figure 5, with a two-dimensional 1GHz modulated gaussian point source 30 cm above the nominal ground surface (which can be chosen to be either planar or rough), and a 10 cm by 5 cm plastic mine-like target buried 10cm below the ground surface. The entire computational grid is terminated with a soil-tuned Perfectly Matched Layer absorbing boundary condition [9].

Figure 5 FDTD scattering geometry

Figure 6 shows the total field with target, the incident field with no target, and the scattered field due just to the target, for a flat ground surface with constant residual moisture at a time when the initial circular wave has propagated out past the lattice boundary. The first image is representative of the actual field available to be measured when the mine is present. Clearly, only the field above the ground can be measured, but the field distribution below the ground surface around the mine gives information about how the surrounding environment effects the target scattering. The second image would in general not be available, since it represents the given environment after the mine has been removed. The third image represents the field scattered solely by the mine-like target. It is the job of the mine detection algorithm to recognize the features of the third image in the first image, by ignoring the fields scattered by the soil boundary of the second image. For the 5% constant background soil moisture with planar boundary, picking out these characteristics is relatively easy.

For uniformly wet soil, the dielectric contrast of the non-conducting, non-metallic mine target with the surrounding background is greater than for the previous dry soil case. The target scattering is stronger, and, since the wave velocity is slower in wetter soil, the delay between ground surface scattering and target scattering is greater. The target should thus be easier to detect. Figure 7 shows this case with 20% constant moisture and a planar boundary. It is apparent that the scattered amplitude in the third image is greater, and that it appears later compared to the ground scattered wave. The longer delay makes it easier to separate the target scattered signal from the surface signal.

A more realistic moisture model for a manually applied water scenario is considered in generating Figure 8. For this case, the previously developed continuously varying moisture model causes a stronger surface scattered signal, but weaker target scattered signal. Also, the target delay is not as great as for the uniform wet soil. In fact, this realistic wetting situation combines the worst aspects of the two previous constant cases: the ground clutter is greatest, while the target signature is weakest.

These three cases are repeated in Figures 9-11 for a rough ground surface. With this configuration, the ground clutter confuses the target signal considerably. For 5% moisture, Figure 9, the short delay between the target scattered wave and the ground scattered signal makes it more difficult to distinguish the two. In

Figure 10, the stronger scattered wave from the ground, and the subsequent multiple scattering effects of local surface perturbations makes the target signal much harder to recognize. For the realistic moisture profile, Figure 11, it is almost impossible to separate the target scattered field from the ground scattered field in the total field image at the top.

4 CONCLUSIONS

The effects of non-uniform wetting of soil on the scattered field of small buried non-metallic mine-like targets has been explored. For smooth, flat ground surfaces, there are target detection advantages to both uniformly wet and dry soil backgrounds. However, when water is added to dry soil in an attempt to enhance the dielectric contrast, if insufficient water is applied, the ability to detect target signals is degraded. With rough ground surfaces, wetter, high dielectric contrast soil contribute more surface scattering clutter, which may overwhelm the larger target signal. For continuously varying soil moisture on a rough surface, the target signal is much harder to recognize than for either uniformly moist soil background. The main conclusion is that adding water will only enhance target detectability if the ground is saturated for several minutes.

Multiscale Methods for the Segmentation and Reconstruction of Signals and Images

Michael K. Schneider, *Student Member, IEEE*, Paul W. Fieguth, *Member, IEEE*, William C. Karl, *Member, IEEE*, and Alan S. Willsky, *Fellow, IEEE*

Abstract—This paper addresses the problem of both segmenting and reconstructing a noisy signal or image. The work is motivated by large problems arising in certain scientific applications, such as medical imaging. Two objectives for a segmentation and denoising algorithm are laid out: it should be computationally efficient and capable of generating statistics for the errors in the reconstruction and estimates of the boundary locations. The starting point for the development of a suitable algorithm is a variational approach to segmentation [1]. This paper then develops a precise statistical interpretation of a one-dimensional (1-D) version of this variational approach to segmentation. The 1-D algorithm that arises as a result of this analysis is computationally efficient and capable of generating error statistics. A straightforward extension of this algorithm to two dimensions would incorporate recursive procedures for computing estimates of inhomogeneous Gaussian Markov random fields. Such procedures require an unacceptably large number of operations. To meet the objective of developing a computationally efficient algorithm, the use of recently developed multiscale statistical methods is investigated. This results in the development of an algorithm for segmenting and denoising which is not only computationally efficient but also capable of generating error statistics, as desired.

Index Terms—Denoising, multiscale statistical models, segmentation.

I. INTRODUCTION

MUMFORD and Shah have developed a theoretical framework in which to address the problem of simultaneous image denoising and segmentation [2], [3]. In this framework, the goal is to decompose a given noisy image into piecewise smooth regions bounded by contours on which the image intensity is allowed to change abruptly. This is accomplished by minimizing a particular functional jointly over the image boundaries and a reconstruction of the image. The minimizing reconstruction of the original image has been denoised through smoothing everywhere except along the detected boundary contours. The

Mumford and Shah functional has many nice mathematical and psychovisual properties [4]; however, it is difficult to compute minimizers because of the discrete nature of the image boundary terms.

Various people have tried to address these computational difficulties by making small alterations in the Mumford and Shah framework [5]–[7]. In this revised setting, there are also two objects computed by the algorithm: a reconstruction of the original image and a continuous-valued edge-strength function. The reconstruction is a denoised version of the unprocessed, noisy image which does not suffer from the edge blurring effects of some simple linear reconstruction algorithms (e.g., low-pass filtering). The edge-strength function provides information about the optimal spatially-varying amount of smoothing that should be applied to produce the reconstruction. The function varies between the values 0 and 1, taking on the value 1 where no smoothing should be done and 0 in areas where full smoothing is performed. While the edge-strength function itself is not an explicit estimate of image edges, it is demonstrably a more robust indicator of edge likelihood than standard gradient maps. In particular, the edge-strength function displays substantial robustness to noise and automatically avoids problems of dynamic range exhibited by gradient maps of noisy images (see Section VI). As a consequence, generating explicit edge contours from edge-strength functions can be accomplished robustly as shown in [1] using thresholding and [8] using curve evolution.

The approach to segmentation and denoising taken in this paper begins with a novel Bayesian interpretation of the revised Mumford and Shah variational approach to segmentation. This interpretation follows in the footsteps of some recent work in which close connections are made between certain variational and statistical approaches to image processing [9], [10]. The principal advantage of the Bayesian framework is that it provides a theoretical structure for the interpretation and computation of error statistics. Error statistics provide a quantitative measure of the quality of the reconstruction and estimate of the edge-strength function. Such a measure of quality is very important in certain scientific applications. One of the main contributions of this paper is the development of a segmentation algorithm which produces not only a reconstruction of the image and an estimate of the edge-strength function but also error statistics. Furthermore, this paper contains a careful evaluation of the nature and quality of the information provided by these error statistics.

While the Bayesian interpretation can be equally well applied to both one and two-dimensional (2-D) signals, there is a significant difference in computational complexity in solving the

resulting problems. As a consequence, a thorough analysis of the problem is first presented in a one-dimensional (1-D) setting. Markov random field prior (MRF) models appear in the corresponding 2-D Bayesian estimation problems. Unfortunately, algorithms for solving estimation problems involving 2-D MRF priors require a large number of computations to generate exact estimates and a prohibitively large computational load to calculate error statistics. Our objective here is to develop an algorithm with constant per-pixel complexity that also produces useful error statistics.

There are two possible approaches to achieving such an objective, namely *approximating the solution* (i.e., replacing the solution to the estimation problem with one which is easier to compute) or *approximating the problem* (i.e., replacing the estimation problem with one which has similar characteristics but which can be solved exactly using an efficient algorithm). An approach of the former type is described in [11]. In this paper, an approach of the latter type is developed by altering the prior model appearing in the problem formulation. In particular, this paper examines the usefulness of multiscale prior models for image segmentation. Multiscale models, which were introduced and studied in [9], admit algorithms with constant per-pixel complexity for the calculation of both estimates and error variances. They have also been shown to be useful in defining alternative approaches to problems in computer vision which are often posed in a variational context [9], [10], [12], [13]. These previous investigations, however, dealt with problems that resulted in linear estimation algorithms. In contrast, image segmentation is fundamentally a nonlinear problem, and thus, this paper represents the first work on using multiscale stochastic models to solve a nonlinear problem in image processing and computer vision. The algorithm that results not only has a modest computational load but also yields good performance.

The work presented in this paper builds primarily upon the two areas of variational methods for segmentation and multiscale methods for image processing. Section II summarizes the relevant material on variational methods for segmentation. Section III provides an overview of the multiscale modeling framework. The overview is not meant to be comprehensive, however, and many details are not discussed but may be found in the literature [9], [10], [12]–[15]. The subsequent Sections IV and V discuss the specifics of the 1-D scenario, and Section VI is devoted to the 2-D scenario.

II. VARIATIONAL METHODS IN IMAGE SEGMENTATION

A family of functionals proposed by Ambrosio and Tortorelli for image segmentation and denoising [5], [6] lies at the core of a segmentation and denoising algorithm developed by Shah [1] and extended by Pien and Gauch [7] among others. A member of this family of functionals, parameterized by ρ , is of the form

$$E(f, s) = \int \int_{\Omega} \left\{ r^{-1}(g - f)^2 + \lambda |\nabla f|^2 (1 - s)^2 + \frac{\beta}{2} \left(\rho |\nabla s|^2 + \frac{s^2}{\rho} \right) \right\} dx dy \quad (1)$$

where $\Omega \subset \mathbf{R}^2$ is the image domain, $g: \Omega \rightarrow \mathbf{R}$ is the image data, $f: \Omega \rightarrow \mathbf{R}$ is a piecewise smooth approximation to g , and $s: \Omega \rightarrow [0, 1]$ is an estimate of the edge-strength function, indicating high probability for the presence of an edge where it takes values close to one. The first and second terms constrain the approximating surface f to match the data as best as possible and also to be smooth in those places where s is close to zero. The third term ensures that s remain reasonably smooth and does not tend to 1 everywhere. As shown in [6], the minima of (1) converge to a minimum of the Mumford and Shah functional as $\rho \rightarrow 0$. The general approach Shah and Pien use to minimize (1) is coordinate descent: one alternates between fixing s and minimizing

$$\int \int_{\Omega} (r^{-1}(g - f)^2 + \lambda |\nabla f|^2 (1 - s)^2) dx dy \quad (2)$$

over possible f , and fixing f and minimizing

$$\int \int_{\Omega} \left(\lambda |\nabla f|^2 (1 - s)^2 + \frac{\beta}{2} \left(\rho |\nabla s|^2 + \frac{s^2}{\rho} \right) \right) dx dy \quad (3)$$

over possible s . Based on empirical evidence, Shah [1] and Pien and Gauch [7] have noted that this coordinate descent scheme converges to a reasonable solution and that the results are not significantly affected by the initial condition or whether one starts by estimating f or s .

III. MULTISCALE MODELS

Consider a prototypical quadratic minimization problem: minimize

$$E(f) = r^{-1} \|g - f\|^2 + \lambda \|Lf\|^2 \quad (4)$$

where f and g are vectors consisting of a lexicographic ordering of pixels in an image and L is a matrix chosen to ensure that the minimizer of (4) is smooth (e.g., L could take first differences of nearest neighbors as an approximation of a derivative). Minimization of (4) is equivalent to maximization of

$$p(f, g) = e^{-(r^{-1} \|g - f\|^2 + \lambda \|Lf\|^2)}. \quad (5)$$

One can now view $p(f, g)$ as a joint Gaussian probability distribution. In fact $p(f, g)$ is the joint distribution for f and g given by the measurement and model equations

$$g = f + \sqrt{r}v \quad \sqrt{\lambda}Lf = w \quad (6)$$

where v and w are independent zero-mean Gaussian random vectors with identity covariance. For a given value of g , the maximum of $p(f, g)$ over f occurs at the conditional mean of the Gaussian, $E[f|g]$. What's more, $E[f|g]$ is the Bayes least-squares estimate of f , according to the distribution induced by the modeling equations (6). Thus, one can view the problem of minimizing (4) from the perspective of optimization or of statistical estimation [9], [10], [16].

The main advantage of the Bayesian interpretation is that it casts the problem into a probabilistic framework in which it is natural to examine the accuracy of the resulting estimates. This is especially relevant in scientific applications such as remote

Fig. 1. Nodes of a tree, such as the quad-tree pictured here (typically one uses a binary tree for 1-D applications and a quad-tree for 2-D applications), are the index sets of the multiscale processes discussed in this paper. The operation of $\bar{\gamma}$ on an index is described as follows: if ν is the index of some node, then $\nu\bar{\gamma}$ denotes the parent of that node.

sensing, in which one may be, for example, assessing if features in a reconstruction are meaningful or statistically insignificant artifacts. In addition, this statistical formulation brings into focus the role played by the regularization term as a prior model, opening up the possibility of using alternate models that offer certain advantages.

Specifically, one can consider modeling a 1-D or 2-D phenomenon as the finest scale of a stochastic process on a tree. Doing so provides important computational advantages when performing estimation. The tree modeling framework used in this paper was introduced in [14] and further developed in [9], [10], [12], [13], [15]. In these references, one can find more detailed discussions of the following concepts.

The multiscale processes that are of interest in this paper are specified in terms of an autoregression on a tree (see Fig. 1). The root-to-leaf recursion takes the form

$$x(\nu) = A(\nu)x(\nu\bar{\gamma}) + B(\nu)w(\nu) \quad (7)$$

where the notation $\nu\bar{\gamma}$ refers to the parent of node ν . This recursion is a generalization of the standard state-space recursion for modeling a phenomenon evolving in time. In (7), the $w(\nu)$ and the state $x(\text{root})$ at the root node are independent zero-mean Gaussian random vectors, the w 's with identity covariance and $x(\text{root})$ with prior covariance P_{root} . The A and B matrices are deterministic quantities which define the statistics of the process on the tree. Observations $y(\nu)$ of the state variables have the form

$$y(\nu) = C(\nu)x(\nu) + v(\nu) \quad (8)$$

where the $v(\nu)$ are independent Gaussian random vectors, and the matrices $C(\nu)$ are deterministic. The least-squares estimates of process values at all nodes on the tree given all observations and the associated error variances can be calculated with an $O(N)$ recursive algorithm [14], [17], where N is the number of finest scale nodes on the tree. The algorithm consists of a fine-to-coarse recursion in which data in successively larger subtrees are fused up to the root node of the tree, and a subsequent coarse-to-fine recursion which produces both the optimal estimates and their error covariances. This algorithm generalizes the standard Kalman filter and Rauch–Tung–Striebel smoother.

The class of processes representable as the finest scale of a tree process includes some very important processes. In particular, Luetgten [18] has shown that any 1-D Gauss–Markov process can be represented on a tree using a model with a three-dimensional (3-D) state. The 1-D results in this paper make use of this model. The 2-D results make use of and extend the $1/f$ -like model used previously for the computation of optical flow and ocean surface reconstruction [10], [13]. This $1/f$ -like model and its extension are presented in Section VI.

IV. STATISTICAL INTERPRETATION OF SEGMENTATION IN ONE DIMENSION

The first step in applying the multiscale modeling framework to segmentation in 1-D is to develop a statistical interpretation of the discretized version of (1). One possibility for discretizing this functional is to replace the functions $f(x)$, $g(x)$, and $s(x)$ with regularly spaced collections of samples $f(i)$, $g(i)$, and $s(i)$; the integrals with sums over i ; and the derivatives with first differences. The result in 1-D is the discrete functional

$$\begin{aligned} E(f, s) = & r^{-1} \sum_{i=1}^n (f(i) - g(i))^2 \\ & + \lambda \sum_{i=1}^{n-1} (1 - s(i))^2 (f(i+1) - f(i))^2 \\ & + \frac{\beta}{2} \left(\rho \sum_{i=1}^{n-2} (s(i+1) - s(i))^2 + \frac{1}{\rho} \sum_{i=1}^{n-1} s(i)^2 \right) \end{aligned} \quad (9)$$

where n denotes the number of data points $g(i)$ ¹. As was done in [1], [7], one can use coordinate descent to minimize (9), thereby decomposing this complex problem into two simpler ones.

The problem of fixing s and finding the f that minimizes (9) is equivalent to finding the f that minimizes the discrete functional

$$\begin{aligned} E_s(f) = & r^{-1} \sum_{i=1}^n (f(i) - g(i))^2 \\ & + \sum_{i=1}^{n-1} \lambda (1 - s(i))^2 (f(i+1) - f(i))^2. \end{aligned} \quad (10)$$

A slightly more compact form can be written by collecting the samples $f(i)$, $g(i)$, and $s(i)$ into vectors f and $g \in \mathbf{R}^n$ and $s \in \mathbf{R}^{n-1}$. Specifically, let L_n be the $(n-1) \times n$ matrix that takes first differences of n samples, and let $S = \text{diag}(1 - s_1, \dots, 1 - s_{n-1})$. Then, (10) simplifies to $E_s(f) = \|f - g\|_{r^{-1}I}^2 + \lambda \|L_n f\|_{S^T S}^2$, where $\|x\|_W^2 = x^T W x$. Finding the minimum of E_s for fixed invertible S is then equivalent to finding the least-squares estimate of f assuming the following measurement and prior model

$$g = f + \sqrt{r}v_f \quad L_n f = \frac{1}{\sqrt{\lambda}} S^{-1} w_f \quad (11)$$

¹In this discretization, s has a length which is one sample less than that of f . This is because the samples of the discretized s lie between the samples of the discretized f . More details are provided in [19].

where v_f and w_f are independent zero-mean Gaussian random vectors with identity covariance. Notice that for i such that $s(i) \approx 1$, the multiplier of $w_f(i)$, $1/(1 - s(i))$, is very large. Thus, at these locations, the variance of $f(i+1) - f(i)$ in the prior model is high, and a least-squares estimator will allow big jumps to occur in the estimate of f . This is exactly what one wants the estimator to do at edge locations.

The problem of fixing f and finding s that minimizes (9) is equivalent to minimizing

$$\lambda \sum_{i=1}^{n-1} (f(i+1) - f(i))^2 (1 - s(i))^2 + \frac{\beta\rho}{2} \sum_{i=1}^{n-2} (s(i+1) - s(i))^2 + \frac{\beta}{2\rho} \sum_{i=1}^{n-1} s(i)^2. \quad (12)$$

Defining $a(i) = \lambda(f(i+1) - f(i))^2$, $b = \beta/2\rho$, $c = \beta\rho/2$, and $\gamma(i) = a(i)/(a(i) + b)$, one finds that, after completing the square, (12) can be rewritten

$$\sum_{i=1}^{n-1} ((a(i) + b)(\gamma(i) - s(i))^2 + a(i)(1 - \gamma(i))^2 - b\gamma(i)^2) + c \sum_{i=1}^{n-2} (s(i+1) - s(i))^2. \quad (13)$$

Ignoring terms which do not depend on s , one observes that minimizing (12) over s is equivalent to minimizing

$$E_f(s) = \sum_{i=1}^{n-1} (a(i) + b)(\gamma(i) - s(i))^2 + c \sum_{i=1}^{n-2} (s(i+1) - s(i))^2. \quad (14)$$

By defining the diagonal matrix

$$A = \text{diag}(\sqrt{\lambda(L_n f)_1 + b}, \dots, \sqrt{\lambda(L_n f)_{(n-1)} + b})$$

and the vector

$$\gamma = \left(\frac{\lambda(L_n f)_1^2}{\lambda(L_n f)_1 + b} \cdots \frac{\lambda(L_n f)_{(n-1)}^2}{\lambda(L_n f)_{(n-1)} + b} \right)^T$$

where $(L_n f)_k$ corresponds to the k th row of $L_n f$, one can rewrite (14) as

$$E_f(s) = \|\gamma - s\|_{A^T A}^2 + c \|L_{n-1} s\|^2. \quad (15)$$

In the original functional (1), s is constrained to lie within $[0, 1]$. If one removes this constraint, the problem of finding the s that minimizes (15) is equivalent to the problem of estimating s given the following measurement and prior model:

$$\gamma = s + A^{-1} v_s \quad L_{n-1} s = \frac{1}{\sqrt{c}} w_s \quad (16)$$

where v_s and w_s are independent zero-mean Gaussian random vectors with identity covariance. Notice that γ plays the role of an observation of s and that its components take on values near one where the difference between consecutive samples of f is large and near zero where the difference is small. Observe also that $\gamma(i)$ lies within $[0, 1]$; thus, the first term in (15) provides an increased penalty for s that does not stay within $[0, 1]$. This

is desirable because a solution to the unconstrained minimization of (15) that lies within $[0, 1]$ is an optimal solution of the constrained problem. As it turns out, this is often the case, as discussed in Section V.

As an aside, we note that one of the benefits of formulating a minimization problem in terms of statistics is that it yields natural interpretations of the parameters. These interpretations, in turn, can be used to form a loose set of guidelines for picking parameter values suitable for a particular segmentation application. Specifically, simple calculations lead to the following observations which can be used to pick the signal-dependent parameters λ , b , c , and r .

- λ is inversely proportional to the variability in the reconstructed signal f at locations where no edges are present. In particular, $E[(f(i+1) - f(i))^2 | s(i) = 0] = 1/\lambda$.
- r is the measurement noise variance term, determined in many applications by sensor specifications.
- c is proportional to the width of the edges. Specifically, the model for the edge-strength function s implies $E(s(i+1) - s(i))^2 = 1/c$.
- b controls the degree of edginess. In particular, choosing a value for it is related to the issue of defining what level of variability in f we wish to call an edge. Since the observations appearing in the model for the edge-strength function s have the form

$$\gamma(i) = \frac{\lambda(f(i+1) - f(i))^2}{\lambda(f(i+1) - f(i))^2 + b}$$

one desires that for i at edge locations

$$b \gg \lambda E[(f(i+1) - f(i))^2 | s(i) = 0] = 1, \\ b \ll \lambda(f(i+1) - f(i))^2.$$

These rules guided the choice of parameter values used for the numerical results presented in the subsequent section. More discussion concerning the parameters, including Monte Carlo results, can be found there and in [19].

V. NUMERICAL RESULTS

Based on the Gauss-Markov estimation problem formulations specified by (11) and (16), one can compute estimates \hat{f} and \hat{s} using any one of a variety of efficient methods. These include direct methods for solving the associated normal equations and Kalman filter smoothing. For the simulation results that follow, estimates \hat{f} and \hat{s} as well as error variances P_f and P_s were computed by a multiscale recursive estimation algorithm [13], [17], [18] (see also Section III). One detail concerning the implementation of this and other algorithms is that they require the specification of prior variances P_0 on $f(0)$ and $s(0)$, the first samples of the probabilistic models for f and s . However, the precise interpretation of the variational formulation as an estimation problem corresponds to viewing the initial value as unknown, which is equivalent to an infinitely large prior variance. While it is possible to accommodate this in the estimation formulation with no effect on algorithmic complexity, it is common to use an alternate approach in which one closely approximates the solution to the original problem by setting the prior covariance P_0 to a relatively large number. For the purposes of this

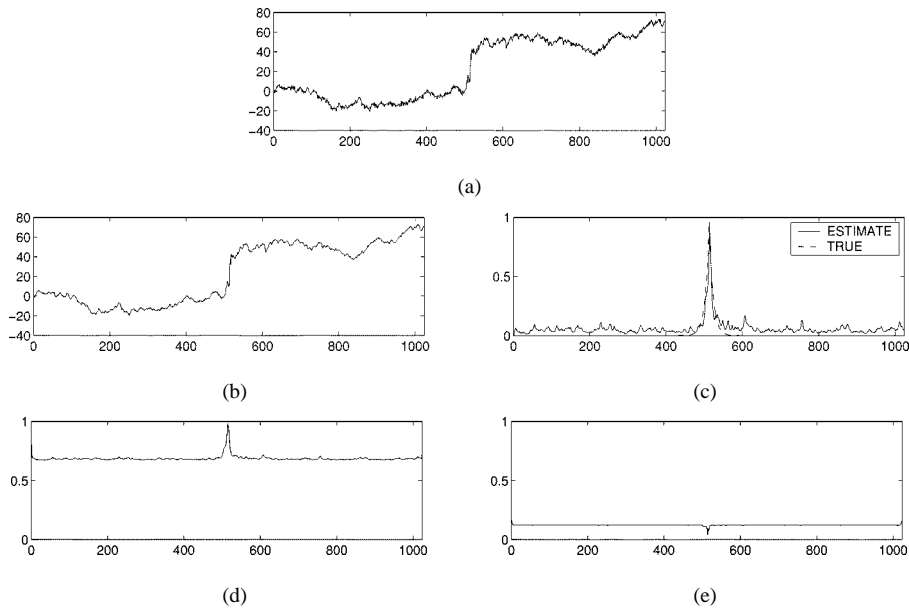

Fig. 2. The results for segmenting the data pictured in (a), a noisy observation of a process whose statistics are dictated by (11) for the true edge-strength function given by (17). The measurement noise is white and Gaussian with unit variance. All parameters are set as in Table I. (a) Data g , (b) reconstruction \hat{f} , (c) estimate of the edge-strength function \hat{s} ; (d) reconstruction error standard deviations $\sqrt{P_f}$; and (e) estimate of edge-strength function error standard deviations $\sqrt{P_s}$.

paper, P_0 is set large relative to $1/\lambda$ and $1/c$. This segmentation algorithm requires the specification of two parameters in addition to that of P_0 :

- ϵ : Since estimating f requires that $1/(1-s)^2$ be well-behaved, we must also enforce a constraint on the range of s . A simple solution is to clip each estimate of the edge-strength function so that for some small ϵ , $s \in [0, 1 - \epsilon]$. This solution proves adequate.
- Δ : As the segmentation algorithm is iterative in nature, one must specify a stopping criterion. For all of the results in this section, the algorithm stops when the percentage change in the functional (9) falls below Δ .

Our experience has been that a single pair of values of ϵ and Δ can be used to produce good segmentations of a variety of signal types. The parameter Δ specifies when to stop, but one also needs an initial guess with which to start the iterative algorithm. For the results in this section, the algorithm starts by estimating

f using an initial estimate of the edge-strength function $s^0 = 0$. A list of all of the algorithm's parameters are listed in Table I.

To illustrate the operation of the algorithm, some examples follow. These, in turn, are followed by some Monte Carlo experiments designed to assess quantitatively the performance of the algorithm.

A. Examples

Fig. 2 illustrates a segmentation of a synthetic signal. The data g in Fig. 2(a) consists of a signal f to which unit intensity white Gaussian measurement noise has been added. The signal f is a realization of a Gaussian process described by (11). The process is started with initial condition $f(0) = 0$ and generated using for s the double-sided exponential function

$$0.97 \times \exp(-|i - 512|/10). \quad (17)$$

The values of the parameters used are listed in Table I. Now, recall that where the edge-strength function is approximately one,

Fig. 3. Segmentation of a noisy unit step as plotted in part (a). The measurement noise is white and Gaussian with standard deviation 0.2. All parameters are given in Table I. (a) Data g , (b) reconstruction \hat{f} , (c) estimate of the edge-strength function \hat{s} , (d) reconstruction error standard deviations $\sqrt{\hat{P}_f}$, and (e) estimate of edge-strength function error standard deviations $\sqrt{\hat{P}_s}$

the variance of the increment in the model of f increases. This is clearly evident in Fig. 2(a) in which the particular realization of f displays a clear jump in its value in the vicinity of the edge-strength function's peak.

The data in Fig. 2(a) are then fed into the iterative segmentation and denoising algorithm. The results displayed in the remaining parts of Fig. 2 are after five iterations of the algorithm, at which point, the value of the functional (9) was changing by less than $\Delta = 0.01\%$. No clipping was necessary during the course of the run, and thus, the results are true to the discrete form of the variational formulation (9). The final reconstruction is a smoother version of the data, but the edge has not been smoothed away. The final estimate of the edge-strength function has a strong peak at the location of the edge. These are the desired results of the segmentation algorithm. In addition, the estimation error variance for f in Fig. 2(d) displays the characteristic one would expect: away from the expected edge, considerable lowpass filtering is effected, reducing the noise variance. However, in the vicinity of the edge, one expects greater variability and, in essence, the estimator performs less noise filtering, resulting in a larger error variance. Note also that the variance in the estimate of the edge process is almost constant, with a slight drop in the vicinity of the edge, i.e., where f changes abruptly, reflecting greater confidence that an edge is present in this vicinity. The results for the preceding example are good, but not completely convincing by themselves since f is matched to the algorithm by its construction. Consider a prototypical signal not matched to the model, namely a step edge. Fig. 3 displays results for data consisting of a unit step embedded in white Gaussian noise. The estimates are shown after 12 iterations. Once again, no clipping was necessary in the iterative process. The results demonstrate that the algorithm works as desired. It removes almost all of the noise away from the edge, while accurately preserving the discontinuity. Note that P_f increases near the outer ends because there are fewer measure-

ments in the vicinity and λ is large. As in the case of the first example, however, the error statistics reflect the fact that, near the edge, one expects less noise reduction in estimating f and has higher confidence in the estimate of the edge process because of the abrupt change in value of f .

B. Monte Carlo Experiments

Two different sets of Monte Carlo experiments are presented here. The first set provides some information for interpreting the error statistics. The second set shows that the algorithm is robust to parameter settings.

1) *Error Statistics:* In this section, a more careful look is taken at the error statistics provided by the segmentation algorithm in order to assess their accuracy and utility. Since the full iterative algorithm is nonlinear, the exact error variances in estimating f and s are not easily computed. The statistics calculated by our algorithm represent approximations that result from the linear estimation problems for each of the two separate coordinate descent steps for f and s . Fig. 4 presents Monte Carlo results comparing the error statistics computed by the segmentation algorithm with the actual error variances. Each experiment in this simulation corresponds to (a) generating a realization f of the process described by (11) for the fixed edge-strength function s given by (17) and with the initial value $f(0)$ set to 0; (b) adding white Gaussian measurement noise with unit intensity; and (c) applying the segmentation algorithm using the parameters in Table I to obtain the estimates \hat{f} of the realization f and \hat{s} of the edge-strength function s as well as P_f and P_s , the error variances for these estimates that the algorithm generates.

The quantities of interest for each run are $e_f = (\hat{f} - f)$, $e_s = (\hat{s} - s)$, and the error statistics P_f and P_s computed by the algorithm. From 100 independent runs, the following quantities are estimated: $E e_f^2$, $\text{Var}(e_f)$, $E P_f$, $E e_s^2$, $\text{Var}(e_s)$, and $E P_s$. These are plotted in Fig. 4 along with Monte Carlo error bars

Fig. 4. Comparison of various error statistics compiled using Monte Carlo techniques for segmenting synthetic data. The data are realizations of a process whose statistics are given by (11) for the exponential edge-strength function given by (17). Part (a) of this figure displays statistics concerning the reconstruction errors, $e_f = (\hat{f} - f)$, and the reconstruction error standard deviations generated by the algorithm, P_f . Part (a-iv) displays the optimal error standard deviations for estimating f given that the true edge-strength function given by (17) is known. Part (b) of this figure displays the statistics concerning the errors in estimating the edge-strength function, $e_s = (\hat{s} - s)$. (a-i) Mean squared error for estimating f ($E e_f^2$), (a-ii) variance of the error for estimating f ($\text{Var}(e_f)$), (a-iii) segmentation error variance for estimating f ($E P_f$), (a-iv) true segmentation error variance for estimating f ($P_{f|s}$), (b-i) mean squared error for estimating s ($E e_s^2$), (b-ii) variance of the error for estimating s ($\text{Var}(e_s)$), and (b-iii) segmentation error variance for estimating s ($E P_s$).

set at 2 standard deviations. Comparing Fig. 4(a)-i for $E e_f^2$ and Fig. 4(a)-ii for $\text{Var}(e_f)$, one sees that these are quite close in value, indicating that the estimate produced by our algorithm is essentially unbiased. Comparing these two figures with the plot of $E P_f$, one observes that the error variance computed by our algorithm has essentially the same shape, reflecting the fact that it accurately captures the nature of the errors in estimating f . Fig. 4(a)-iv shows a plot of the error variance for an estimator that is given perfect knowledge of the edge process. Comparing this to Fig. 4(a)-iii, one notices that the segmentation algorithm performs nearly as well as if s were known perfectly and did not have to be estimated.

The error statistics for the edge-strength function are depicted in Fig. 4(b). $E e_s^2$ and $\text{Var}(e_s)$ being small relative to one indicate that the estimate of the edge-strength function is quite accurate and that the error does not vary considerably from sample path to sample path. In addition, the shapes of these plots have several interesting features related to the behavior of the estimator in the vicinity of the edge. Note first that, as can be seen in Fig. 2, the algorithm tends to estimate edge-strength functions that are slightly narrower than the actual edge-strength function. This is

actually preferable for segmentation, for which the peak locations in the estimates of the edge strength-functions are more important than the estimates' shapes. Because of this bias toward tighter edge localization, \hat{s} is a slightly biased estimate of s given by (17), as evidenced by the broader peak of $E e_s^2$ as compared to $\text{Var}(e_s)$.

A second interesting point is that $E e_s^2$ increases slightly in the vicinity of the edge, while the variance computed by the estimation algorithm, $E P_s$, decreases. The reason for this can be explained as follows. Specifically, the estimator believes that it has more information about s when the gradient of f is large. Thus, in the vicinity of an edge, the estimator indicates a reduction in error variance for estimating s . However, if the estimate of the *location* of the edge is in error, then the difference $e_s = (\hat{s} - s)$ will exhibit large, very localized errors, both positive and negative (just as one would see in the difference of two discrete-time impulses whose locations are slightly different). Thus, rather than providing an accurate estimate of the size of the estimation error variance in this vicinity, this dip in the error variance should be viewed as a measure of confidence in the presence of an edge in the vicinity.

Fig. 5. Average value of W for the step edge example of Fig. 3 but for different values of λ .

2) *Parameter Selection*: Fig. 5 presents results from a Monte Carlo simulation designed to characterize how well the algorithm can segment signals for different values of the parameter λ . In this experiment, the algorithm is segmenting a unit step edge. The quantity computed from each segmentation is W , the number of values of the estimated edge-strength function that lie above a given threshold set close to one. This corresponds roughly to the sum of the widths of the edges in the segmentation. In the case of the step edge, the desired value of W is one. Except for λ , the algorithm's parameters take on the values listed in Table I for Fig. 3. The threshold is set to 0.9. The results in Fig. 5 are for 500 runs, and the error bars are set at one standard deviation.

Recall that the amount of smoothness the algorithm expects in f where there is no edge is directly related to λ . For $\lambda = 2.5 \times 10^3$, the algorithm generates the very flat step estimate of Fig. 3. However, one can not set λ too high because, as Fig. 5 shows, the average value of W increases with λ . Remember that W is a measure of how many points are very likely to be edges. If λ is set too high, the algorithm will put edges in many places and set the estimate of the function f almost constant between edges. Although the results of the algorithm depend on λ , the slope of the curve in Fig. 5 is not very steep. This indicates that small perturbations in the value of λ will not severely diminish the performance of the algorithm.

Similar experiments have been performed in which other parameters were adjusted. These can be found in [19]. To summarize, the effect of these parameters on the results coincide with the simple guidelines presented in Section IV. Furthermore, these Monte Carlo experiments indicate that the results are robust to small changes in the parameter settings.

VI. A MULTISCALE METHOD FOR IMAGE SEGMENTATION

As discussed in [19], solving the exact 2-D counterparts to the estimation problems in the 1-D segmentation and denoising algorithm is not an easy task. In particular, the calculations in 2-D correspond to solving estimation problems with prior models that are 2-D Markov random fields (MRF) or, equivalently, to solving elliptic partial differential equations and computing the diagonal elements of the inverses of elliptic operators [9]. There

Fig. 6. How discontinuities are incorporated into the $1/f$ -like multiscale model.

exist no known algorithms which can compute the necessary quantities for this general problem with fewer than $O(n^3)$ operations, where n is the linear dimension of the image.

Since the objective is to generate estimates and error variances with constant computational complexity per pixel (i.e., with $O(n^2)$ operations), one is confronted with the need to develop approximations. The approach taken here is to alternately estimate a reconstruction and an edge-strength function assuming multiscale prior models. When the prior is a multiscale model, there is an efficient algorithm for producing the estimates, and the associated error variances of the reconstruction and edge-strength function [14], [17] (see also Section III). These two estimation steps replace the two coordinate descent step in Shah and Pien's variational approach to segmentation as discussed in Section II. The estimation is performed in an overlapped domain, as described in [20]. Thus, the multiscale models do not directly model f and s but the corresponding lifted versions \mathbf{f} and \mathbf{s} . The two models, one for each of the lifted fields \mathbf{f} and \mathbf{s} , are described in Section VI-A. Note that there are two principal distinctions between our multiscale modeling approach and some other quad-tree approaches to solving image processing problems. The first is that the variables on the tree are states that decorrelate regions of the image, and the second is that the associated estimation algorithm passes information everywhere along the tree so as to produce globally optimal estimates of the lifted fields.

A. Multiscale Models for Segmentation

Consider first, the model used for the estimation of \mathbf{s} . As discussed in [9], [10], [12], [13], [16], the smoothness penalty associated with the gradient, used for example in (2) and (3), corresponds to a fractal penalty in that it is roughly equivalent to a $1/f$ -like prior spectrum for the random field being modeled. This type of spectrum has a natural scaling law; namely, the variances of increments at finer and finer scales decrease geometrically. In [9], [10], [12], [13], it was demonstrated that a very simple multiscale model having this same scaling property leads to estimates that are very similar to those produced using the original smoothness penalty. A model of this type is used for the lifted version \mathbf{s} of the edge-strength function. Specifically

$$\mathbf{s}(\nu) = \mathbf{s}(\nu\bar{\gamma}) + d(\nu)B_s w_s(\nu) \quad (18)$$

TABLE II
DESCRIPTION OF PARAMETERS, IN THE MULTISCALE METHOD

Parameter	Description	Value for the Results in Figs.		
		7	8	9
b	b affects the edginess of the estimate of the edge-strength function.	30		10

I	I is the number of iterations of estimating f and s .	2		

where B_s is a constant, and the $w_s(\nu)$ are independent unit variance Gaussian random variables. As described in [12], [15], the $d(\nu)$ are constants that decrease from one scale to the next finer scale and depend on the amount of overlap used. The measurements and measurement error variances used in conjunction with the model for \mathbf{s} in (18) are exactly analogous to those specified by γ and A^{-2} in 1-D. The only difference in 2-D is that a sum of the squares of the first differences in each direction replaces the square of the first difference in one direction. Details are specified in [19].

The multiscale model for the lifted version of the reconstruction \mathbf{f} is, to some extent, similar to the one for the edge-strength function. However, significant modification to this model is needed in order to capture the presence of discontinuities, as indicated by the edge estimates. In particular, in the 1-D case, as captured in (11), the increments of f have a variance which is inversely proportional to the corresponding value of $(1 - s)^2$. Thus, the variance of the increment of f is large near an edge (i.e., where s is approximately one in value). In a similar manner, one needs to capture the idea that increments of \mathbf{f} , as one moves to finer scales, should have variances that reflect the presence of edges (i.e., that are again inversely proportional to $(1 - s)^2$). This is done as follows. Note that each node on the tree can be thought of as representing the center of a subregion of the image domain. A 2-D example is depicted in Fig. 6. The dots in this figure correspond to the center points of the regions associated with different nodes on the tree. The dots are shaded according to the scale of the corresponding node on the tree; the darker the dot, the coarser the scale. Thus, for example, the node ν_0 represents the entire large square region, while the node ν_3 at the next finest scale represents the upper-right quadrant of this large square. Now, if there is an edge located between ν_0 and ν_3 (i.e., if the values of s at image domain

pixels between these nodes indicate the presence of an edge), the variance of the scale-to-scale increment of \mathbf{f} between these two nodes should increase. More precisely, the model for \mathbf{f} is specified by the recursion

$$\mathbf{f}(\nu) = \mathbf{f}(\nu\overline{\gamma}) + \eta(\nu)d(\nu)B_f w_f(\nu) \quad (19)$$

where B_f is a constant, $w_f(\nu)$ are independent unit variance Gaussian random variables, and $\eta(\nu)$ is the sum of $1/(1 - \hat{s}(i, j))^2$ for estimates of the edge-strength function values which fall on the line connecting ν and $\nu\overline{\gamma}$. In this manner, additional uncertainty is put into the recursion for \mathbf{f} at the appropriate locations.

B. Numerical Results

This section presents numerical results on two test images, a synthetic image of a circle and an MRI brain scan. Table II lists the algorithm's parameters and values². The execution times for each example were on the order of minutes when run using MATLAB on a Sparc Ultra.

The segmentation of a synthetic 64×64 image of a circle is presented in Fig. 7. The circle image provides a simple example for which one can observe the desired outputs of the algorithm. The reconstruction contains very little of the noise present in the original data. Furthermore, the edges of the circle have not been smoothed over in the reconstruction. The estimate of the edge-strength function is close to zero everywhere except at the edge of the circle, where the estimate tends to unity. This indicates the algorithm has successfully identified edges and has ignored the spurious changes in intensity in the data due to noise.

²The parameters b , λ , B_s , B_f , and r have interpretations analogous to those presented in Section IV for the parameters b , λ , c , and r appearing in the 1-D problem. The interpretations were used to guide the choice of parameters used in the numerical examples of the multiscale method for segmentation.

Fig. 7. Segmentation of a synthetic circle image computed using the multiscale method. (a) Data g , (b) reconstruction \hat{f} , (c) estimate of the edge-strength function \hat{s} ; (d) reconstruction error standard deviations $\sqrt{P_f}$; and (e) estimate of edge-strength function error standard deviations $\sqrt{P_s}$.

Fig. 8. This figure illustrates the difference between a gradient map and the estimate of the edge-strength function for a noisy circle image. (a) Data g , (b) magnitude of the gradient, and (c) estimate of the edge-strength function \hat{s} .

Fig. 8 illustrates the difference between a gradient map and the estimate of the edge-strength function. As for the example in Fig. 7, the unprocessed image is a circle embedded in white noise. The standard deviation of the noise is six. The magnitude of the gradient is very noisy, but the edge-strength function is only moderately noisy and clearly indicates the location of the underlying circle.

In addition to the reconstruction and estimate of the edge-strength function, the multiscale algorithm computes the standard deviations of the error in the reconstruction and estimate of the edge-strength function. Notice that the error standard deviations for the reconstruction increase near edges and, for the estimate of the edge-strength function, decrease near edges, as in the 1-D case. Thus, one expects that the error standard

(a) Data g , (b) reconstruction \hat{f} , (c) estimate of the edge-strength function \hat{s} ; (d) reconstruction error standard deviations $\sqrt{P_f}$; and (e) estimate of edge-strength function error standard deviations $\sqrt{P_s}$.

deviations in Figs. 7 and 9 are of similar significance to those generated in 1-D. Another consequence of the above-mentioned properties of the error standard deviations is that they can be used not only to estimate one's confidence in segmenting the image but also to improve one's estimate of the boundary locations. This is a consequence of the error standard deviations marking the edges in the image as well or better than the estimate of the edge-strength function.

Fig. 9 displays a multiscale segmentation of a 256×256 MRI brain scan³. There are many different potential uses of MRI brain segmentation. Associated with each of these different uses are different goals of the segmentation. One of these goals is to

³An MRI image with pixel values ranging over more than 800 integers was shifted and scaled to produce the data for this figure. The dynamic range of the scaled MRI data is close to that of the circle images.

demarcate the boundaries of the ventricles, the two hollow regions in the middle of the brain. Another goal is to determine the boundary between gray and white matter in the brain. The estimate of the edge-strength function displayed in Fig. 9 does a good job at indicating likely boundaries both of the ventricles and of the gray and white matter.

VII. CONCLUSION

In this paper, we have described a new approach to the reconstruction and segmentation of noise corrupted signals and images. The points of departure for our work are the variational formulation of Mumford and Shah [2] and, more explicitly, the relaxed variational formulation of Ambrosio and Tortorelli [5].

The latter formulation leads to the simultaneous computation of both a reconstructed signal or image and an edge-strength function which provides a measure of the likely locations of edges or abrupt changes in the image or signal values.

The contributions of this paper are several. First, we provide precise statistical interpretations of the steps involved in estimating both the reconstructed signal or image and the edge-strength function. This interpretation not only establishes an intellectual bridge to statistical estimation, but it also leads directly to the extension of the algorithm to produce error variances for the reconstructed image and edge-strength function.

Moreover, this statistical interpretation leads us to another significant extension and new algorithm, in the case of 2-D image processing. In particular, replacing the random field image models implied by the variational formulations in [1], [7] with a multiscale prior model with similar characteristics yields an extremely efficient algorithm for the simultaneous estimation of the reconstructed image and edge-strength function. Furthermore, the new algorithm can efficiently compute the variances of the errors in these estimates. The algorithm for computing both estimates and error variances given a multiscale model has constant computational complexity per pixel. In contrast, the best known algorithm for computing estimates and error variance given a random field model has a complexity per pixel that increases as the square root of the total number of pixels.

In addition to these substantial computational advantages, we have also demonstrated the efficacy of these algorithms through several experimental studies. In 1-D, we demonstrated the accuracy of the error variance calculations that our algorithm automatically produces for the reconstructed image. In 2-D, we also demonstrated the ability of our algorithm to produce reliable estimates even in the presence of very high noise. In particular, we demonstrated that the estimates of edge-strength functions produced by our approach are much more robust to noise than image gradient maps. Thus, the edge-strength function estimates can be subsequently processed to produce robust and accurate edge estimates, e.g., by thresholding [1] or more sophisticated methods such as curve evolution [8].

Michael K. Schneider (S'93) received the B.S.E. degree in electrical engineering from Princeton University, Princeton, NJ, in 1994, and the M.S. degree in electrical engineering from the Massachusetts Institute of Technology (MIT), Cambridge, in 1996. He is currently pursuing the Ph.D. degree at MIT.

His research interests include statistical signal and image processing and numerical linear algebra.

Paul W. Fieguth (S'87–M'96) received the B.A.Sc. degree from the University of Waterloo, Waterloo, Ont., Canada, in 1991, and the Ph.D. degree from the Massachusetts Institute of Technology (MIT), Cambridge, in 1995, both in electrical engineering.

He joined the University of Waterloo in 1996, where he is currently Assistant Professor in systems design engineering. Prior to this, he held postdoctoral positions with the Department of Computer Science, University of Toronto, Toronto, Ont., and in the Laboratory for Information and Decision Systems,

MIT. His research interests include statistical signal and image processing, hierarchical algorithms, and interdisciplinary applications of such methods, particularly to remote sensing.

William C. Karl (M'91) received the S.M., E.E., S.B., and Ph.D. degrees in electrical engineering and computer science from the Massachusetts Institute of Technology, Cambridge.

He was Staff Research Scientist with Brown-Harvard-MIT Center for Intelligent Control Systems and the MIT Laboratory for Information and Decision Systems, Cambridge, from 1992 to 1994. He joined the faculty of Boston University, Boston, MA, in 1995, where he is currently Assistant Professor of electrical, computer, and systems engineering. Since

January 1996, he has held a joint appointment in the Department of Biomedical Engineering. His research interests are in the areas of multidimensional and multiscale signal and image processing, geometric estimation, detection, and medical signal and image processing.

Dr. Karl is associate editor of the *TRANSACTIONS ON IMAGE PROCESSING*. He is a member of Sigma Xi.

Alan S. Willsky (S'70-M'73-SM'82-F'86) received the S.B. and Ph.D. degrees from the Massachusetts Institute of Technology (MIT), Cambridge, in 1969 and 1973, respectively.

He joined the MIT faculty in 1973 and his present position is Professor of electrical engineering. From 1974 to 1981, he served as Assistant Director of the Laboratory for Information and Decision Systems, MIT. He is also a founder and member of the board of directors of Alphatech, Inc., and is currently a member of the U.S. Air Force Scientific Advisory

Board. He has held visiting positions at Imperial College, London, U.K., L'Université de Paris-Sud, and the Institut de Recherche en Informatique et Systèmes Aléatoires, Rennes, France. He is the author of the research monograph *Digital Signal Processing and Control and Estimation* and is the co-author of the undergraduate text *Signals and Systems*. His research interests are in development and application of advanced methods of estimation and statistical signal and image processing. Methods he has developed have been successfully applied in a wide variety of applications including failure detection in high-performance aircraft, advanced surveillance and tracking systems, electrocardiogram analysis, computerized tomography, and remote sensing.

Dr. Willsky received the Donald P. Eckman Award from the American Automatic Control Council in 1975. He was Program Chairman for the 17th IEEE Conference on Decision and Control, has been an associate editor of several journals and special guest editor for several special issues, and has served as a member of the Board of Governors and Vice President for Technical Affairs of the IEEE Control Systems Society. In 1988, he was made a Distinguished Member of the IEEE Control Systems Society. He has given plenary and keynote lectures at a number of major scientific meetings including the 20th IEEE Conference on Decision and Control, the 1991 IEEE International Conference on Systems Engineering, the 1991 SIAM Conference on Applied Linear Algebra, the 1992 Inaugural Workshop for the National Centre for Robust and Adaptive Systems, Canberra, Australia, the 1992 INRIA 25th Anniversary Symposium in Paris, the 1993 IEEE Symposium on Image and Multidimensional Signal Processing, Cannes, France, and the 1997 Wavelet Applications in Signal and Image Processing Conference. He was awarded the 1979 Alfred Noble Prize by the ASCE and the 1980 Browder J. Thompson Memorial Prize Award by the IEEE for a paper excerpted from his monograph.

A Statistical Method for Efficient Segmentation of MR Imagery *

J. Kaufhold[†], M. Schneider[‡], W. C. Karl[§], A. S. Willsky[‡]

Abstract

Magnetic resonance imaging (MRI) has become a widely used research and clinical tool in the study of the human brain. The ability to robustly, accurately, and repeatably quantify morphological measures from such data is aided by the ability to accurately segment the MRI data set into homogeneous regions such as gray matter, white matter, and cerebro spinal fluid. The large amount of data associated with typical MRI scans makes completely manual segmentation prohibitive on a large scale. In this paper an efficient approach to the segmentation of such MRI imagery is presented. The approach uses an estimation-theoretic interpretation of the segmentation problem to develop a computationally efficient, statistically-based recursive technique for its solution. Being statistically based, the method also provides associated measures of uncertainty of the resulting estimates, which are extremely important both for evaluation of the estimates as well as their combination with other sources of information.

1 Introduction

Magnetic resonance imaging (MRI) has become a widely used research and clinical tool in the study of the human brain. The size and shape (i.e. the morphology) of the various structures of the brain which can be obtained from such imagery correlate with various developmental differences, disease states, and injuries. In [1] independent measures of brain volumes, shapes, and positions are readily correlated with behavioral as well as physiological measures. For instance, [2] suggests that Rett syndrome, a progressive disorder associated with regression of psychomotor development and slow brain growth to age one, could be diagnosed by precise volumetric analysis of cortical and nuclear structures over time. Also, in [3], it was shown that the female brain is approximately 10% smaller than a male brain but the disproportionate variation in the volumes of male and female brain regions and substructures reported was not consistent with a simple allometric explanation for the sexual dimorphism. Shenton et. al [4] measured post mortem left temporal lobe volumes in schizophrenics. Certain anatomical differences from normals in these volumes correlated with schizophrenia. In [5], clinically relevant frontal brain lesion volumes were measured morphologically

by MR imaging and validated by measuring CT blood flow in the same volume. These are only a few examples which strongly suggest the ability to robustly, accurately, and repeatably quantify such morphological measurements is extremely important.

Accurate and reproducible quantification depends on accurate segmentation and classification of the MRI brain data set into constituent functional parts. In particular, this overall goal is aided by the segmentation of the raw MRI data into homogeneous regions such as gray matter, white matter, and cerebro spinal fluid (CSF). These regions and their boundaries have typically been delineated through a labor intensive procedure by specially trained technicians, at great expense in time, money, and effort and with the greater variability that comes with human intervention [6]. The incorporation of automation in the segmentation process has been shown to reduce variability across technicians and across morphological structure measurements [7]. Such results have prompted greater interest in increasing the automation of this component of the analysis process, which is the long term focus of this work.

One promising approach that has been taken to automating such segmentation problems in the computer vision literature is the use of a variational or cost-functional framework [8–14]. In these approaches to segmentation an energy functional captures desired properties of the resulting segmentation, such as smoothness within homogeneous regions, preservation of boundaries between homogeneous regions, etc. The minimum energy the functional can attain given the observed image is chosen as the segmentation. The advantage of such methods is the ease with which various desirable effects can be directly incorporated into the energy functional and reflected in the resulting segmentation. Unfortunately, obtaining the minimum of these energy functions leads to large and computationally taxing optimization problems. In addition, while these deterministic methods can provide estimates of the underlying components and their boundaries, they do not provide information about the uncertainty in these estimates. Such measures of uncertainty are important both for direct evaluation of the estimates themselves, as well as providing the information necessary to fuse these estimates with other sources of knowledge, such as probabilistic atlases, images from other modalities, etc. Further, while the addition of many terms capturing various effects is conceptually simple, the specification of the corresponding weights or importance given to these terms can be challenging.

Alternative statistical formulations of such segmentation problems based on Markov random field (MRF) prior models [15–17], while also providing visually desirable solutions, also lead to computationally taxing optimization problems. Indeed, the resulting optimization problems are very similar to the variationally derived ones. Furthermore, while these Bayesian approaches conceptually provide a framework for the calculation of measures of uncertainty (i.e. estimation error variances), in practice, such measures are virtually never obtained due to the great computational cost involved. Thus current methods for the automation of MRI segmentation are computationally costly and, further, do not provide rational measures of uncertainty.

To overcome the above limitations of existing methods, in this paper we present a statistically-based recursive approach to the segmentation of MRI imagery which is computationally efficient and provides measures of uncertainty of the resulting estimates. The approach is based on an interpretation of the segmentation problem as an equivalent recursive estimation problem. This enables the use of efficient, near-optimal recursive filtering methods for its solution. As a result, rather than solving the large overall segmentation problem all at once, the problem is decomposed into a sequence of smaller estimation problems, yielding computational efficiency in addition to uncertainty measures.

The paper is organized as follows. In Section 2 we present a summary of the variationally-based image segmentation on which we build. We then present an interpretation of the segmentation

problem as an estimation problem in Section 3. In Section 4 we show how this problem may be solved recursively and thus efficiently. In Section 5 we show examples of brain segmentations using our approach. We then present our conclusions in Section 6.

2 A Variational Formulation of the Segmentation Problem

2.1 Problem Statement

We base our approach to the segmentation of MRI imagery on a variational formulation of the segmentation problem presented in [8,9,12]. This formulation simultaneously produces a segmented image estimate \hat{f} and edge map estimate \hat{s} as the minimizers of the following energy functional:

$$E(f, s) = \int_{\Omega} \underbrace{\mu(g - f)^2}_{\text{Data Fidelity}} + \underbrace{\lambda(1 - s)^2 |\nabla f|^2}_{\text{Smoothness}} + \underbrace{\nu \left(\rho |\nabla s|^2 + \frac{1}{\rho} s^2 \right)}_{\text{Edge Penalty}} dx dy \quad (1)$$

where g denotes the observed image data, f denotes the piecewise smooth approximating field, s denotes the corresponding continuous edge strength image, Ω is the image domain and μ , λ , ν , and ρ are scalar weights specifying the relative importance of the terms. The edge image s can be viewed as an indication of edge or boundary strength at each location in the observed image, and ranges in value between 0 and 1. There are three types of terms in (1) – a data fidelity term, a smoothness term, and edge penalty terms. These terms ensure that the pair \hat{f} , \hat{s} that minimizes (1) has the properties that \hat{f} is close to the data g , that \hat{f} is nearly flat except where s is close to 1 (indicating the presence of an edge), that the edge field \hat{s} itself is smooth, and that the number of edges (i.e. the size of \hat{s}) is not too great, preventing over-segmentation. Note that as $\rho \rightarrow 0$ it is shown in [12] that the solution of (1) approaches the binary edge formulation of [10].

In practice, (1) is solved by alternatively fixing s and minimizing with respect to f and then fixing f and minimizing with respect to s , as shown in Figure 1. This corresponds to alternatively estimating the values of homogeneous image regions assuming that the location of the boundaries between them are known and then estimating the location of the boundaries assuming the values within the smooth, homogeneous regions are known. In particular, with the edge field s considered fixed, the following energy functional is minimized for the segmented image values f :

$$E_s(f) = \int_{\Omega} \mu(g - f)^2 + \lambda(1 - s)^2 |\nabla f|^2 d\Omega \quad (2)$$

Note, in this step a penalty, $|\nabla f|^2$, enforces smoothness on the resulting estimated field f *except* where the edge field s is close to 1.

For the other step, the image f is considered fixed and the minimum of the functional with respect to s is sought. This step can be shown to be equivalent to minimizing the following energy functional for s [18]:

$$E_f(s) = \int_{\Omega} \left(\lambda |\nabla f|^2 + \frac{\nu}{\rho} \right) \left[\frac{\lambda |\nabla f|^2}{\lambda |\nabla f|^2 + \frac{\nu}{\rho}} - s \right]^2 + \nu \rho |\nabla s|^2 d\Omega \quad (3)$$

The second term is a penalty that will impose smoothness on the resulting edge field everywhere, while the first term contains an equivalent derived “observation” of the edge field based on a normalized gradient of the image f . In particular, note that this observation, $\lambda |\nabla f|^2 / (\lambda |\nabla f|^2 + \frac{\nu}{\rho})$, has values in the range $[0, 1]$ and will be close to 1 where the gradient of f is large.

2.2 Discretization

In practice, we work on a discrete grid of sample points and approximate the gradient operator with a finite difference scheme. In particular, we assume that both f and s are sampled on the same $n \times n$ row-column grid containing a total of n^2 points. It will prove convenient to define the n -vectors $\mathbf{f}(j)$ and $\mathbf{s}(j)$, obtained by stacking the sampled image values $(f)_{ij}$ and sampled edge field values $(s)_{ij}$ in column j , respectively, as illustrated for the f field in Figure 2. We also define \mathbf{f} and \mathbf{s} as the overall n^2 -vectors of these sampled points, obtained by stacking the $\mathbf{f}(j)$ and $\mathbf{s}(j)$, respectively. Similarly, we define $\mathbf{g}(j)$ to be the n -vector obtained by stacking the sampled observation values $(g)_{ij}$ in column j and define $\mathbf{h}(j)$ to be the n -vector obtained by stacking the sampled values of the s -field “observation” $\lambda|\nabla f|^2 / (\lambda|\nabla f|^2 + \nu/\rho)$ in column j . In particular, the latter samples are given by $\mathbf{h}(j)_i = ([f]_{ij} - [f]_{i,j-1}]^2 + [f]_{ij} - [f]_{i-1,j}]^2 / ([f]_{ij} - [f]_{i,j-1}]^2 + [f]_{ij} - [f]_{i-1,j}]^2 + \frac{\nu}{\lambda\rho})$ and serve as a normalized gradient observation, lying in the range $[0, 1]$.

With this notation, a discrete version of the field energy term $E_s(\mathbf{f})$ given in (2) may be obtained as¹:

$$E_s(\mathbf{f}) = \sum_{j=1}^n \|\mathbf{g}(j) - \mathbf{f}(j)\|_{\mu I}^2 + \|D_r \mathbf{f}(j)\|_{V(j)}^2 + \|\mathbf{f}(j) - \mathbf{f}(j-1)\|_{V(j)}^2 \quad (4)$$

where $\|\mathbf{x}\|_M^2 = \mathbf{x}^T M \mathbf{x}$ and D_r is a first-order difference operator along the rows of each column given by:

$$D_r = \begin{bmatrix} -1 & 1 & & \\ & \ddots & \ddots & \\ & & -1 & 1 \end{bmatrix}. \quad (5)$$

The weighting matrices $V(j)$ are diagonal and capture the spatially varying, edge-dependent weights on column j of the gradient term in (2). In particular, $V(j)_{ii} = \lambda[1 - (s)_{ij}]^2$.

Similar to (4), a discrete version of the edge energy term $E_f(\mathbf{s})$ given in (3) may be obtained as:

$$E_f(\mathbf{s}) = \sum_{j=1}^n \|\mathbf{h}(j) - \mathbf{s}(j)\|_{W(j)}^2 + \|D_r \mathbf{s}(j)\|_{\nu \rho I}^2 + \|\mathbf{s}(j) - \mathbf{s}(j-1)\|_{\nu \rho I}^2 \quad (6)$$

where D_r is the row-derivative operator defined in (5) and the weighting matrices $W(j)$ are diagonal and capture the spatially varying weights on column j of the data term in (3). In particular, $W(j)_{ii} = \lambda[(f)_{ij} - (f)_{i,j-1}]^2 + \lambda[(f)_{ij} - (f)_{i-1,j}]^2 + \frac{\nu}{\rho}$.

The solution to the overall segmentation problem is then obtained by alternately minimizing each of the two quadratic energies $E_s(\mathbf{f})$ in (4) and $E_f(\mathbf{s})$ in (6), as shown in Figure 1. Each of these minimizations is a large, computationally intensive, optimization problem, which must be performed repeatedly to obtain a segmentation. Direct solution of the system of equations defining the minimum of (4) or (6) at any stage of the algorithm would involve $O(n^6)$ calculations and, since n is typically in the range of 10^2 – 10^3 , would be prohibitively expensive. In practice, therefore, the solution is approximated to an arbitrary degree of accuracy via an iterative method, such as conjugate gradient [19] or multigrid [20]. Even with such methods, solution of the large set of equations is computationally challenging. Further, only the *estimate* of the image field $\hat{\mathbf{f}}$ or edge process $\hat{\mathbf{s}}$ is provided, with no measure of reliability.

To avoid these difficulties we use an interpretation of the problems (4) and (6) in an estimation theoretic context [18]. Such an interpretation of this segmentation problem allows a variety of

¹For clarity of presentation we ignore edge effects in the discrete formulations of (4),(5). Such edge effects only increase the notational complexity of the development.

statistically-motivated approaches to be taken. For example, in [18] a novel multiresolution estimation approach is used. In this work, however, we interpret the underlying spatial estimation problem as an equivalent *dynamic* estimation problem. Based on this interpretation we are able to formulate an efficient, statistically-based recursive solution. This statistically-based approach provides not only estimates of the fields themselves, but also corresponding measures of uncertainty. For simplicity we focus on the problem of processing two-dimensional MRI slices – i.e. images. The development to follow, however, carries over naturally to the case of three (or even higher) dimensional fields (i.e. volumes), where the computational gains should be even greater. Such results are the focus of present research.

3 An Estimation-Theoretic Interpretation

We now provide an estimation-theoretic interpretation of the quadratic minimization problems (4) and (6) as equivalent recursive estimation problems. To this end, note that (4) and (6) have the following common form:

$$E(\mathbf{x}) = \sum_{i=1}^n \|\mathbf{d}(j) - \mathbf{x}(j)\|_{R_1^{-1}(j)}^2 + \|D_r \mathbf{x}(j)\|_{R_2^{-1}(j)}^2 + \|\mathbf{x}(j) - \mathbf{x}(j-1)\|_{Q^{-1}(j)}^2 \quad (7)$$

where the weighting matrices $R_1(j)$, $R_2(j)$, and $Q(j)$ are diagonal, and the vector $\mathbf{x}(j)$ contains the elements from column j of the overall unknown desired image vector $\mathbf{x} = [\mathbf{x}^T(1) | \dots | \mathbf{x}^T(n)]^T$.

Now, it is straightforward to show [21–23] that the value of $\hat{\mathbf{x}}$ or, equivalently, $\hat{\mathbf{x}}(j)$ for each j , that minimizes the quadratic energy (7) is the same as the maximum-likelihood estimate of $\mathbf{x}(k)$ for each k based on the following set of observations and constraints:

$$\mathbf{x}(j) = \mathbf{x}(j-1) + \mathbf{q}(j-1), \quad \mathbf{q}(j) \sim \mathcal{N}(0, Q(j)) \quad (8)$$

$$\mathbf{y}(j) = C(j) \mathbf{x}(j) + \mathbf{r}(j), \quad \mathbf{r}(j) \sim \mathcal{N}(0, R(j)) \quad (9)$$

for $j = 1, \dots, n$, where $\mathbf{x} \sim \mathcal{N}(\mathbf{m}, P)$ denotes a Gaussian random vector with mean \mathbf{m} and covariance P , the initial condition is given by $\mathbf{x}(0) = 0$ and $Q(0) = \lim_{\alpha \rightarrow \infty} \alpha I$, and the variables $\mathbf{y}(j)$, $C(j)$ and $R(j)$ are defined as:

$$\mathbf{y}(j) = \begin{bmatrix} \mathbf{d}(j) \\ \mathbf{0} \end{bmatrix}, \quad C(j) = \begin{bmatrix} I \\ D_r \end{bmatrix}, \quad R(j) = \begin{bmatrix} R_1(j) & \mathbf{0} \\ \mathbf{0} & R_2(j) \end{bmatrix} \quad (10)$$

Given the form we have written (8)–(9) in we can see that another, equivalent interpretation of these equations specifies a dynamic estimation problem for the $\mathbf{x}(j)$. In particular, the components $\hat{\mathbf{x}}(j)$ of the minimizer $\hat{\mathbf{x}}$ of (7) are *precisely the same* as the series of smoothed estimates of $\mathbf{x}(j)$ based on the dynamic equation (8) and the observation (9) for $1 \leq j \leq n$. The advantage of the formulation (8)–(9) is that we may use efficient, recursive Kalman filtering based techniques for its solution. In effect, by recursively processing $\mathbf{x}(j)$ we are recursively estimating the columns of the segmented image. In effect, we trade solving a single large problem (estimating the entire image) for solving a series of smaller problems (estimating the values in a column). In addition, these estimation-theoretic methods provide not only estimates of the field, but also corresponding measures of uncertainty. Finally, the statistical smoothing view of (8)–(9) suggests a statistical interpretation of the parameters of the original formulation, which can provide a rational guide to their selection in practice.

4 A Recursive Filter-Based Solution

In this section we show how to efficiently solve (8),(9). First note that what is needed is the optimal estimate $\hat{\mathbf{x}}(j)$ for each j based on *all* the data $\mathbf{y}(k)$, $k = 1, \dots, n$. This is known as the optimal *smoothed* estimate [24]. There are a number of efficient ways to generate this estimate, as described in [25–27]. In this work we use the Mayne-Fraser two-filter form of the optimal smoother [25, 26]. In this approach, the smoothed estimates and associated error variances are obtained by combining the outputs of two independent Kalman filters based on (8),(9) – one starting at column $j = 1$ and running forward (i.e. left to right) and the other starting at column $j = n$ and running backward (i.e. right to left), as depicted in Figure 3. Since each filter is independent, they may be run in parallel for greater throughput. The separate forward and backward estimates are then combined by weighting them by the inverse of their respective error variances, as detailed in [25, 26]. The key, then, is to find an efficient method for performing the independent filtering steps, which we focus on next. In particular, we focus on the forward filtering step. The backward step is equivalent and the weighted averaging operation straightforward.

4.1 An Information Form Filter

To perform the filtering based on (8),(9) we will use an efficient version of the *information form* of the Kalman filter developed in [22]. In particular, an optimal information-form filtering algorithm for the system (8)–(10) is provided by the following recursive algorithm [22]:

Information Filter Algorithm:

Prediction:

$$\bar{L}(j) = Q^{-1}(j) - Q^{-1}(j) \left(Q^{-1}(j) + \tilde{L}(j-1) \right)^{-1} Q^{-1}(j), \quad (11)$$

$$\bar{\mathbf{x}}(j) = \tilde{\mathbf{x}}(j-1), \quad (12)$$

$$\bar{\mathbf{z}}(j) = \bar{L}(j)\bar{\mathbf{x}}(j) \quad (13)$$

Update:

$$\tilde{L}(j) = \bar{L}(j) + R_1^{-1}(j) + D_r^T R_2^{-1}(j) D_r, \quad (14)$$

$$\tilde{\mathbf{z}}(j) = \bar{\mathbf{z}}(j) + R_1^{-1} \mathbf{d}(j) \quad (15)$$

$$\tilde{L}(j)\tilde{\mathbf{x}}(j) = \tilde{\mathbf{z}}(j) \quad (16)$$

where D_r is the derivative operator defined in (5) and note that $R_1(j)$, $R_2(j)$, and $Q(j)$ are diagonal matrices. The matrices $L(j)$ appearing in the above algorithm are the *information matrices* corresponding to the estimate, and are equal to the inverse of the estimation error covariance for the filtered estimate of column j . The filtered solution to (8)–(10) provided by the use of (11)–(16) is exact and, when optimally combined with the corresponding backward filtered estimates provides an estimate which is the same as the minimizer of (7). However, the above algorithm and interpretation break the problem into a series of smaller recursive steps and also provide measures of uncertainty for the estimates through the associated estimation error variances, which are the diagonal elements of $L^{-1}(j)$.

For the sake of computational efficiency we go even further and approximate this exact solution. In particular, as done in [22], we use a two term series expansion of the matrix inverse in parentheses and replace the exact expression (11) for the predicted information matrix with:

$$\bar{L}(j) \approx Q^{-1}(j) - Q^{-1}(j) \left(\Lambda^{-1}(j) - \Lambda^{-1}(j)\Omega(j)\Lambda^{-1}(j) \right) Q^{-1}(j) \quad (17)$$

where $\Lambda(j)$ is the diagonal part of $Q^{-1}(j) + \tilde{L}(j-1)$ and $\Omega(j)$ is the remaining, off-diagonal part. This simple approximation to (11) yields results close to the exact solution of the variational formulation in most cases. If greater fidelity to the original variational formulation is required additional terms may certainly be added to the above approximate expansion, at the cost of more computation, larger models, and greater storage requirements. The fidelity of such approximations will depend on quantities such as the specific choice of parameters for the original variational problem along with the structure of the image. Such relationships are a topic of current investigation.

Finally, note that calculation of the updated estimate in (16) requires the solution of a system of equations. While this system of equations is much smaller than that appearing in the original problem, it can still be a computationally intensive task. Fortunately, the structure of this segmentation problem coupled with the approximation (17) combine to ensure that $\tilde{L}(j)$ will remain sparse and banded (in particular, tridiagonal). In this case, the inversion operation implied in (16) can itself be efficiently performed via iterative methods, such as multigrid [20] or preconditioned conjugate gradient [19]. In our present implementation we use the conjugate gradient method preconditioned with the diagonal of $\tilde{L}(j)$.

4.2 The Smoothed Estimate

Once the separate forward and backward filtered estimates are found using (8),(9) together with the efficient variant of (11)–(16), the individual estimates are then combined to obtain the resulting smoothed estimate $\hat{\mathbf{x}}(j)$ together with its uncertainty. Let $\hat{\mathbf{x}}_f(j)$ and $\hat{\mathbf{x}}_b(j)$ denote the output of the forward and backward filtering operations, respectively, and let $L_f(j)$ and $L_b(j)$ denote the information matrices corresponding to these filtered estimates. Then the overall smoothed estimate at column j , $\hat{\mathbf{x}}(j)$, is obtained as the solution of:

$$[L_f(j) + L_b(j)] \hat{\mathbf{x}}(j) = L_f(j) \hat{\mathbf{x}}_f(j) + L_b(j) \hat{\mathbf{x}}_b(j) \quad (18)$$

which we again solve using the diagonally preconditioned conjugate gradient technique. The corresponding error variances are given by the diagonal elements of $(L_f(j) + L_b(j))^{-1}$, which we approximate by the reciprocal of the corresponding diagonal elements of $L_f(j) + L_b(j)$. These error variances give us a measure of the uncertainty of the corresponding estimates.

5 Examples

In this section, we present numerical examples of segmented MRI imagery using the techniques we have described. We use the global segmentation algorithm shown in Figure 1 with the energy terms $E_s(\mathbf{f})$ and $E_f(\mathbf{s})$ described in (4) and (6), respectively. We initialize the \mathbf{s} field estimate to zeros and terminate the iteration when the percent change in $E(f, s)$ falls below a threshold. For the experiments shown here we used a 2% change as the indication of convergence. This structure is common to all the examples. What will differ is how the subproblems of minimization of $E_s(\mathbf{f})$ or $E_f(\mathbf{s})$ are performed. In particular, we compare straightforward solution of (4),(6) to the proposed recursive estimation-theoretic based technique. In both cases note that the formulation of (1) assumes that the value of the edge field s lies in the range $[0, 1]$ while our solutions to the subproblem (6) contain no such constraint. To ensure the global iterations are well defined we simply truncate the edge function to the range $[0, 1 - \epsilon]$ for some small ϵ at each iteration if necessary. In practice, the solution to the unconstrained problem almost always lie in the required range anyway.

Comparison of estimates obtained with direct and recursive approaches

Here we compare images segmented using the algorithm of Figure 1 and exact solution of the normal equations to those obtained using the proposed efficient recursive technique. For these experiments we used parameter values of $\mu = 1$, $\lambda = 3$, $\nu = 1200$, and $\rho = \frac{1}{2}$. In Figure 4 we show the original proton density weighted MR image. In Figure 5, the two segmentations are shown. On the left is the solution obtained through direct minimization of the energy functionals (4) and (6) via exact solution of the corresponding normal equations or, equivalently, Euler equations. On the right is the corresponding solution for both \mathbf{f} and \mathbf{s} obtained by using the near optimal recursive approach. The images show that the recursive technique produces results that are almost identical to the direct solutions. To emphasize this point, in Figure 6 we show a histogram of the differences between the field estimates obtained by the two techniques. These histograms show the relative frequency (i.e. the histogram area equals one) of the corresponding errors as a percent of the corresponding full scale value. As can be seen all the values are clustered around zero. Both segmentations appear to do well in capturing the main boundaries between gray and white matter despite the presence of a significant gradient in absolute intensity across the image. In Figure 8 we show the result of thinning the thresholded edge field obtained in Figure 5.

Uncertainty Estimates

While the segmentations obtained by direct energy minimization and our recursive approach are quite similar, since our Kalman-filter-based technique is derived from an estimation-theoretic interpretation of the segmentation problem, we also generate associated error variance information, and thus measures of segmentation uncertainty. Such measures are important not only for the direct evaluation of the estimates themselves, but also for the fusion of such estimates with other sources of information, which we demonstrate later. While many approaches have been proposed for the segmentation of such MRI imagery, few have addressed this issue of error statistics. In Figure 9 we show the error standard deviation fields corresponding to the estimates in Figure 5. On the left is the standard deviation field corresponding to the smoothed field while on the right is the standard deviation field corresponding to the edge field. As can be seen, the error standard deviations for the field itself increase near edges while those of the edge field decrease near edges, as we would expect. In areas where the edges are weak, the corresponding error field indicates low reliability. These error measures are obtained as a by product of the processing in the recursive technique, and thus are obtained for free.

Computational Cost

We compare the computational cost of solving the segmentation problem represented in Figure 1 both through direct minimization of the energies and by our recursive method. The direct method finds the minimum of the energies (4),(6) at each iteration by explicitly solving the resulting system of so called normal or Euler equations. In practice, such large systems of equations are usually solved via iterative techniques, such as preconditioned conjugate gradient. Thus, for our comparison here we find the minimum of the energies (4),(6) at each stage using the conjugate gradient technique preconditioned with the diagonal of the corresponding normal equations [19]. Our recursive approach has already been described.

First we consider only the field estimates. In this case, both techniques took 4 global iterations to converge. Our recursive approach required approximately 20% fewer computations per iteration compared to the direct minimization approach. These solutions were obtained in a few minutes on

a SPARC 20 using unoptimized MATLAB code.

Next we compare the cost of calculating *both* the estimates of \mathbf{f} and \mathbf{s} together with the corresponding error measures (i.e. the error variances). For the direct approach, this calculation essentially corresponds to finding the diagonal elements of the *inverse* of the large matrix arising in the normal equations of the optimization problem, and since it requires inverting the matrix, is extremely costly. In contrast, for our recursive approach these error measures are obtained as a by product of the processing and thus are effectively free. In particular, in computing both these quantities the direct approach required a factor of approximately 10^4 more computations than our recursive method.

Fusion of Multichannel Data

Here we demonstrate the use of the error statistics provided by our technique for the fusion of edge information from multichannel data, in particular from registered T_1 , T_2 and PD imagery. Our goal here is to demonstrate the potential usefulness of such uncertainty information through a prototype fusion problem.

There are at least two ways our approach can accomplish this fusion of edge information. The first method is based on the direct use of the three channels in a single overall variational formulation, as proposed in [8]. In this case all three channels are simultaneously used to directly obtain a *single* edge field. This single edge map is used as the basis for the generation of a piecewise smooth estimate of the intensity of each separate channel. Our approach to this method also provides the associated uncertainty measure for the aggregate edge map and individual channel estimates, and thus provides one rational means to obtain such overall measures for multichannel data. In particular, note that the measures obtained for each channel will reflect the effects of the information in all the channels. Since this approach is a direct extension of that in [8] we will not pursue it here.

An alternative approach to the fusion of the edge or segmentation information from such multichannel data is to perform a segmentation on each channel separately and then use the resulting uncertainty measures obtained for each edge image to subsequently fuse the individual edge maps. In effect, this approach treats the separate edge field estimates from each channel as independent observations of the edge field with uncertainty provided by the associated error variance measure. Such an approach serves as a paradigm of a variety of similar fusion problems, in which it is desired to combine information obtained from a variety of sources. In particular, suppose at a given image pixel location (i, j) , each channel provides a corresponding edge field estimate at that pixel, denoted by s_{T_1} , s_{T_2} , s_{PD} , respectively. In addition, suppose that $\sigma_{T_1}^2$, $\sigma_{T_2}^2$, σ_{PD}^2 are the corresponding error variances associated with that pixel value as, for example, provided by our technique. If these edge estimates are uncorrelated from pixel to pixel and from channel to channel, then the optimal linear estimate of the overall edge field value at that pixel is provided by the quantity:

$$s = \frac{\sigma_{T_1}^{-2}s_{T_1} + \sigma_{T_2}^{-2}s_{T_2} + \sigma_{PD}^{-2}s_{PD}}{\sigma_{T_1}^{-2} + \sigma_{T_2}^{-2} + \sigma_{PD}^{-2}} \quad (19)$$

and the associated overall error variance σ^2 for the combined edge field estimate at that pixel is given by:

$$\sigma^2 = \frac{1}{\sigma_{T_1}^{-2} + \sigma_{T_2}^{-2} + \sigma_{PD}^{-2}} \quad (20)$$

As stated above, this assumes that the edge estimates obtained for each channel correspond to uncorrelated random variables. While this will not be the case, in general, the formulas (19) and

(20) still provide a rational way to combine such data. Note that if other sources of edge information are available with associated uncertainty measures, they may also be included in this framework.

Figure 10 shows T1 and T2 weighted MRI images that correspond to the PD weighted image in Figure 4. We generated separate edge estimates for each of these images using our technique. For the T1 image we used the parameters $\mu = 1$, $\lambda = 3$, $\rho = \frac{1}{2}$ and $\nu = 1000$, while for the T2 image we used the parameters $\mu = 1$, $\lambda = 3$, $\rho = \frac{1}{2}$ and $\nu = 1000$. In Figure 11 the resulting estimated edge fields for the T1 and T2 images are shown. The edge field for the PD weighted image was shown on the right in Figure 5. We then combined these individual edge estimates and corresponding uncertainty measures using the formulae in (19) and (20). The resulting fused edge image is shown on the left of Figure 12. Note that it contains edge information that does not exist in the edge image of any single channel. For instance, in the fused edge estimate, the boundary indicated by the arrow has been reinforced, indicating the incorporation of collateral edge information, since the same boundary in the PD edge estimate is incomplete. Note also how the estimation error, shown on the right of Figure 12 decreases as more information is added to the fused estimate of the edge field and more confidence in its value is developed.

6 Conclusions

In this paper we have presented a recursive approach to the segmentation of MRI imagery. This approach was based on an estimation theoretic interpretation of the segmentation problem and while efficient, provides solutions indistinguishable from direct solution of an equivalent variational problem. In addition to its efficiency, being statistically based the method also provides associated measures of uncertainty of the resulting estimates. Such measures are critical not only for evaluation of the segmentation but also for subsequent stages of the processing. An illustration of the use of such information was demonstrated through the fusion of edge information obtained from registered multichannel (PD, T1, and T2) imagery. This example demonstrated how the collateral information present in such data can be rationally combined when such measures of uncertainty are available. We are in the process of extending this approach to the 3-D case, which while providing greater computational challenges, should also provide greater gains. A systematic study of the robustness of this approach in a clinical setting together with the usefulness and interpretation of the associated uncertainty measures that are generated is also currently being undertaken.

Abstract

Many large multidimensional space-time signal processing and data inversion applications (e.g. deconvolution) require some form of regularization to extract meaningful information. A popular approach to regularizing such problems in a statistical context is via a Gauss-Markov Random Field (GMRF) prior model in a Maximum A Posteriori (MAP) estimation framework. While providing good reconstructions, the high dimensionality of these problems can lead to prohibitive computational constraints which limit their practical applicability, particularly in real or near-real time applications. It has recently been shown that GMRF models possess a particular recursive structure. Conversely, complementary work in suboptimal filtering has been based on reduced order GMRF modeling. In this work, we combine these two results to present a suboptimal filter design which repeatedly takes advantage of this recursive GMRF structure to subdivide a large problem into a series of smaller, more tractable problems. In this way we present a method for approximate, model-based, recursive solution to such high dimensional problems based on their inherent recursive structure.

1 Introduction

Many large multidimensional space-time signal processing and data inversion applications require a method of regularization to extract meaningful information. These applications include large static spatial deconvolution problems, such as noise suppression in 3D diffusion-weighted (vector-valued) magnetic resonance imagery (MRI) and mine detection in EM ground sensor array data, as well as space-

time problems, such as arise in physical oceanography, space-time inverse scattering problems, visual field reconstruction and functional MRI (fMRI). A popular approach to regularizing such problems in a statistical context is via a Gauss-Markov Random Field (GMRF) prior model in a Maximum A Posteriori (MAP) estimation framework. While such approaches provide good reconstructions, the difficulty in their direct application to large spatial or space-time problems is that their exact solution leads to impractically large and complex optimization problems due to high dimensionality. This limits the practical applicability and power of such GMRF-based formulations, particularly in real or near-real time applications. In this work we combine existing results on the recursive structure of GMRFs with reduced order model-based recursive filtering techniques to present a rational basis for approximate, model-based, recursive approaches to efficiently solve such problems.

2 Problem Statement

For simplicity, we will consider MAP estimation problems of the following form:

$$y = x + w, \quad w \sim \mathcal{N}(0, R) \quad (1)$$

$$x \sim \mathcal{N}(0, M) \quad (2)$$

where M corresponds to the covariance of a GMRF and R is the diagonal covariance of the observation noise, w . In particular, M^{-1} has a sparse banded structure reflecting the nearest neighbor interactions of the lexicographically ordered data [1]. The problem in (1) and (2) is representative of many estimation problems. For example, M is often chosen to capture a “smoothness prior” in which case $M^{-1} \approx D^T D$, where D is a derivative operator. The challenge posed by the applications we are considering is due to size and dimensionality. For example, consider the space-time problem posed by enhancing a 3D fMRI data set. In this problem, we would need

to estimate over 10^9 elements (*e.g.* typical dimensions are 256 columns \times 256 rows \times 60 slices \times 60 time points). Direct solution or inversion of corresponding normal equations is currently prohibitive if not impossible.

3 Dynamic Reformulation

It is known that the *inverse* of the covariance matrix of a GMRF, M^{-1} in equation (2), termed the “potential matrix” in [3] and more commonly known as the “information matrix” [4], is sparse and banded with a particular structure. Recently, it was shown that the information matrix, M^{-1} of a GMRF possesses a certain highly interesting recursive structure [3]. Specifically, it was shown that the structure of the information matrix can be exploited to define an equivalent implicit autoregressive model on the subelements of the field of the form:

$$y_k = x_k + w_k, \quad w_k \sim N(0, R_k) \quad (3)$$

$$x_{k+1} = A_k x_k + v_k, \quad v_k \sim N(0, Q_k) \quad (4)$$

where the subelements x_k and y_k now define a “slice” (*e.g.* the rows or columns of an image) of the original field, and R_k and Q_k are diagonal covariance matrices with compatible partitions. For appropriate choices of R_k , A_k , and Q_k , It can be shown that that equations (3) and (4) yield the same overall covariance structure as the GMRF defined by M in the original problem. This equivalent dynamic model is derived through a Cholesky factorization of the corresponding information matrix, M^{-1} .

To understand this, suppose we have a symmetric positive definite block tridiagonal matrix, $M^{-1} = U$ of the following form:

$$U = \begin{bmatrix} U_{11} & U_{12} & & & \\ U_{12}^T & U_{22} & U_{23} & & \\ & U_{23}^T & U_{33} & & \\ & & & \ddots & \\ & & & & U_{(n-1)n}^T & U_{nn} \end{bmatrix}$$

where U is composed of block tridiagonal subblocks, U_{ii} on the block diagonal and diagonal subblocks, U_{ii+1} on the upper block off diagonal. Then we can uniquely decompose it as $M^{-1} = U = G^T G$ where G is the Cholesky factor of U and is of the form:

$$G = \begin{bmatrix} G_{11} & G_{12} & & & \\ & G_{22} & G_{23} & & \\ & & G_{33} & & \\ & & & \ddots & \\ & & & & G_{(n-1)n} & G_{nn} \end{bmatrix}. \quad (5)$$

The blocks of G are related to the blocks of U as follows: G_{11} is the Cholesky factor of U_{11} . $G_{ij} = G_{ii}^{-1} U_{ij}$ for all off-diagonal blocks where $i = j - 1$, and G_{jj} is the Cholesky factor of $U_{jj} - G_{ij}^T G_{ij}$ for all other diagonal blocks.

Equations (3) and (4) can be derived from equation (1) and the Cholesky factor of M^{-1} in equation (5). First, defining equation (3) entails decomposing the diagonal covariance, R , and the observation vector, y , of equation (1) into subelements indexed to be compatible with the partitioning the equation (4). Now equation (4) is defined using the Cholesky factor in equation (5). In particular, $Q_{n-i+1}^{-1} = G_{ii}^T G_{ii}$ and $A_{n-i+1} = (G_{ii}^T G_{ii})^{-1} G_{ij}$ where $j = i+1$. This fact allows us to recast (1) and (2) as an equivalent *dynamic* estimation problem of the form given in equations (3) and (4). Note that this equivalence is exact, with no approximations. Conceptually, this dynamic model, obtained via Cholesky factorization, enables the optimal processing of the field with efficient techniques such as Kalman filter-based smoothing (*e.g.* Rauch, Tung, Striebel; Mayne-Fraser) algorithms.

While this approach indeed transforms the original large problem into a sequence of smaller problems and while providing storage advantages, the overall amount of computation is still the same as that obtained if we exploited the banded MRF structure from the outset in the solution of the original complete normal equations. As we have argued, for the large practical problems we are considering, this amount of computation is still too large. Thus, to reduce the computational burden, some form of suboptimal approach is necessary. We discuss next a particular suboptimal approach to recursive filtering based on reduced order GMRF modeling of the estimation error field [1] which is particularly well-matched to our proposed solution.

4 GMRF-based Kalman Filter

In [1], an efficient suboptimal approach to Kalman filtering for large problems, such as in (3) and (4), is presented. In this development, a suboptimal variant of the information form of the Kalman Filter for (3) and (4), consisting of the following prediction and update steps is implemented:

PREDICTION STEP

$$D \triangleq \text{diag}(A_k^T Q_k^{-1} A_k + \hat{L}_k) \quad (6)$$

$$\Omega \triangleq (A_k^T Q_k^{-1} A_k + \hat{L}_k) - D \quad (7)$$

$$K_{k+1} = D^{-1} - D^{-1} \Omega D^{-1} \dots \quad (8)$$

$$\bar{L}_{k+1} = Q_k^{-1} - Q_k^{-1} A_k K_{k+1} A_k^T Q_k^{-1} \quad (9)$$

$$\bar{x}_{k+1} = A_k \hat{x}_k \quad (10)$$

$$\bar{z}_{k+1} = \bar{L}_{k+1} \bar{x}_{k+1} \quad (11)$$

UPDATE STEP

$$\hat{L}_{k+1} = \bar{L}_{k+1} + R_{k+1}^{-1} \quad (12)$$

$$\hat{z}_{k+1} = \bar{z}_{k+1} + R_{k+1}^{-1} y_{k+1} \quad (13)$$

$$\hat{L}_{k+1} \hat{x}_{k+1} = \hat{z}_{k+1} \quad (14)$$

where, in the filtering equations above, as applied to (3) and (4), K_{k+1} is a series expansion to $(A_k^T Q_k^{-1} A_k + \hat{L}_k)^{-1}$, \bar{L}_{k+1} is the predicted information matrix, \bar{x}_{k+1} is the predicted state, \hat{L}_{k+1} is the updated information matrix, and \hat{x}_{k+1} is the updated state as described in [1]. The suboptimal filter structure of [1] is based on the idea of imposing a reduced order GMRF-type model of the error field, as reflected in the structure of \bar{L}_{k+1} , the predicted information matrix in (9). In particular, \bar{L}_{k+1} is constrained to have a sparse, banded MRF structure with the number of bands reflecting an imposed reduced-order GMRF neighborhood. Notice that such a structure, once imposed on \bar{L}_{k+1} , is maintained throughout (10)-(14) and imparted to \hat{L}_{k+1} . In summary, at each iteration, \hat{L} and \bar{L} are constrained to have an MRF-like structure.

5 Nested Solution

The main computational bottleneck in the approximate implementation of (6)-(14) can be traced to solving the implicit equation (14) for the updated state \hat{x}_{k+1} . In [1], (14) was solved iteratively by Gauss Seidel Successive Over Relaxation (SOR), exploiting the sparse structure of \hat{L}_{k+1} . Note, however, that (14) can be viewed as *another* static spatial estimation problem, which is of the following form:

$$y_{k+1} = \hat{x}_{k+1} + \hat{v}_{k+1}, \quad \hat{v}_{k+1} \sim \mathcal{N}(0, R_{k+1}) \quad (15)$$

$$\hat{x}_{k+1} \sim \mathcal{N}(0, \bar{L}_{k+1}^{-1}) \quad (16)$$

where the prior model, \bar{L}_{k+1}^{-1} again corresponds to a covariance of a GMRF. This is true precisely because of the GMRF approximation imposed in (9). It is *not true* in the exact Kalman filtering equations where \bar{L}_{k+1} is full in general. The problem in (15) and (16) is of the same form as the overall problem stated in equations (1) and (2). Therefore, we can apply the same technique we applied to solve the original problem, by performing a Cholesky factor of \bar{L} to again repose this subproblem as a dynamic estimation problem amenable to Kalman smoothing. In

this way, we *nest* the recursive solution to the overall high-dimensional problem, casting it as a series of progressively lower dimensional problems. This is the original contribution of this work.

6 Approximations

6.1 Incomplete Cholesky

While conceptually, a Cholesky factorization of M^{-1} in (2) provides the dynamics necessary to define an equivalent recursive smoothing problem, performing such a factorization is computationally prohibitive. The computational cost of computing an exact Cholesky factor of the block tridiagonal matrices we are considering following the definition given in Section 3 is $O(nn_b^3)$ where n is the number of blocks on the block diagonal, and n_b is the dimension of each block. For instance, for the fMRI example discussed previously, n may correspond to 60 time points, and n_b would be the number of voxels in each volume. In addition to the prohibitive computational cost of computing the Cholesky factor, fill-in occurs between the diagonal and off diagonal bands, destroying the structure of the problem so carefully preserved for efficiency in the suboptimal Kalman filter design in (6) through (14). Thus, in keeping with the reduced order GMRF modeling philosophy, we instead find an incomplete Cholesky factor, G_{inc} [2], such that $G_{\text{inc}}^T G_{\text{inc}} \approx \bar{L}$. In particular, the incomplete Cholesky factorization we use maintains the structure of the nearest-neighbor approximation scheme set up in the information form Kalman filtering equations.

A range of incomplete Cholesky factorization algorithms appear in the computational linear algebra literature for preconditioning sparse linear systems. A problem with most incomplete Cholesky factorization algorithms is that their computational cost, although smaller than $O(nn_b^3)$, is not linear in the block size. For the problem sizes we are considering, we seek an incomplete Cholesky factorization with computational cost linear in the block size.

The prohibitive computation in this process described in Section 3 can be traced to the inverse required for computing every off-diagonal block of the factor; this inverse is also the operation which leads to fill-in. For diagonally dominant diagonal blocks, G_{ii} , this inverse may be well-approximated by the inverse of each block's diagonal, which has computational cost $O(nn_b)$ rather than $O(nn_b^3)$. This diagonal approximation to the inverse also imposes the overall sparsity pattern of the U matrix onto its factor, G . For applications we have examined, this approxima-

tion is usually reasonable.

6.2 Dynamic and Observation Equations

Although the exact dynamic reformulation of the GMRF MAP estimation problem in equations (1) and (2) is given in Section 3, and the reformulation is analogous for the incomplete Cholesky factor we compute, certain operations in the reformulation destroy the structure of the subproblems. In particular, the inverse in the definition of each A_k destroys its GMRF structure, making it full in general. Because Q_k^{-1} is constructed from the multiplication of two nondiagonal matrices, it is no longer diagonal in general. As has been the modeling philosophy to alleviate similar issues in the rest of this paper, to maintain the required sparsity patterns for Q_k^{-1} and A_k , we make sparse approximations to each. For Q_k^{-1} , we retain only its diagonal elements. For A_k , we make the same two-term series expansion approximation we make to K_{k+1} in equation (8) of the Kalman filter, which again, is a rational approximation to the inverse which preserves the sparsity pattern of the underlying GMRF model. However, even this approximation to A_k is not completely adequate for the filter structure as it is presented in equations (6) through (14). Specifically, the bandwidth of \bar{L}_{k+1} will grow in equation (9). To remedy this issue, the \bar{L}_{k+1} matrix is truncated at every step through the filter, preserving its structure to reflect the original GMRF structure of the overall problem.

7 Examples

We have implemented our nested recursive approach to MAP estimation of Markov Random Fields on a test volume. The small example problem is an edge-preserving smoothing operation. Three simultaneous cross-sections of the underlying volume, a sphere of ones on a background of zeros, are shown in a slice display format in Figure 1. This underlying volume is the state, x , we are trying to estimate in equations (1) and (2). This sphere is observed in white Gaussian additive noise with diagonal covariance, or $r \sim (0, R = 1/\mu I)$ in equation (1). The observation is $y = x + r$, shown in Figure (2). The prior model for the volume in equation (2) is a 3D GMRF prior where M^{-1} is a discrete approximation to the gradient operator weighted by a function of the given edge process shown in Figure (3), such that the 3D GMRF prior has a large covariance at the pixels indicated by the edges, and a small covariance at all

Figure 1: Original Volume

Figure 2: Observed Volume

other pixels. In Figure 4, we show an example of our nested recursive filtering method applied to processing the observed volume shown in Figure 2 given the normal equations corresponding to the GMRF model discussed above.

Figure 3: Given Edge Locations

Figure 4: Restored Volume (by nested recursion)

8 Discussion

In the edge-preserving smoothing example above, we illustrate 3 concepts. Most importantly, it demonstrates Kalman filtering as a means for volumetric data processing. Specifically, it illustrates the idea of splitting the GMRF neighborhood structure in 3D into an equivalent neighborhood structure in 2D along with a prior term which depends on the previous slice of data. This splitting is powerful, and can be used for multidimensional data where the state dimension may be much larger. Secondly, for such an approach, the storage space for the sparse matrices required to define the dynamic and observation equations in the Kalman filtering grows linearly with the number of pixels in the volume. Finally, the computation is $O(n)$ rather than $O(n^3)$, where n is the total number of elements in the field. For computing simultaneously the approximate MAP estimate of the state as well as the approximate MAP estimation error. These are the primary motivations for the suboptimal nested recursive filtering approach.

The specific performance of our method depends on a host of factors, including the degree of diagonal dominance of the information matrices, and the order of the GMRF being processed. These factors are consequences of the overall parameterization of the GMRF. Thus, the parameterization of the GMRF impacts the approximation error of the proposed nested recursive method. Specifically, for GMRFs enforcing strong regularization (i.e. for a large local correlation strength and large neighborhood sizes), approximation error will be larger. The relationship between smoothing in the GMRF definition and approximation error is of practical importance and is a focus of current investigation.

9 Conclusion

We have combined a recursive interpretation of GMRF's with an approximate information form Kalman filter based precisely on reduced order GMRF spatial models to develop a nested and efficient recursive approach to solution of GMRF regularized spatial estimation problems. In particular, we exploit the specific structure of the overall problem to reduce a large optimization problem into a series of dynamic equations amenable to solution by Kalman filtering techniques. We choose a specific information form Kalman filtering technique which allows us to exploit the sparse banded structure of the information matrix to make rational approximations to the prediction and update step. These approximations preserve the sparse banded GMRF structure of the original problem. Preserving this structure allows us to reformulate subproblems arising in the information form Kalman filter as a series of yet smaller dynamic equations. This *nested* recursive structure of the overall problem is elegant and also serves to make the solution more efficient. For higher dimensional problems, preliminary calculations suggest that this method will save more computation than traditional techniques for solving spatial estimation problems.

Northeastern University, Boston, MA 02115, USA

Received 31 May 1996

Abstract. A generalized diffraction tomographic (DT) algorithm is derived for subsurface imaging from multifrequency multi-monostatic ground penetrating radar (GPR) data. The algorithm is based on the Born approximation for vector electromagnetic scattering and incorporates realistic nearfield models for the receiving and transmitting antennas. The forward scattering model is inverted analytically using the regularized pseudoinverse operator to yield an algorithm for imaging the underground region based on scattered field measurements at a set of receiving antennas. Whereas the usual inversion algorithms of DT require a lossless background medium and ideal point sources and receivers, the algorithm described here allows an attenuating background and arbitrary transmitting and receiving antennas. The algorithm places no restrictions on the radar frequency, and can thus include shallow imaging applications where the wavelengths are on the same order as the depth of buried objects of interest. Versions of the algorithm are given for both the three dimensional and the 2.5-dimensional cases. Results are given of computer simulations designed to test the algorithm.

1. Introduction

In this paper we present a new approach for subsurface imaging from multifrequency multi-monostatic data measurements obtained using ground penetrating radar (GPR) in a reflection geometry. The method employs a linear scattering model for electromagnetic wavefields based on the Born approximation, which is inverted analytically to yield an image of the subsurface based on scattered field measurements. Thus, our imaging algorithm is related to the well established method of *diffraction tomography* (DT), which is used in various forms for such applications as optical inverse scattering [15], medical ultrasonic imaging [6, 14], and geophysical imaging [7, 8, 20, 26–29]. However, in contrast with many applications of DT [6, 7], in GPR imaging background losses are significant, and evanescent wavefield components are important since radar wavelengths are often times on the same order as the depth and size of underground objects of interest [22]. Therefore in this development, unlike the usual treatments of DT, we incorporate soil attenuation into the mathematical inversions, and include evanescent components to help combat the restrictions on image resolution imposed by the relatively low frequencies used. Moreover, we employ realistic nearfield models for the transmitting and receiving antennas, in contrast with most treatments of DT that employ ideal point sources and receivers. Our method can be used with bandlimited

pulses, and can include a constant spatial offset between the transmitter and receiver in each monostatic experiment.

Several authors have addressed, within the context of DT, the problem of inverse scattering using multi-monostatic field measurements. In [19] exact inversion formulae, within the Born approximation, are derived using broadband multi-monostatic measurements conducted on planar, spherical, and cylindrical surfaces. The authors use an ideal point source and receiver approximation, and assume the distance to scattering objects is much greater than a wavelength. This treatment requires transmitted pulses which are not bandlimited although the authors suggest Wiener filtering as a means to circumvent this restriction. An iterative, time domain, approach to the multi-monostatic imaging problem is suggested in [25] based on the Born approximation. The background medium is assumed to be lossless and nondispersive, and the ideal point source and receiver approximation is used. In [27] DT algorithms for GPR imaging are derived and tested on experimental data. The Born approximation is employed, as well as the approximations that the background is lossless and the distance between antennas and scatterers is much greater than a wavelength. A target detection algorithm is also given which can incorporate an attenuating background. Efficient DT imaging methods are described in [29] using multifrequency multi-monostatic data for both constant and vertically varying backgrounds. Inversion formulae are given using both the Born and the physical optics approximations, assuming a lossless background medium and ideal point sources and receivers. With these algorithms the final image is formed by coherent superposition of subimages from each frequency, whereas we show in this paper that an optimum multifrequency algorithm must exploit the correlation between the data at different frequencies.

The approach employed in this paper consists of several steps. We first define a vector electromagnetic forward scattering model based on the Born approximation, which incorporates nearfield characteristics of the transmitting and receiving antennas via the scattering matrix models developed by Kerns [13]. This model then yields a coupled set of integral equations relating the data at each excitation frequency to the sought after ‘object function’ defining the complex index of refraction profile of the subsurface. After casting the integral equations in a mathematical operator formalism, we are then able to find the minimum L^2 -norm solution to the object function by deriving and applying the regularized pseudoinverse operator [2, 17, 21]. The method is found to be similar to *filtered backpropagation algorithms* of DT described in the literature [4, 6, 7], and like these algorithms it is quantitative, and is designed to yield a solution which is mathematically consistent with the measured data. The inversion is fully analytic, and therefore relatively efficient to compute.

In section 2 we derive the forward scattering model in detail, then in section 3 we derive the regularized inversion of this model for the case when the scatterer is three dimensional and monostatic experiments are conducted over the xy plane defining the ground surface. In section 4 we modify the three-dimensional method to the 2.5-dimensional case where the scatterer is invariant in the \hat{y} -direction and experiments are conducted along the \hat{x} -axis. The paper includes computed results from synthetic data in section 5, as well as a discussion of future directions for the methodology of this paper in section 6.

2. Forward model for electromagnetic scattering

By probing the earth with electromagnetic wavefields we wish to estimate the electrical permittivity distribution in the underground region $z < 0$ from scattered field measurements at the surface $z = 0$ (where the orientation of the coordinate axes is illustrated in figure 1).

Figure 1. Geometry for multi-monostatic radar imaging.

The incident (probing) fields are generated by a ground penetrating radar (GPR) system operating in either a pulsed time domain or step frequency mode. Our scattering model is developed here in the frequency domain, related to the time domain through the standard Fourier and inverse Fourier transform definitions.

The GPR survey is assumed to consist of a number of monostatic experiments, each corresponding to a different location of the transmitting/receiving antenna on the ground surface, and each incorporating data collected over a band of frequencies ω . In each experiment the scattered field results from the interaction of the incident field with inhomogeneities in the subsurface, described by the *object function*

$$O(\mathbf{r}, \omega) = 1 - \frac{\epsilon(\mathbf{r}, \omega)}{\epsilon_0(\omega)}.$$

Here, $\mathbf{r} = (x, y, z)$ is the three-dimensional spatial coordinate and $\epsilon(\mathbf{r}, \omega) = \epsilon'(\mathbf{r}, \omega) + i\sigma(\mathbf{r}, \omega)/\omega$ is the complex permittivity in the underground, i.e. the soil with the embedded inhomogeneities. The quantity $\epsilon'(\mathbf{r}, \omega)$ is the real dielectric constant and $\sigma(\mathbf{r}, \omega)$ is the conductivity, while $\epsilon_0(\omega)$ is the complex permittivity of the homogeneous background soil medium. It is assumed that the magnetic permeability in the underground is equal to μ_0 in a vacuum. Throughout the discussion, MKS units are used.

The Fourier amplitude of the electric field vector generated in any given experiment satisfies the well known Lippmann Schwinger equation [3, 11, 16]

$$\begin{aligned} \mathbf{E}(\mathbf{r}, \omega) &= \mathbf{E}_{\text{inc}}(\mathbf{r}, \omega) + \mathbf{E}_{\text{scat}}(\mathbf{r}, \omega) \\ &= \mathbf{E}_{\text{inc}}(\mathbf{r}, \omega) - k_0^2(\omega) \int d^3 r' \bar{\mathbf{G}}(\mathbf{r} - \mathbf{r}', \omega) \cdot \mathbf{E}(\mathbf{r}', \omega) O(\mathbf{r}', \omega) \end{aligned} \quad (1)$$

where $\mathbf{E}_{\text{inc}}(\mathbf{r}, \omega)$ is the incident field for the experiment, $\mathbf{E}_{\text{scat}}(\mathbf{r}, \omega)$ is the scattered field component of the electric field vector, $k_0(\omega) = \omega\sqrt{\epsilon_0(\omega)\mu_0}$ is the complex wavenumber of the homogeneous background soil medium, and the Green's dyadic $\bar{\mathbf{G}}(\mathbf{r}, \omega)$ satisfies

$$\nabla \times \nabla \times \bar{\mathbf{G}}(\mathbf{r}, \omega) - k_0^2(\omega) \bar{\mathbf{G}}(\mathbf{r}, \omega) = \bar{\mathbf{I}}\delta(\mathbf{r}).$$

In the above equation the scattering effects of the air–soil surface interface are ignored but could, in principle, be incorporated in the Green's dyadic.

The Born approximation to the electric field is the leading term in the Liouville Neumann expansion of the solution of the above integral equation and results in the following expression for the scattered field component of the electric field vector [7, 16]:

$$\mathbf{E}_{\text{scat}}(\mathbf{r}, \omega) = -k_0^2(\omega) \int d^3 r' \bar{\mathbf{G}}(\mathbf{r} - \mathbf{r}', \omega) \cdot \mathbf{E}_{\text{inc}}(\mathbf{r}', \omega) O(\mathbf{r}', \omega). \quad (2)$$

It is evident that the Born approximation results in the replacement of the total field $\mathbf{E}(\mathbf{r}', \omega)$ within the \mathbf{r}' integration by the incident field $\mathbf{E}_{\text{inc}}(\mathbf{r}', \omega)$. Thus, the Born approximation is valid for applications where multiple scattering effects can be neglected. The Born approximation is convenient for us because it allows a linear relation between $O(\mathbf{r}, \omega)$ and $\mathbf{E}_{\text{scat}}(\mathbf{r}, \omega)$, which will generally be easier to invert than the nonlinear equation (1), where $\mathbf{E}_{\text{scat}}(\mathbf{r}, \omega)$ appears implicitly both on the left-hand side and within the \mathbf{r}' integration. It has been shown [24] that DT using the Born approximation is adequate for quantitatively reconstructing objects with roughly

$$\left(0.8 \leq \left| \frac{\epsilon(\mathbf{r}, \omega)}{\epsilon_0(\omega)} \right| \leq 1.2 \right)$$

or a 20% contrast, when the object size is on the order of a wavelength. This size-to-wavelength ratio is not unrealistic for GPR imaging, therefore the Born approximation should not be overly restrictive. Generally, as the object size decreases the allowable contrast increases. Thus, our algorithm is suitable not only for imaging larger weak scatterers, but also for imaging smaller diameter strong scatterers such as metal pipes. The Born approximation is often used, either implicitly or explicitly, for inverse problems in geophysics [7, 20, 26, 27] and it is assumed to be valid throughout this discussion.

To incorporate the characteristics of the transmitting and receiving antennas into the scattering equation, we first transform equation (2) into the spatial frequency domain, and then use Kerns' antenna scattering matrix formulation [13] to model the near-field interactions between antennas and scatterers. To convert equation (2) to the spatial frequency domain we employ the *plane wave expansion* for the Green's dyadic [3]

$$\tilde{\mathbf{G}}(\mathbf{r} - \mathbf{r}', \omega) = \frac{i}{8\pi^2} \int_{-\infty}^{\infty} \frac{d^2 \mathbf{K}}{\gamma(\mathbf{K}, \omega)} \left[\tilde{\mathbf{I}} + \frac{\mathbf{k}^+(\omega) \mathbf{k}^+(\omega)}{k_0^2(\omega)} \right] e^{i\mathbf{k}^+(\omega) \cdot (\mathbf{r} - \mathbf{r}')} \quad (3)$$

where we have assumed $z > z'$ and where $\mathbf{K} = K_x \hat{\mathbf{x}} + K_y \hat{\mathbf{y}}$ is the spatial frequency variable, $\mathbf{k}^+(\omega) = \mathbf{K} + \gamma(\mathbf{K}, \omega) \hat{\mathbf{z}}$ is the wave vector for each planewave $e^{i\mathbf{k}^+(\omega) \cdot (\mathbf{r} - \mathbf{r}')}$ in the expansion, and $\gamma(\mathbf{K}, \omega) = \pm \sqrt{k_0^2(\omega) - \mathbf{K} \cdot \mathbf{K}}$ with the sign chosen to render $\Im(\gamma) \geq 0$. For the lossless case (real k_0) the above plane wave expansion includes both *homogeneous* (propagating) plane waves ($|\mathbf{K}| \leq k_0$) having purely real wave vectors $\mathbf{k}^+(\omega)$ and *evanescent* (non-propagating) plane waves ($|\mathbf{K}| > k_0$) whose wave vectors are complex and which decay exponentially with increasing $(z - z')$. In the lossy case treated here (complex k_0) all plane waves will have complex wave vectors, however those corresponding to the higher spatial frequency range $|\mathbf{K}| > \Re[k_0]$ will decay quickest with increasing $(z - z')$. Thus, in the lossy case the term 'evanescent' is often applied to planewaves corresponding to the range $|\mathbf{K}| > \Re[k_0]$. In most formulations of DT the evanescent waves are discarded [7] since it is tacitly assumed that the measurements are conducted more than several wavelengths from the scatterers, i.e. $(z - z') \gg \frac{2\pi}{\Im[k_0]}$. In GPR imaging we should not discard evanescent components since objects of interest may be near the surface and wavelengths are relatively long (for adequate penetration), and therefore evanescent waves may contain valuable information [22].

We substitute equation (3) into equation (2) and evaluate the resulting expression at $z = 0$ to find the scattered electric field at the ground surface. We then convert this expression to the spatial frequency domain by Fourier transforming relative to the $\mathbf{X} = x\hat{\mathbf{x}} + y\hat{\mathbf{y}}$ coordinate to obtain

$$\tilde{\mathbf{E}}_{\text{scat}}(\mathbf{K}, \omega) = \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} d^2 \mathbf{X} e^{-i\mathbf{K} \cdot \mathbf{X}} [\mathbf{E}_{\text{scat}}(\mathbf{r}, \omega)]_{z=0}$$

$$= \frac{-ik_0^2(\omega)}{8\pi^2\gamma(\mathbf{K}, \omega)} \int_{z' < 0} d^3r' e^{-i\mathbf{k}^+(\omega) \cdot \mathbf{r}'} \left[\bar{\mathbf{I}} + \frac{\mathbf{k}^+(\omega)\mathbf{k}^+(\omega)}{k_0^2(\omega)} \right] \cdot \mathbf{E}_{\text{inc}}(\mathbf{r}', \omega) O(\mathbf{r}', \omega). \quad (4)$$

Using Kerns' scattering matrix formulation, a transmitting antenna centred at a position $\mathbf{X}_j \equiv x_j \hat{\mathbf{x}} + y_j \hat{\mathbf{y}}$ on the ground surface and driven by matched terminal voltage $C(\omega)$ will give rise to the following plane wave expansion for the incident electric field propagating in the negative $\hat{\mathbf{z}}$ -direction: [13, 23]

$$\mathbf{E}_{\text{inc}}(\mathbf{r}, \omega) = C(\omega) \int_{-\infty}^{\infty} d^2K_0 e^{-i\mathbf{K}_0 \cdot \mathbf{X}_j} S_{10}(\mathbf{K}_0, \omega) e^{i\mathbf{k}_0^-(\omega) \cdot \mathbf{r}} \quad (5)$$

where $\mathbf{K}_0 = K_{0x} \hat{\mathbf{x}} + K_{0y} \hat{\mathbf{y}}$ and $\mathbf{k}_0^-(\omega) = \mathbf{K}_0 - \gamma(\mathbf{K}_0, \omega) \hat{\mathbf{z}}$. Similarly, the matched terminal voltage at a receiver centred at \mathbf{X}_j (a monostatic experiment) is given by [13, 23]

$$V(\omega; \mathbf{X}_j) = \int_{-\infty}^{\infty} d^2K e^{i\mathbf{K} \cdot \mathbf{X}_j} S_{01}(\mathbf{K}, \omega) \cdot \tilde{\mathbf{E}}_{\text{scat}}(\mathbf{K}, \omega). \quad (6)$$

In equations (5) and (6), S_{10} and S_{01} are off-diagonal scattering matrix coefficients for the antennas, with each vector component corresponding to a Cartesian electric field polarization. It should be emphasized that equations (5) and (6) are valid in the nearfield of the antennas, thus, we need not make the point source approximation typical to other inversion algorithms of diffraction tomography. If the transmitting and receiving antennas are reciprocal, as would be the case for a typical monostatic radar system, then [13, 23]

$$Y_0(\omega) S_{01}(\mathbf{K}, \omega) = \frac{\gamma(\mathbf{K}, \omega)}{\omega \mu_0} S_{10}(-\mathbf{K}, \omega) \quad (7)$$

where Y_0 is the antenna terminal admittance.

Combining equations (4)–(7), the measured voltage $V(\omega)$ for a single monostatic experiment with the transmitter/receiver centred at \mathbf{X}_j is:

$$\begin{aligned} V(\omega; \mathbf{X}_j) &= P(\omega) \int_{-\infty}^{\infty} d^2K \int_{-\infty}^{\infty} d^2K_0 e^{-i(\mathbf{K}_0 - \mathbf{K}) \cdot \mathbf{X}_j} B(\mathbf{K}, \mathbf{K}_0; \omega) \\ &\times \int_{-\infty}^0 dz' e^{-i[\gamma(\mathbf{K}, \omega) + \gamma(\mathbf{K}_0, \omega)]z'} \int_{-\infty}^{\infty} d^2X' e^{-i(\mathbf{K} - \mathbf{K}_0) \cdot \mathbf{X}'} O(\mathbf{r}') \end{aligned} \quad (8)$$

where

$$B(\mathbf{K}, \mathbf{K}_0; \omega) \equiv S_{10}(-\mathbf{K}, \omega) \cdot \left[\bar{\mathbf{I}} + \frac{\mathbf{k}^+(\omega)\mathbf{k}^+(\omega)}{k_0^2(\omega)} \right] \cdot S_{10}(\mathbf{K}_0, \omega)$$

and

$$P(\omega) = \frac{-iC(\omega)k_0^2(\omega)}{8\pi^2\omega Y_0(\omega)\mu_0}.$$

If the receiver in each experiment is spatially offset from the transmitter by a constant amount \mathbf{X}_0 , then we must multiply $B(\mathbf{K}, \mathbf{K}_0; \omega)$ given above by the factor $e^{i\mathbf{K} \cdot \mathbf{X}_0}$.

Notice that in equation (8) the object function is expressed as a frequency independent (dispersionless) quantity $O(\mathbf{r}, \omega) = O(\mathbf{r})$. This assumption, although not necessary, allows us to couple the measured data at each frequency, thus, incorporating more information into the mathematical inversions and leading to ‘better’ solutions for the object function. There are alternatives to this approach that will work using the methodology of this paper, including: (i) solve for the frequency dependent object function $O(\mathbf{r}, \omega)$ independently at each single radar frequency; (ii) treat the object function as the product of a known frequency dependent factor $\Theta(\omega)$ and an unknown frequency independent factor $O(\mathbf{r})$,

then incorporate the known function $\Theta(\omega)$ into $P(\omega)$ given above, subsequently solving for the unknown $O(\mathbf{r})$ in the standard manner discussed below. In any case, we note that the assumption of a dispersionless object function in GPR is common (e.g. [27]) and models many important applications over relatively large frequency bands.

A typical GPR survey consists of multiple experiments, each corresponding to a different position \mathbf{X}_j for the transmitting/receiving antennas, thus we have a coupled set of equations, each in the form of equation (8). The objective of the present work is to estimate the object function $O(\mathbf{r})$ by inverting the coupled equations using the regularized pseudoinverse formula as described below.

3. Data inversion for three-dimensional surveys

In this section we construct a mathematical operator formalism for the coupled set of equations (8), where each equation corresponds to a different transmitter/receiver position. This mathematical framework allows us to use well known linear inversion methods to analytically solve for the object function in terms of the measured data.

We consider a three-dimensional survey where a series of monostatic experiments are performed over the ground surface at evenly spaced locations corresponding to points on a two-dimensional grid. For each experiment we store data from N different excitation frequencies ω_n . If the grid spacing is small enough to satisfy the Nyquist sampling criterion for the voltage measurements, we can treat the transmitter/receiver position as a continuous variable $\mathbf{X} = (x, y)$ (below we discuss the spatial sampling requirements in further detail). Thus, from equation (8) the measured voltage as a function of frequency and transmitter/receiver position is

$$V(\omega_n; \mathbf{X}) = P(\omega_n) \int_{-\infty}^{\infty} d^2 K \int_{-\infty}^{\infty} d^2 K_0 e^{-i(\mathbf{K}_0 - \mathbf{K}) \cdot \mathbf{X}} B(\mathbf{K}, \mathbf{K}_0; \omega_n) \\ \times \int_{-\infty}^0 dz' e^{-i[\gamma(\mathbf{K}, \omega_n) + \gamma(\mathbf{K}_0, \omega_n)]z'} \int_{-\infty}^{\infty} d^2 X' e^{-i(\mathbf{K} - \mathbf{K}_0) \cdot \mathbf{X}'} O(\mathbf{r}').$$

We make the change of variable $\bar{\mathbf{K}} = \mathbf{K} - \mathbf{K}_0$, and drop the bar notation on $\bar{\mathbf{K}}$ to yield

$$V(\omega_n; \mathbf{X}) = \int_{-\infty}^{\infty} d^2 K e^{i\mathbf{K} \cdot \mathbf{X}} P(\omega_n) \int_{-\infty}^{\infty} d^2 K_0 B(\mathbf{K} + \mathbf{K}_0, \mathbf{K}_0; \omega_n) \\ \times \int_{-\infty}^0 dz' e^{-i[\gamma(\mathbf{K} + \mathbf{K}_0, \omega_n) + \gamma(\mathbf{K}_0, \omega_n)]z'} \int_{-\infty}^{\infty} d^2 X' e^{-i\mathbf{K} \cdot \mathbf{X}'} O(\mathbf{r}'). \quad (9)$$

We now spatially Fourier transform equation (9) with respect to the \mathbf{X} variable to obtain

$$\tilde{V}(\omega_n; \mathbf{K}) \equiv \frac{1}{(2\pi)^2} \int_{-\infty}^{\infty} d^2 X e^{-i\mathbf{K} \cdot \mathbf{X}} V(\omega_n; \mathbf{X}) \\ = P(\omega_n) \int_{-\infty}^{\infty} d^2 K_0 B(\mathbf{K} + \mathbf{K}_0, \mathbf{K}_0; \omega_n) \\ \times \int_{-\infty}^0 dz' e^{-i[\gamma(\mathbf{K} + \mathbf{K}_0, \omega_n) + \gamma(\mathbf{K}_0, \omega_n)]z'} \int_{-\infty}^{\infty} d^2 X' e^{-i\mathbf{K} \cdot \mathbf{X}'} O(\mathbf{r}'). \quad (10)$$

It is important to define Hilbert spaces for the various quantities entering into equation (10) and to express this equation in compact operator formalism. Thus, we introduce the vector space U of object functions $O(\mathbf{r})$ and the vector space Y of transformed measured voltages $\tilde{V}(\omega_n; \mathbf{K})$. We will employ the standard L^2 -inner products in both spaces and will assume the elements of each space to have finite L^2 -norms, i.e.

- $O(\mathbf{r}) \in U$, where U is the space of square integrable functions on $-\infty < (x, y) < \infty$, $-\infty < z < 0$;
- $\tilde{V}(\omega_n; \mathbf{K}) \in Y$, where Y is the direct product space of square integrable functions on $-\infty < (K_x, K_y) < \infty$ with the finite-dimensional vector space Y_0 of functions of the discrete variable ω_n .

With these definitions we can write equation (10) in the compact form

$$\tilde{V}(\omega_n; \mathbf{K}) = H O(\omega_n; \mathbf{K}) \quad (11)$$

where H is a linear operator which maps U into Y .

Our goal is to find the object function $O(\mathbf{r}')$ which satisfies the set of equations (11). Since we use only a finite number of excitation frequencies, the set of equations (11) are underdetermined so that there are an infinite number of object functions which will produce the data. The minimum L^2 -norm solution is approximately found by applying the regularized pseudoinverse operator [1, 2, 12, 17] to the data, i.e.

$$\hat{O}_\beta(\mathbf{r}) = H^\dagger [H H^\dagger + \beta I]^{-1} \tilde{V}(\mathbf{r}) \quad (12)$$

where H^\dagger is the Hermitian adjoint of H . In the limit as β goes to zero, $\hat{O}_\beta(\mathbf{r})$ is equal to the minimum L^2 -norm solution to equation (11)[†]. The number β is known as the Tikhonov–Phillips regularization parameter [21, 17], and is necessary to stabilize the inversion against noise from measurements or numerical truncations. The regularization parameter is also necessary in the event that $(H H^\dagger)^{-1}$ does not exist. Generally there is a tradeoff between selecting β small enough such that $\hat{O}_\beta(\mathbf{r})$ approximately satisfies the data yet large enough that the inversion is stable, and typically β is selected by trial and error. We show below that equation (12) is in the form of a filtered backpropagation operation, where $[H H^\dagger + \beta I]^{-1}$ is the filtering operator and the H^\dagger is a coherent sum over frequencies of the filtered, backpropagated, data.

Before proceeding with the inversion algorithm, we should make several comments about our solution strategy. First, in GPR imaging there will be a significant amount of noise associated both with the receiver electronics and scattering from ground clutter, and this noise may profoundly affect computed solutions. One can modify equation (11) to include this additive noise component n explicitly as follows:

$$\tilde{V} = H O + n.$$

The minimum variance (Wiener filtering) solution [2, 12] to this equation is

$$\hat{O}_w = R_V H^\dagger [H R_V H^\dagger + R_n]^{-1} \tilde{V} \quad (13)$$

where \tilde{V} and n are assumed to be zero-mean random processes having covariances R_V and R_n , respectively. If \tilde{V} and n are Gaussian white processes with variances σ_V^2 and σ_n^2 , respectively (the Gaussian white assumption may be sensible if no other information is available), then equation (13) reduces to [2, 12]

$$\hat{O}_w = H^\dagger [H H^\dagger + \sigma_n^2 / \sigma_V^2]^{-1} \tilde{V}. \quad (14)$$

Note that equations (12) and (14) are identical for $\beta = \sigma_n^2 / \sigma_V^2$, and thus we expect that the optimum value for β in Tikhonov–Phillips regularization is roughly proportional to

[†] In practice one does not have access to an infinite number of monostatic measurements, rather the received voltage is sampled at discrete spatial intervals over a finite area of the xy plane. Representing this sampled voltage as $\tilde{V} = R F^{-1} \tilde{V} = R F^{-1} H O$, where R is the sampling operator and F^{-1} is the inverse Fourier transform, we can show that $\hat{O}_{\beta=0}$ from equation (12) is also the minimum L^2 norm solution to $\tilde{V} = R F^{-1} H O$ if the linear operator $(R F^{-1})$ can be inverted. In practice, $(R F^{-1})$ can be inverted if the Nyquist sampling criterion is satisfied and the spatial extent of the sampling area is large relative to the support region dimensions (depth and horizontal) of the object function.

the noise variance. Note that there are other robust alternatives to Tikhonov–Phillips regularization and Wiener filtering, for example the reduced rank pseudoinverse operator [1, 10]. We choose the method of Tikhonov–Phillips regularization because it allows us to derive analytical formulae.

Let us now analytically expand the operator notation in equation (12) to obtain explicitly the pseudoinverse solution. Given the vector space definitions, the Hermitian adjoint H^\dagger of H maps the space Y onto the space U so that

$$\langle H O_\beta, \tilde{V} \rangle_Y = \langle O_\beta, H^\dagger \tilde{V} \rangle_U.$$

From this inner product relation the action of H^\dagger is found to be

$$\begin{aligned} H^\dagger \hat{\tilde{V}}(\mathbf{r}') \equiv \hat{O}_\beta(\mathbf{r}') &= \sum_{n=1}^N P^*(\omega_n) \int_{-\infty}^{\infty} d^2 K' \int_{-\infty}^{\infty} d^2 K'_0 B^*(\mathbf{K}' + \mathbf{K}'_0, \mathbf{K}'_0; \omega_n) \\ &\times e^{i[\gamma^*(\mathbf{K}' + \mathbf{K}'_0, \omega_n) + \gamma^*(\mathbf{K}'_0, \omega_n)]z'} e^{i\mathbf{K}' \cdot \mathbf{X}'} \hat{\tilde{V}}(\omega_n; \mathbf{K}') \end{aligned} \quad (15)$$

where the $(*)$ denotes the complex conjugate, $\mathbf{r}' = (\mathbf{X}', z')$, and where we have added a ‘hat’ to \tilde{V} for later notational purposes. In typical filtered backpropagation algorithms [4, 6, 7] the backpropagation operation is the adjoint of the forward propagation. Similarly, each term in the summation in equation (15) is the adjoint of the forward scattering operator at a single excitation frequency. Because of this analogy, we refer to each term in the summation as a backpropagation, although this is not true in the usual sense.

Let us now consider the operation $\hat{\tilde{V}} = [HH^\dagger + \beta I]^{-1} \tilde{V}$, which corresponds to the filtering operation in standard DT filtered backpropagation algorithms, where $\hat{\tilde{V}}$ is the filtered data and \tilde{V} is the raw, unfiltered, data. From equations (10) and (15), the inverse of the filtering operation is

$$\begin{aligned} \tilde{V}(\omega_m; \mathbf{K}) &= [HH^\dagger + \beta I] \hat{\tilde{V}}(\omega_m; \mathbf{K}) \\ &= \sum_{n=1}^N P(\omega_m) P^*(\omega_n) \int_{-\infty}^{\infty} d^2 K' \hat{\tilde{V}}(\omega_n; \mathbf{K}') \\ &\times \int_{-\infty}^{\infty} d^2 K_0 \int_{-\infty}^{\infty} d^2 K'_0 B(\mathbf{K} + \mathbf{K}_0, \mathbf{K}_0; \omega_m) B^*(\mathbf{K}' + \mathbf{K}'_0, \mathbf{K}'_0; \omega_n) \\ &\times \int_{-\infty}^0 dz' e^{-i[\gamma(\mathbf{K} + \mathbf{K}_0, \omega_m) + \gamma(\mathbf{K}_0, \omega_m) - \gamma^*(\mathbf{K}' + \mathbf{K}'_0, \omega_n) - \gamma^*(\mathbf{K}'_0, \omega_n)]z'} \\ &\times \int_{-\infty}^{\infty} d^2 X' e^{-i(\mathbf{K} - \mathbf{K}') \cdot \mathbf{X}'} \\ &+ \beta \hat{\tilde{V}}(\omega_m; \mathbf{K}). \end{aligned}$$

The integral over \mathbf{X}' reduces to a Dirac delta function, and the integral over z' can be solved since $\Im(\gamma) > 0$, therefore

$$\tilde{V}(\omega_m; \mathbf{K}) = \sum_{n=1}^N R_{mn}(\mathbf{K}) \hat{\tilde{V}}(\omega_n; \mathbf{K}) + \beta \hat{\tilde{V}}(\omega_m; \mathbf{K})$$

where

$$\begin{aligned} R_{mn}(\mathbf{K}) &= \int_{-\infty}^{\infty} d^2 K_0 \int_{-\infty}^{\infty} d^2 K'_0 \\ &\times \frac{4i\pi^2 P(\omega_m) P^*(\omega_n) B(\mathbf{K} + \mathbf{K}_0, \mathbf{K}_0; \omega_m) B^*(\mathbf{K} + \mathbf{K}'_0, \mathbf{K}'_0; \omega_n)}{[\gamma(\mathbf{K} + \mathbf{K}_0, \omega_m) + \gamma(\mathbf{K}_0, \omega_m) - \gamma^*(\mathbf{K} + \mathbf{K}'_0, \omega_n) - \gamma^*(\mathbf{K}'_0, \omega_n)]} \end{aligned} \quad (16)$$

For each value of \mathbf{K} this set of equations can be written in the matrix notation

$$\begin{bmatrix} \tilde{V}(\omega_1; \mathbf{K}) \\ \tilde{V}(\omega_2; \mathbf{K}) \\ \vdots \\ \tilde{V}(\omega_N; \mathbf{K}) \end{bmatrix} = \begin{bmatrix} R_{11}(\mathbf{K}) + \beta & R_{12}(\mathbf{K}) & \cdots & R_{1N}(\mathbf{K}) \\ R_{21}(\mathbf{K}) & R_{22}(\mathbf{K}) + \beta & \cdots & R_{2N}(\mathbf{K}) \\ \vdots & \vdots & \ddots & \vdots \\ R_{N1}(\mathbf{K}) & R_{N2}(\mathbf{K}) & \cdots & R_{NN}(\mathbf{K}) + \beta \end{bmatrix} \begin{bmatrix} \hat{\tilde{V}}(\omega_1; \mathbf{K}) \\ \hat{\tilde{V}}(\omega_2; \mathbf{K}) \\ \vdots \\ \hat{\tilde{V}}(\omega_N; \mathbf{K}) \end{bmatrix} \quad (17)$$

which can be inverted by standard methods of linear algebra to yield the filtered data $\hat{\tilde{V}}$ in terms of the raw, unfiltered data \tilde{V} . The regularized pseudoinverse solution $\hat{O}_\beta(\mathbf{r})$ can then be found by operating on the filtered data by the backpropagation operator H^\dagger as given in equation (15).

As an example of the object function reconstruction, let us consider the case where there are two radar frequencies ω_1 and ω_2 . Inverting the 2×2 version of equation (17), we have the following solutions for the filtered data:

$$\hat{\tilde{V}}(\omega_1; \mathbf{K}) = \frac{(R_{22}(\mathbf{K}) + \beta)}{\Delta(\mathbf{K})} \tilde{V}(\omega_1; \mathbf{K}) - \frac{R_{12}(\mathbf{K})}{\Delta(\mathbf{K})} \tilde{V}(\omega_2; \mathbf{K})$$

and

$$\hat{\tilde{V}}(\omega_2; \mathbf{K}) = -\frac{R_{21}(\mathbf{K})}{\Delta(\mathbf{K})} \tilde{V}(\omega_1; \mathbf{K}) + \frac{(R_{11}(\mathbf{K}) + \beta)}{\Delta(\mathbf{K})} \tilde{V}(\omega_2; \mathbf{K})$$

where

$$\Delta(\mathbf{K}) = [R_{11}(\mathbf{K}) + \beta][R_{22}(\mathbf{K}) + \beta] - R_{21}(\mathbf{K})R_{12}(\mathbf{K}).$$

According to equation (12), we then reconstruct the object function $\hat{O}_\beta(\mathbf{r})$ by backpropagating the filtered data using equation (15) with $N = 2$.

4. Data inversion for 2.5-dimensional surveys

The 2.5-dimensional case corresponds to assuming a two-dimensional object function $O(x, z)$, invariant in the \hat{y} -direction, but fully three-dimensional incident and scattered wavefields. We can treat the 2.5-dimensional case in a manner completely analogous to the three-dimensional analysis of section 3. Whereas for the three-dimensional case we conducted a series of monostatic experiments over a two-dimensional grid on the xy plane, here we conduct experiments at intervals along a one-dimensional line corresponding to the \hat{x} -axis. From the scattered field measurements we wish to reconstruct the object function $O(x, z)$. The receiver voltage for each experiment is related to the object function by equation (8). We emphasize that the antennas are three dimensional, such that the incident and scattered electric fields vary in three dimensions and have three Cartesian polarizations.

For each experiment we store data from N different excitation frequencies ω_n . We assume the interval spacing along the \hat{x} -axis is small enough to satisfy the Nyquist sampling criterion for the voltage measurements, thus we can treat the measured voltage $V(\omega_n; x)$ as a function of the continuous variable x (the discussion of the sampling requirements from the footnote in section 3 is valid here also). The data are defined as the spatial Fourier transform relative to the x coordinate of the measured voltage. By methods similar to the three-dimensional analysis, these data are found to be

$$\tilde{V}(\omega_n; K_x) \equiv \frac{1}{2\pi} \int_{-\infty}^{\infty} dx e^{-iK_x x} V(\omega_n; x)$$

$$\begin{aligned}
&= 2\pi P(\omega_n) \int_{-\infty}^{\infty} d^2 K_0 B(K_x \hat{\mathbf{x}} + \mathbf{K}_0, \mathbf{K}_0; \omega_n) \int_{-\infty}^0 dz' e^{-i[\gamma(K_x \hat{\mathbf{x}} + \mathbf{K}_0, \omega_n) + \gamma(\mathbf{K}_0, \omega_n)]z'} \\
&\quad \times \int_{-\infty}^{\infty} dx' e^{-iK_x x'} O(x', z') = A O(\omega_n; K_x).
\end{aligned} \tag{18}$$

Here we use the Hilbert space definitions;

- $O(x, z) \in W$, where W is the space of square integrable functions on $-\infty < x < \infty$, $-\infty < z < 0$;

- $\tilde{V}(\omega_n; K_x) \in Z$, where Z is the direct product space of square integrable functions on $-\infty < K_x < \infty$ with the finite-dimensional vector space Y_0 of functions of the discrete variable ω_n ;

- A is a linear operator which maps W into Z .

We seek the regularized pseudoinverse solution for the object function

$$\begin{aligned}
\hat{O}_\beta(x, z) &= A^\dagger [AA^\dagger + \beta I]^{-1} \tilde{V}(x, z) \\
&= A^\dagger \hat{\tilde{V}}(x, z).
\end{aligned} \tag{19}$$

Given the vector space definitions, the adjoint of A is specified by the action

$$\begin{aligned}
A^\dagger \hat{\tilde{V}}(x', z') &\equiv \hat{O}_\beta(x', z') = \sum_{n=1}^N 2\pi P^*(\omega_n) \int_{-\infty}^{\infty} dK'_x \int_{-\infty}^0 dz' d^2 K'_0 B^*(K'_x \hat{\mathbf{x}} + \mathbf{K}'_0, \mathbf{K}'_0; \omega_n) \\
&\quad \times e^{i[\gamma^*(K'_x \hat{\mathbf{x}} + \mathbf{K}'_0, \omega_n) + \gamma^*(\mathbf{K}'_0, \omega_n)]z'} e^{iK'_x x'} \hat{\tilde{V}}(\omega_n; K'_x).
\end{aligned} \tag{20}$$

The filtered data $\hat{\tilde{V}}$ and the raw, unfiltered, data \tilde{V} are related by the filtering relation $\hat{\tilde{V}} = [AA^\dagger + \beta I]^{-1} \tilde{V}$, which is expanded by combining equations (18) and (20) and evaluating the x' and z' integrals as in section 3. In this manner we obtain the following relation between the filtered and unfiltered data:

$$\tilde{V}(\omega_m; K_x) = \sum_{n=1}^N Q_{mn}(K_x) \hat{\tilde{V}}(\omega_n; K_x) + \beta \hat{\tilde{V}}(\omega_m; K_x) \tag{21}$$

where

$$\begin{aligned}
Q_{mn}(K_x) &= \int_{-\infty}^{\infty} d^2 K_0 \int_{-\infty}^0 dz' d^2 K'_0 \\
&\quad \times \frac{8i\pi^3 P(\omega_m) P^*(\omega_n) B(K_x \hat{\mathbf{x}} + \mathbf{K}_0, \mathbf{K}_0; \omega_m) B^*(K_x \hat{\mathbf{x}} + \mathbf{K}'_0, \mathbf{K}'_0; \omega_n)}{[\gamma(K_x \hat{\mathbf{x}} + \mathbf{K}_0, \omega_m) + \gamma(\mathbf{K}_0, \omega_m) - \gamma^*(K_x \hat{\mathbf{x}} + \mathbf{K}'_0, \omega_n) - \gamma^*(\mathbf{K}'_0, \omega_n)]}.
\end{aligned}$$

For each value of K_x , equation (21) can be written in the matrix notation

$$\begin{aligned}
\begin{Bmatrix} \tilde{V}(\omega_1; K_x) \\ \tilde{V}(\omega_2; K_x) \\ \vdots \\ \tilde{V}(\omega_N; K_x) \end{Bmatrix} &= \begin{Bmatrix} Q_{11}(K_x) + \beta & Q_{12}(K_x) & \cdots & Q_{1N}(K_x) \\ Q_{21}(K_x) & Q_{22}(K_x) + \beta & \cdots & Q_{2N}(K_x) \\ \vdots & \vdots & \ddots & \vdots \\ Q_{N1}(K_x) & Q_{N2}(K_x) & \cdots & Q_{NN}(K_x) + \beta \end{Bmatrix} \begin{Bmatrix} \hat{\tilde{V}}(\omega_1; K_x) \\ \hat{\tilde{V}}(\omega_2; K_x) \\ \vdots \\ \hat{\tilde{V}}(\omega_N; K_x) \end{Bmatrix}
\end{aligned} \tag{22}$$

which can be inverted by standard methods of linear algebra to yield the filtered data $\hat{\tilde{V}}$ in terms of the raw, unfiltered data \tilde{V} . The regularized pseudoinverse solution $\hat{O}_\beta(\mathbf{r})$ can then be found by operating on the filtered data by the operator A^\dagger as given in equation (20).

5. Computed results from synthetic data

We present here the results of computer simulations designed to test the reconstruction algorithm. For simplicity, we treat the two-dimensional problem where the transmitted electric field has only a $\hat{\mathbf{y}}$ polarization, and the antennas and scatterers do not vary in the $\hat{\mathbf{y}}$ -direction[†]. Thus, $\mathbf{K} = K\hat{\mathbf{x}}$, $\mathbf{K}_0 = K_0\hat{\mathbf{x}}$, $\mathbf{X} = x\hat{\mathbf{x}}$, and $S_{10}(\mathbf{K}, \omega) = S_{10}(K, \omega)\hat{\mathbf{y}}$. Using this two-dimensional model, we can simplify all results in sections 2 and 3 by converting vector quantities to scalars, reducing by one the-dimensions of all integrations over \mathbf{K} , \mathbf{K}_0 , and \mathbf{r} , and changing some constant factors.

Figure 2. Original object function for frequency domain simulations. $O(x, z) = 0.2$ within the cross region at all frequencies.

More explicitly, the forward model for the two-dimensional case can be shown to be

$$\begin{aligned} \tilde{V}(\omega_n; K_x) &= 2\pi P(\omega_n) \int_{-\infty}^{\infty} dK_0 B(K_x + K_0, K_0; \omega_n) \int_{-\infty}^0 dz' e^{-i[\gamma(K_x + K_0, \omega_n) + \gamma(K_0, \omega_n)]z'} \\ &\quad \times \int_{-\infty}^{\infty} dx' e^{-iK_x x'} O(x', z'). \end{aligned} \quad (23)$$

As we discussed in the previous sections, the object function is reconstructed by a filtered backpropagation algorithm. The filtering operation consists of inverting the matrix equation (22) for each value of K_x where, for the two-dimensional case, the matrix elements can be shown to be

$$\begin{aligned} Q_{mn}(K_x) &= \int_{-\infty}^{\infty} dK_0 \int_{-\infty}^{\infty} dK'_0 \\ &\quad \times \frac{8i\pi^3 P(\omega_m) P^*(\omega_n) B(K_x + K_0, K_0; \omega_m) B^*(K_x + K'_0, K'_0; \omega_n)}{[\gamma(K_x + K_0, \omega_m) + \gamma(K_0, \omega_m) - \gamma^*(K_x + K'_0, \omega_n) - \gamma^*(K'_0, \omega_n)]}. \end{aligned} \quad (24)$$

[†] In practice, this model will be valid for one-dimensional linear antennas, and scatterers that vary slowly in the $\hat{\mathbf{y}}$ -direction.

Figure 3. Magnitude of the filter versus spatial frequency K_x and $\beta = 10^{-3}, 10^{-6}, 10^{-9}$ for a single frequency simulation with $\lambda = 1.5$ m.

Figure 4. Pseudoinverse reconstruction based on a single excitation frequency corresponding to $\lambda = 1.5$ m. The penetration depth in the soil is 3 m.

Once the data is filtered, the object function is reconstructed by the following two-dimensional backpropagation, analogous to equations (15) and (20):

$$\hat{O}_\beta(x', z') = \sum_{n=1}^N 2\pi P^*(\omega_n) \int_{-\infty}^{\infty} dK'_x \int_{-\infty}^{\infty} dK'_0 B^*(K'_x + K'_0, K'_0; \omega_n) \times e^{i[\gamma^*(K'_x + K'_0, \omega_n) + \gamma^*(K'_0, \omega_n)]z'} e^{iK'_x x'} \hat{V}(\omega_n; K'_x). \quad (25)$$

Figure 2 shows a purely real two-dimensional object function $O(x, z)$ which is embedded in a soil background having a penetration depth of 3 m at all frequencies. The

Figure 5. Pseudoinverse reconstruction based on nine different excitation frequencies corresponding to $0.375 \text{ m} < \lambda < 3.375 \text{ m}$. The penetration depth in the soil is 3 m for all frequencies.

Figure 6. Cross sections at $x = 0$ for pseudoinverse reconstructions computed from 9, 15, and 24 frequencies corresponding to $0.375 \text{ m} < \lambda < 3.375 \text{ m}$.

value of the object function is $O(x, z) = 0.2$ within the cross region at all frequencies, therefore the dielectric contrast is $\frac{\epsilon(r, \omega)}{\epsilon_0(\omega)} = 0.8$. The antennas are characterized as being fairly directional, with (two-dimensional scalar) transmitting coefficients given by[†]

$$S_{10}(K, \omega) = \frac{e^{-a(\omega)K^2}}{\gamma(K, \omega)} \quad (26)$$

[†] For comparison, it can be shown from the planewave expansion of the Green's dyadic in equation (3) that a thin linear antenna, exciting an omni-directional field, will have the transmitting coefficient $S_{10}(K, \omega) = 1/\gamma(K, \omega)$. The exponential numerator in equation (26) makes the antenna directional.

Figure 7. Error = $\int d^2r |O(r) - \hat{O}_\beta(r)|^2$ versus number of frequencies used in the reconstruction. Frequencies correspond to the range $0.375 \text{ m} < \lambda < 3.375 \text{ m}$.

where $a(\omega)$ is a constant chosen such that $e^{-a(\omega)[\Re(k_0)]^2} \approx \frac{1}{10}$. For each simulation, the synthetic data are obtained by numerically applying equation (23) to the object of figure 2.

We initially compute a reconstruction based on a single radar frequency corresponding to the wavelength $\lambda = 1.5 \text{ m}$. To accomplish this task we first filter the data according to the equation

$$\hat{V}(\omega_1; K_x) = \frac{\tilde{V}(\omega_1; K_x)}{Q_{11}(K_x) + \beta} \quad (27)$$

(with $Q_{11}(K_x)$ given in equation (24)) which is the inverse of the 1×1 version of equations (22). The minimum norm reconstruction is then obtained by backpropagation as defined by equation (25) with $N = 1$. The magnitude of the filter $1/(Q_{11}(K_x) + \beta)$ is plotted versus the spatial frequency K_x in figure 3 for several different values of the regularization parameter β . It is evident that this filter tends to amplify the high spatial frequency components of the data relative to the low frequency components. Without regularization, high frequency components from additive noise will be amplified without bound, thus leading to unstable inversions. By using a non-zero β this amplification is limited, thus stabilizing the inversion. The real part of the minimum norm reconstruction is shown in figure 4, where $\beta = 1e - 9$ was chosen by trial and error. The criterion used in the selection of β was that both the original object of figure 2 and the reconstruction of figure 4 should yield nearly identical data since they are both solutions to equation (23). Note from figure 4 that the outline of the original object function is evident, however, there is considerable periodic ambiguity in the image.

Next we compute a reconstruction based on nine frequencies corresponding to $0.375 \text{ m} < \lambda < 3.375 \text{ m}$ using the $N = 9$ versions of equations (25) and (22). The regularization parameter is set to $\beta = 1e - 9$, as before. It can be noted from the real part of the reconstruction, shown in figure 5, that by using multiple frequencies the periodic ambiguity observed in figure 4 is diminished, and we obtain a fairly good representation of the original scattering object. In figure 6 we plot the cross section of figure 5 along the line $x = 0$, as well as cross sections from reconstructions using 15 and 21 frequencies

Figure 8. (a) Real part of the data $\tilde{V}(\omega_n; K_x)$ corresponding to $\lambda = 1.125$ m as computed from equation (23) on both the original object of figure 2 and the reconstruction of figure 5 computed with nine frequencies. (b) The same plot as (a), for data from the frequency corresponding to $\lambda = 2.25$ m.

corresponding to the range $0.375 \text{ m} < \lambda < 3.375 \text{ m}$. It is evident that increasing the number of frequencies leads to a significant quantitative improvement. This concept is also supported by figure 7, which shows decreasing error $= \int d^2r |O(\mathbf{r}) - \hat{O}_\beta(\mathbf{r})|^2$ with increasing numbers of frequencies corresponding to the range $0.375 \text{ m} < \lambda < 3.375 \text{ m}$.

As a test that the minimum norm reconstruction is consistent with the data, and therefore satisfies equation (23), we implement the forward scattering relation of equation (23) on both the original object function of figure 2 and the reconstructed object function of figure 5 computed from nine frequencies. The real part of the data $\tilde{V}(\omega_n; K_x)$ is plotted in figures 8(a) and (b) for both the original and reconstructed object functions, at two of the nine frequencies corresponding to $\lambda = 1.125$ m and $\lambda = 2.25$ m (to avoid redundancy, data

from all the frequencies are not plotted). Based on the excellent match obtained between data from the original and reconstructed objects at all frequencies (the plots are almost completely overlapping in the scale shown), we conclude that the reconstruction in figure 5 is consistent with the data, as expected.

6. Discussion

In this paper we derived a direct, non-iterative, inversion formula for multi-monostatic GPR data which was tested successfully on synthetic radar data. To solve this problem we cast the forward scattering relation in a mathematical operator framework, allowing computationally efficient, analytical expressions to be found for both the adjoint and pseudoinverse operators. This type of approach has been used with similar success in other tomographic imaging applications [4], and we anticipate future uses as well.

We mentioned above that significant noise will be inevitable in realistic GPR imaging applications. In preliminary studies, we have verified that our algorithm is robust in the presence of both additive noise at receivers, and noise due to scattering from ground clutter. In these noisy simulations, the results were quite sensitive to the value of the regularization parameter β , as expected. In a future publication we plan to present the results of these noisy simulations, as well as results using experimental GPR data.

Abstract

A rigorous three-dimensional (3-D) electromagnetic model is developed to analyze the scattering from anti-personnel (AP) nonmetallic mine-like target when it is buried near a clutter object under two-dimensional (2-D) random rough surfaces. The Steepest Descent Fast Multipole Method (SDFMM) is implemented to solve for the unknown electric and magnetic surface currents on the ground surface, on the target and on the clutter object. A comprehensive numerical investigation of two clutter sources; the ground roughness and the nearby benign object, is presented based on using more than 800 random rough surface realizations which could not be achieved without using fast algorithms such as the SDFMM. The statistics of the scattered near-electric fields are computed using the Monte Carlo simulations for both polarizations. For the parameters used here, the results show that the average and the standard deviation of the target signature represent 5-7% and 3-3.5% of the total scattered signal, respectively, while they represent 16-20% and 7-12% of the signal for the clutter object, respectively. This study indicates the high possibility of a false alarm during the detection process when the target is located nearby a realistic object such as a piece of a tree root.

Key words: Multiple buried objects, subsurface sensing, rough surface scattering, SDFMM, Monte Carlo simulations, clutter statistics.

I. INTRODUCTION

Electromagnetic sensing of targets buried in soil with two-dimensional random rough surface necessitates the investigation of clutter sources that may cause false alarms in the detection process. In real minefields, there are a variety of clutters that can easily obscure the signal of the target such as: the roughness of the ground, nearby benign objects (e.g., tree roots, rocks, etc.), spots of concentrated inhomogeneity in the soil, etc. Detecting small anti-personnel nonmetallic mines is very difficult as it is, but proximity of clutter objects obscures target detection considerably.

The statistics of the scattered waves from the random rough ground were previously investigated in the literature either analytically, [1]-[4], or computationally using the Monte Carlo simulations, [5]-[10]. The challenging part of conducting the Monte Carlo simulations is to run a 3-D computer code hundreds of times when the rough ground has large electrical size and contains multiple penetrable objects buried under the interface. In [1]-[4], integral expressions were developed to calculate the incoherent radar cross section (RCS) of the rough ground (no buried objects). These integrations were basically obtained by considering the ground heights and slopes as random variables producing analytic closed forms in some cases (e.g. at high frequency). On the other hand, conducting the Monte Carlo numerical simulations were used to obtain the incoherent RCS of the rough surface without buried objects in [5]-[8], to obtain the RCS and/or the angular correlation function of a PEC sphere buried under the rough interface [9], and to obtain the statistical average of the scattered near-fields when a penetrable object was buried under the interface in [10].

In our previous work [10] and [11], we implemented the Steepest Descent Fast Multipole Method (SDFMM) [6], [12] to investigate the effect of the ground roughness on the signature of a single target buried under the ground. The $O(N)$ computational complexity of the SDFMM accelerated the calculations of the unknown surface currents on the shallow mine-like object buried beneath a moderately random rough ground especially in conducting the Monte Carlo simulations. Similarly, to study the influence of the ground roughness (with no buried targets) on the scattered signals for different minefields, the SDFMM was used to run the Monte Carlo simulations from Puerto-Rican and Bosnian soils [13].

To the best of our knowledge, no work is published for investigating the statistics of multiple objects buried under the 2-D random rough ground, which is the objective of this paper. In [14], rigorous generalized electromagnetic formulations were developed for scattering from multiple objects buried under the rough ground, where the SDFMM was implemented to speed up the computations. A parametric investigation is conducted in [14] to study the effect on the scattered signature due to the objects proximity, ground roughness, object's material, shape, location, etc. A variety of object shapes were studied in [14], e.g., one object is spheroid and the second object is ellipsoid, spheroid, disk, or horizontal cylinder.

In this paper, we are using the Monte Carlo simulations to conduct a statistical study of mine-like dielectric target's signature versus the clutter signature due to both the ground roughness and a benign object as shown in Fig. 1. Even though, we are emphasizing here only on these two types of clutter, however, there are additional types of clutter that may significantly affect the target signature such as the soil inhomogeneities and the multilayered nature of the ground, which are not accounted for in this work. According to the United States Department of Defense data (US DoD), European agencies and others, it is a fact that there are hundreds of different

types, shapes and manufacturers of the AP-plastic mines. This is one of the reasons that these mines are difficult to detect. In this work, we are not modeling a specific type of these mines but instead modeling a plastic-mine-like target that has a shape very close to an oblate spheroid. Several examples of spheroid-shape types can be obtained from the US DoD CD-ROM Humanitarian Demining Equipment database.

In Section II the formulations of the electromagnetic model developed in [14] are summarized, numerical results are shown in Section III and conclusions are drawn in Section IV.

II. PROBLEM FORMULATIONS

The rigorous electromagnetic model developed in [14] is employed in this work to conduct the Monte Carlo simulations for two objects buried under the 2-D random rough ground as shown in Fig. 1. The inhomogeneous scatterer is composed of four different regions; air R_1 , ground R_2 , target R_3 and clutter object R_4 where the relative permittivity and permeability are (ϵ_1, μ_1) , (ϵ_2, μ_2) , (ϵ_3, μ_3) and (ϵ_4, μ_4) , respectively, as shown in Fig. 2a. The unknown equivalent electric and magnetic surface currents are (\bar{J}_1, \bar{M}_1) on S_1 , (\bar{J}_3, \bar{M}_3) on S_2 , and (\bar{J}_5, \bar{M}_5) on S_3 . The final set of surface integral equations on S_1 , S_2 , and S_3 in Fig. 2a are given by [14]:

$$\bar{E}^{inc}(\bar{r})\big|_{\text{tang.}} = \left[(L_1 + L_2)\bar{J}_1 - (K_1 + K_2)\bar{M}_1 - L_3\bar{J}_3 + K_3\bar{M}_3 - L_4\bar{J}_5 + K_4\bar{M}_5 \right]_{\text{tang.}}, \bar{r} \in S_1 \quad (1a)$$

$$\bar{H}^{inc}(\bar{r})\big|_{\text{tang.}} = \left[(K_1 + K_2)\bar{J}_1 + \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{M}_1 - K_3\bar{J}_3 - \frac{L_3}{\eta_2^2} \bar{M}_3 - K_4\bar{J}_5 - \frac{L_4}{\eta_2^2} \bar{M}_5 \right]_{\text{tang.}}, \bar{r} \in S_1 \quad (1b)$$

$$0 = \left[-L_2\bar{J}_1 + K_2\bar{M}_1 + (L_3 + L_5)\bar{J}_3 - (K_3 + K_5)\bar{M}_3 + L_4\bar{J}_5 - K_4\bar{M}_5 \right]_{\text{tang.}}, \bar{r} \in S_2 \quad (1c)$$

$$0 = \left[-K_2 \bar{J}_1 - \frac{L_2}{\eta_2^2} \bar{M}_1 + (K_3 + K_5) \bar{J}_3 + \left(\frac{L_3}{\eta_2^2} + \frac{L_5}{\eta_3^2} \right) \bar{M}_3 + K_4 \bar{J}_5 + \frac{L_4}{\eta_2^2} \bar{M}_5 \right]_{\text{tang.}}, \bar{r} \in S_2 \quad (1d)$$

$$0 = \left[-L_2 \bar{J}_1 + K_2 \bar{M}_1 + L_3 \bar{J}_3 - K_3 \bar{M}_3 + (L_4 + L_6) \bar{J}_5 - (K_4 + K_6) \bar{M}_5 \right]_{\text{tang.}}, \bar{r} \in S_3 \quad (1e)$$

$$0 = \left[-K_2 \bar{J}_1 + \frac{L_2}{\eta_2^2} \bar{M}_1 + K_3 \bar{J}_3 + \frac{L_3}{\eta_2^2} \bar{M}_3 + (K_4 + K_6) \bar{J}_5 + \left(\frac{L_4}{\eta_2^2} + \frac{L_6}{\eta_4^2} \right) \bar{M}_5 \right]_{\text{tang.}}, \bar{r} \in S_3 \quad (1f)$$

in which the intrinsic impedance is $\eta_i = \sqrt{\mu_i / \epsilon_i}$ in region R_i with $i = 1, 2, \dots, 4$ and L_j and K_j ,

$j = 1, 2, \dots, 6$ are the integro-differential operators given in Appendix A. The tangential

component of the incident electric and magnetic fields on the rough surface S_1 are given by

$\bar{E}^{inc}(\bar{r})|_{\text{tang}}$ and $\bar{H}^{inc}(\bar{r})|_{\text{tang}}$. The surfaces S_1, S_2 and S_3 are discretized into triangular patches

where the unknown equivalent electric and magnetic currents in (1) are approximated by using

the Rao, Wilton and Glisson (RWG) vector basis functions $\bar{j}(\bar{r})$ [15], [16] as:

$$\bar{J}_i(\bar{r}) = \sum_{n=1}^{N_k} I_{in} \bar{j}_{kn}(\bar{r}), \quad \bar{M}_i(\bar{r}) = \eta_1 \sum_{n=1}^{N_k} I_{(i+1)n} \bar{j}_{kn}(\bar{r}), \quad \bar{r} \in S_k, \quad \text{for } i = 1, 3 \text{ and } 5 \quad (2)$$

and $k = (i + 1) / 2$. Upon substituting (2) in (1), and testing using the same vector basis functions,

the linear system of equations is obtained [14]:

$$\bar{\bar{Z}} \bar{\bar{I}} = \bar{\bar{V}} \Rightarrow \begin{pmatrix} \bar{Z}_{11} & \bar{Z}_{12} & \bar{Z}_{13} \\ \bar{Z}_{21} & \bar{Z}_{22} & \bar{Z}_{23} \\ \bar{Z}_{31} & \bar{Z}_{32} & \bar{Z}_{33} \end{pmatrix} \begin{pmatrix} I^1 \\ I^2 \\ I^3 \end{pmatrix} = \begin{pmatrix} \bar{V}_1 \\ 0 \\ 0 \end{pmatrix} \quad (3)$$

The total matrix $\bar{\bar{Z}}$ has order of $2(N_1 + N_2 + N_3) \times 2(N_1 + N_2 + N_3)$, where the number of

unknowns on the ground, on the target and on the clutter object are $2N_1$, $2N_2$ and $2N_3$,

respectively. It is necessary to emphasize that this rigorous electromagnetic model considers all

scattering and interaction scenarios; the self-interactions of the ground (\bar{Z}_{11}), target (\bar{Z}_{22}) and

clutter object (\bar{Z}_{33}), the target with the ground and with clutter object (\bar{Z}_{12} , \bar{Z}_{23}) and the clutter object with the ground \bar{Z}_{13} , etc. The expressions of these submatrices are given in Appendix B. The tested tangential incident electric field \bar{E}^{inc} and the tested normalized magnetic field $\eta_1 \bar{H}^{inc}$ on the exterior surface of the ground are expressed as part of vector \bar{V} in (3) while the vector \bar{I} represents the unknown current coefficients on all involved surfaces.

The emphasis of this study is to investigate the statistics of the target signature versus the clutter signature. The proposed strategy is to use the same sample of random rough surface realizations four times as follows: (i) once to compute the scattering from the rough ground alone (no buried objects); (ii) once to compute the scattering from the rough ground when both the target and clutter object are buried beneath the interface; (iii) once to compute the scattering from the rough ground when only the target is buried beneath the interface; and (iv) once to compute the scattering from the rough ground when only the clutter object is buried beneath the interface. The scattered electric near-fields are obtained in this procedure at single incident angle, single frequency, for specific polarization (e.g., vertical or horizontal), etc. This shows that conducting the Monte Carlo simulations is computationally expensive requiring fast methods such as the SDFMM. In this case, the computational complexity of the problem will be of $O(K = 2N_1 + 2N_2 + 2N_3)$ as described earlier. Once the electric and magnetic surface currents are obtained, then the scattered fields above the ground and in the near-zone can be calculated using the surface integrations given by [17]:

$$\bar{E}^A(x, y, z) = -\frac{1}{4\pi(i\omega\epsilon_0)} \nabla \times \iint_{S'} (\hat{R} \times \bar{J}_1(x', y', z')) \frac{1 + ik_0 R}{R^2} \exp(-ik_0 R) dS' \quad (4a)$$

$$\bar{E}^F(x, y, z) = -\frac{1}{4\pi} \nabla \times \iint_{S'} \bar{M}_1(x', y', z') \frac{\exp(-ik_0 R)}{R} dS' \quad (4b)$$

where the total electric field is $\bar{E}^A + \bar{E}^F$, the superscripts A and F refer to the vector potentials \bar{A} and \bar{F} , the point source (x', y', z') is located on the ground while the observation point (x, y, z) is located above the ground, \hat{R} and R are the unit vector and the distance between the observation and the source points, k_0 , ϵ_0 and μ_0 are the wave number, the permittivity, and permeability of the free space, respectively, and dS' is the differential surface element on the rough ground. Every source point (x', y', z') in (4) is the centroid of every triangular patch on the ground at which the surface currents are approximately evaluated [15].

III. NUMERICAL RESULTS

The principle of computing the target signature at multiple views was employed in [9] and [11] by rotating the incident beam around the target, i.e., changing the azimuth angle of the incident waves. As presented in [14], when the target is buried nearby a second object, a significant electromagnetic interference between the two objects is observed in the scattered fields at single azimuth angle. In this work, the Monte Carlo simulations will be conducted using the incident beam view (azimuth angle) that largely indicates the presence of a clutter object buried nearby the target.

Trying to simulate the ground penetrating radar (GPR) of center frequency 1GHz experiments reported in [18]-[19], the scattered electric fields at $\lambda_0/2$ above the rough ground mean are computed, where λ_0 is the free space wavelength. In addition, to simulate the GPR experimental track, the ground is modeled as a plane of dimensions $8\lambda_0 \times 8\lambda_0$. For the same reason, all simulations are conducted here at 1GHz; however, the current technique was successfully applied for the frequency band 800MHz-1.4GHz (not presented here). The rough ground surface is characterized with Gaussian statistics for the heights, assuming zero mean and

root mean square (rms) σ , and for the autocorrelation function with correlation length l_c . It was observed that the incident beam pattern of the GPR parabolic antenna reported in [18], [19] resembles a Gaussian beam. Thus for simplicity, the incident wave in the current simulations is assumed to be a Gaussian beam tapered toward the edges of the ground with half-beam width of $1.6\lambda_0$ centered at $x = y = 4\lambda_0$ [9], [20]. The incident angle of the beam, measured from the z -direction, is $\theta^i = 30^\circ$ while the azimuth angle ϕ^i will be described. As mentioned in Section I, the AP-mine-like target is modeled here as an oblate spheroid with dimensions $a = 0.15\lambda_0, b = 0.3\lambda_0$ (Fig. 2b) where its center is located at $x = 4.5\lambda_0, y = 3.5\lambda_0$ and $z = -0.4\lambda_0$ (lower right quadrant of the ground as shown in Fig. 3a). While, the clutter object is modeled as a horizontal cylinder (Fig. 2b) such as a piece of a tree root with radius $a = 0.15\lambda_0$ and height $h = 0.9\lambda_0$ with its axis tilted at angle 30° with the x -direction and located at $x = 4.01\lambda_0, y = 4.375\lambda_0$ and $z = -0.4\lambda_0$ measured from the axis mid-point (upper left quadrant of the ground as shown in Fig. 3a). This implies a $1.0\lambda_0$ distance separating the centers of the two objects. In [14], a parametric study was conducted for different ground roughness in which the clutter for $\sigma = 0.1\lambda_0$ was shown, as expected, to be stronger than that of $\sigma = 0.04\lambda_0$ [11]. Therefore, in this work, the rms height is assumed to be $\sigma = 0.1\lambda_0$ with correlation length $l_c = 0.5\lambda_0$. The relative dielectric constants of the soil, the AP-mine-like target, and the tree root object are assumed to be $\epsilon_r = 2.5 - j0.18$ (Bosnian soil with 3.8% moisture at 1GHz) [21], $\epsilon_r = 2.9 - j0.072$ (TNT) [22], and $\epsilon_r = 4.0$ (dry wood) [23], respectively. The near-electric fields are computed using (4) at point receivers located at $z = 0.5\lambda_0$ above the ground with resolution equal to $x = y = 0.04\lambda_0$. Several numerical experiments, depending on the dielectric

constants and on the ground roughness parameters, were conducted to choose the discretization distances on all surfaces. The adopted criterion is to obtain a solution that is independent of these distances. In this work, $0.08\lambda_0$ discretization distance on the rough ground is used leading to 60,000 ($2N_1$) current unknowns on its surface. For the two objects, approximately the same discretization distances are used leading to 600 ($2N_2$) on the AP-mine-like target and 600 ($2N_3$) on the tree root. The triangular mesh for the rough ground, the target (oblate spheroid) and the tree root (horizontal cylinder) is shown in Fig. 2b. To speedup the solution's convergence, a preconditioner consists of the diagonal self-elements of $\bar{\bar{Z}}$ in (3) is used. A relative residual error of 10^{-3} is used in the Transpose-Free-Quasi-Minimal-Residual (TFQMR) iterative solver [24] and $0.32\lambda_0 \times 0.32\lambda_0$ is assumed for the smallest Fast Multipole Method (FMM) block size. Moreover, the SDFMM is validated with the method of moments (MoM) as discussed in [14]. The complex subtraction process is used in this work to remove the clutter due to both the random rough ground and the benign object (tree root) leading to obtain a statistical study of the target signature compared with these sources of clutter [25]. The numerical results are divided into sub-sections as shown below.

A. Multiple views

The azimuth angle of the incident beam is varied as $\phi^i = 0^\circ, 30^\circ, 60^\circ, \dots, 360^\circ$ (i.e., the azimuth angle of the plane of incidence). The fields scattered from just the rough surface realization (no buried objects) is computed and subtracted from those scattered from the same rough surface realization when both the AP-mine-like target and the tree root are buried, and shown in Fig. 3a. The results for the incident horizontal polarization are considered in this case where the electric field is perpendicular to the plane of incidence. Only four results are presented

for $\phi^i = 0^\circ, 60^\circ, 120^\circ$, and 240° in Figs. 3b-e. The results show almost no indication to the presence of two separate objects except at $\phi^i = 120^\circ$ where the mine-like target signature can be distinguished from that of the tree root. At this azimuth angle, the plane of incidence is perpendicular to the tree root axis. The results of Figs. 3b-e are for single rough surface realization. The interesting view at $\phi^i = 120^\circ$ will be used in all Monte Carlo simulations considered in this work for both polarizations.

B. Monte Carlo simulations

A sample of 100 independent random rough surface realizations was used in this work. However, the fields scattered from the geometry shown in Fig. 1 and described above was computed 800 times; 400 times for the horizontal polarization and 400 times for the vertical polarization as described in cases (i-iv) in Section II. The statistical average of the electric fields, i.e., $\langle \bar{E} \rangle$, and the standard deviation (STD), i.e. $\sqrt{\langle |\bar{E}|^2 \rangle - \langle \bar{E} \rangle^2}$, are presented [10]. It is necessary to mention that in the horizontal polarization case, the incident electric field is parallel to the tree root axis, while in the vertical polarization case it is perpendicular to its axis.

(i) Horizontal polarization

The results of the cases (i-iv) are plotted versus the x - and y -directions and shown in Figs. 4a-d, respectively. The slight differences between the results in these figures clearly indicate that the rough ground is dominating the scattering scenario. Then, the results of case (i) are subtracted from those of case (ii) and the output is plotted in Fig. 5a where the average signature of both the clutter object and the target are shown. In addition, a clutter due to the interaction between the tree root and the rough ground is clearly observed in Fig. 5a. Similarly, the results of case (iii)

are subtracted from those of case (ii) and the output is plotted in Fig. 5b where the average signature of just the tree root is shown in addition to clutter due to interaction with the nearby target. Finally, the results of case (iv) are subtracted from those of case (ii) and the output is plotted in Fig. 5c where the average signature of just the target is shown in addition to interaction with the clutter object. It is important to mention that the subtraction process does not completely remove the effect of the rough ground or the nearby object; however, the remainder of these interactions depends on the ground roughness and the object proximity [14]. The results of Figs. 5-c show a remarkable difference between the magnitude of the clutter object average signature (max. of 0.037 V/m) and that of the target average signature (max. of 0.009 V/m). Moreover in Fig. 5a, the presence of the target causes the magnitude of the clutter object signature to slightly increase due to the interactions with the target as discussed in [14]. All these results, which are obtained using the same 100 rough surface realizations, show that a false alarm is highly possible due to the presence of a nearby clutter object (a piece of a tree root in this case).

(ii) Vertical polarization

Upon changing the incident fields to the vertical polarization, then cases (i-iv) are re-computed and plotted in Figs. 6a-d, respectively. In these figures, the maximum magnitude of the average scattered electric fields has dropped by almost 50%, even for the case of rough ground alone, compared with the horizontal polarization results in Fig. 5. This is because the incident electric fields at oblique angle are decomposed into two components; a component in the z-direction and a component parallel to the x-y plane (perpendicular to the tree root axis). While for the horizontally polarized incident fields, all the electric fields are parallel to the x-y plane (parallel to the tree root axis). Similarly, results of Figs. 6a-d show that the rough ground is dominating the scattering mechanism such that a slight difference between the results in Fig. 6a-d

can be observed. The subtraction process is repeated in this case and the average signature of both the clutter object and the target is shown in Fig. 7a, of just the clutter object is shown in Fig. 7b and of just the target is shown in Fig. 7c. The magnitude of the average target signature (max. of 0.0075 V/m) is smaller than that of the clutter object (max of 0.018 V/m), which agrees with the observation in the horizontal polarization case.

The standard deviation of the scattered fields is plotted in Fig. 8a for just the tree root, in Fig. 8b for just the target for the horizontal polarization. In these figures, the maximum standard deviation occurs almost at the location of the tree root as shown in Fig. 8a and of the target as shown in Fig. 8b. For the vertical polarization case, the standard deviation is plotted in Figs. 8c and 8d for the tree root and for the target, respectively. However, the results show that the maximum standard deviation of the clutter object is shifted from the location of the object. This could be attributed to the electromagnetic interference between the target and the clutter object [14]. In addition, the maximum magnitude of the standard deviation of the target signature is almost the same for both polarizations, however, for the tree root it is reduced by almost 50% in the vertical polarization. Therefore, the relative statistics are computed with respect to signature of the ground without buried objects (i.e. object signature/ground signature) as summarized in Table 1.

The total CPU time required for computing the scattered electric fields from one surface realization is less than 3 Hrs (after almost 200 TFQMR iterations) and the required computer memory is 850 MB. These computations were conducted using the Compaq Alpha Server (GS140 EV6) with 667MHz clock speed [14].

Table 1. Maximum relative statistics for the scattered electric fields

	Maximum relative average		Maximum relative STD	
	Clutter object	Target	Clutter object	Target
H-Pol.	20%	5%	12%	3%
V-Pol.	16%	6.5%	7.5%	3.5%

It is necessary to mention that the current work is not a signal processing technique that can be applied to the real measured data [26]. However, the current technique presents a powerful computational tool to analyze, study and statistically estimate some of the causes of false alarms encountered in the detection process.

IV. CONCLUSIONS

The statistics of the target, the rough ground and the clutter object signatures depend on several factors such as the orientation, dielectric constants, proximity between objects, burial depth, etc. For the parameters used in this work, the statistical study showed that the target signature appears much weaker than the clutter object signature even for a small realistic nearby buried object such as a piece of a tree root. Moreover, consistent with our previous work [10]-[11], the rough ground clutter dominates the scattering scenario necessitating its removal in the detection process. The conducted statistical study is based on running the 3-D scattering computer code more than 800 times which could not be achieved without using a fast algorithm such as the SDFMM.

ACKNOWLEDGMENTS

This research was sponsored from the Northeastern University's Demining MURI grant # DAA 0-55-97-0013. The SDFMM was originally developed at the UIUC by V. Jandhyala, E. Michielssen and W. Chew. This work was conducted using the ASCC at NU.

Appendix A

With representing the surface electric and magnetic currents \bar{J} and \bar{M} on S_1 , S_2 and S_3 by the vector \bar{X} , the integro-differential operators L_j and $K_j, j=1, 2, \dots, 6$, are [14], [16]:

$$L_{1,2}\bar{X} = \int_{S_1} \left\{ i\omega\mu_{1,2}\Phi_{1,2}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{1,2}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{1,2} \right\} ds', \quad K_{1,2}\bar{X} = \int_{S_1} \bar{X}(\bar{r}') \times \nabla\Phi_{1,2} ds' \quad (A1)$$

$$L_{3,5}\bar{X} = \int_{S_2} \left\{ i\omega\mu_{2,3}\Phi_{2,3}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{2,3}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{2,3} \right\} ds', \quad K_{3,5}\bar{X} = \int_{S_2} \bar{X}(\bar{r}') \times \nabla\Phi_{2,3} ds' \quad (A2)$$

$$L_{4,6}\bar{X} = \int_{S_3} \left\{ i\omega\mu_{2,4}\Phi_{2,4}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{2,4}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{2,4} \right\} ds', \quad K_{4,6}\bar{X} = \int_{S_3} \bar{X}(\bar{r}') \times \nabla\Phi_{2,4} ds' \quad (A3)$$

Appendix B

The elements of the submatrix \bar{Z}_{11} in (3) are given by [14], [16]

$$\bar{Z}_{11} = \begin{pmatrix} \langle \bar{j}_1, (L_1 + L_2)\bar{j}_1 \rangle_{S_1} & \langle \bar{j}_1, -\eta_1(K_1 + K_2)\bar{j}_1 \rangle_{S_1} \\ \langle \bar{j}_1, \eta_1(K_1 + K_2)\bar{j}_1 \rangle_{S_1} & \left\langle \bar{j}_1, \eta_1^2 \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{j}_1 \right\rangle_{S_1} \end{pmatrix} \quad (B1)$$

in which $\langle \bar{A}, \bar{B} \rangle_S$ denotes the complex inner product between vector functions \bar{A} and \bar{B} on a

surface S . The submatrices \bar{Z}_{12} , \bar{Z}_{13} , and \bar{Z}_{23} are given by

$$\bar{Z}_{12} = \begin{pmatrix} \langle \bar{j}_1, -L_3\bar{j}_2 \rangle_{S_1} & \langle \bar{j}_1, \eta_1 K_3 \bar{j}_2 \rangle_{S_1} \\ \langle \bar{j}_1, -\eta_1 K_3 \bar{j}_2 \rangle_{S_1} & \left\langle \bar{j}_1, -\eta_1^2 \left(\frac{L_3}{\eta_2^2} \right) \bar{j}_2 \right\rangle_{S_1} \end{pmatrix}, \quad \bar{Z}_{13} = \begin{pmatrix} \langle \bar{j}_1, -L_4\bar{j}_3 \rangle_{S_1} & \langle \bar{j}_1, \eta_1 K_4 \bar{j}_3 \rangle_{S_1} \\ \langle \bar{j}_1, -\eta_1 K_4 \bar{j}_3 \rangle_{S_1} & \left\langle \bar{j}_1, -\eta_1^2 \left(\frac{L_4}{\eta_2^2} \right) \bar{j}_3 \right\rangle_{S_1} \end{pmatrix} \quad (B2)$$

$$\bar{Z}_{23} = \begin{pmatrix} \langle \bar{j}_2, L_4\bar{j}_3 \rangle_{S_2} & \langle \bar{j}_2, -\eta_1 K_4 \bar{j}_3 \rangle_{S_2} \\ \langle \bar{j}_2, \eta_1 K_4 \bar{j}_3 \rangle_{S_2} & \left\langle \bar{j}_2, \eta_1^2 \frac{L_4}{\eta_2^2} \bar{j}_3 \right\rangle_{S_2} \end{pmatrix} \quad (B3)$$

Similar expressions can be obtained for all other submatrices in (3).

Using the PML ABC for Air/Soil Wave Interaction Modeling in the Time and Frequency Domains

Carey M. Rappaport, Scott Winton
Northeastern University, 235 Forsyth Building, Boston, MA 02115
email: RAPPAPORT@NEU.EDU

Abstract—The Perfectly Matched Layer (PML) absorbing boundary condition (ABC) is applied to two-dimensional FDTD and FDFD simulations of wave interactions with a two-layer air and soil geometry. Since the soil medium is lossy and dispersive, modeling of wave propagation and scattering is significantly more difficult than for free space and pure dielectrics. In addition, specifying an ABC which efficiently prevents reflections from both the free space termination and the adjacent soil is challenging. The theoretical basis for terminating dispersive media for both the time and frequency domains is presented, and simulation results for plane wave and point source excitations are demonstrated. For the former case, scattering is computed from a buried mine-like target. Although the absorbing characteristics of the PML for the air/soil interface are not as good as for free space, it is shown that maximum local reflections of as low as -15 dB for FDTD and -50 dB for FDFD are possible.

Keywords—FDTD, FDFD, PML, ABC, GPR, Ground Penetrating Radar, Computational Modeling.

I. INTRODUCTION

To understand the effects of the environment surrounding scattering targets, it is important to simulate numerically the propagation, interaction, and scattering of electromagnetic or acoustic waves by buried objects in the surrounding modelled clutter.

This work has been supported by The Army Research Office, Multidisciplinary University Research Initiative Grant No. DAAG55-97-0013

The short pulse and stepped-frequency ground penetrating radar problems are open scattering geometries, with lossy, frequency dependent (temporally dispersive) media, requiring high performance absorbing boundary conditions [1-2]. Finite difference methods are very effective in modeling small-scale variations of environment, including: particular target shapes, rough surface boundaries, and volume inhomogeneities. The time domain version (FDTD) [3-5] is an efficient discretization of Maxwell's equations, which is robust and flexible and can conveniently deal with multiple inhomogeneities. The computation is particularly well-suited to supercomputer platforms, and it yields results that are suitable for animation and other high quality computer graphics capabilities. Memory requirements involve storage of the field values in each of millions of cells. For frequency-dependent media, such as soil, the convolutional relationship of permittivity and electric field requires storage of field values for several time cycles. The finite difference frequency domain method is similar to FDTD, but solves the self-consistent field distribution in open and closed spatial volumes for single frequency[6-8].

Berenger's Perfectly Matched Layer (PML) absorbing boundary condition (ABC) [9] has significantly increased the performance and popularity of the finite difference methods of electromagnetic field computation. While many analyses have considered applying the PML ABC to terminate layered media [10] and lossy dispersive media [11-13] computational grids, its application to layered dispersive media is less well-understood. In particular, the application to the common and important problem of a realistic soil half space, with sources in air above has seen little exposure in the literature. In the subsequent sections, this paper discusses layered, dispersive, lossy PML theory for the frequency and time domains, and then presents numerical examples to confirm this theory.

II. FREQUENCY DOMAIN PML THEORY FOR GENERAL LAYERED MEDIA

In the frequency domain, the equations for a two-dimensional transverse electric (relative to the longitudinal direction z into the paper) PML region terminating a lattice at $x = x_{\max}$ have the form [14]:

$$\frac{\partial H_z}{\partial y} = j\omega\epsilon_s E_x \quad (1a)$$

$$-\frac{\partial H_z}{\partial x} \left(\frac{1}{1 - j\sigma_e(x)/\omega\epsilon_0} \right) = j\omega\epsilon_s E_y \quad (1b)$$

$$\frac{\partial E_y}{\partial x} \left(\frac{1}{1 - j\sigma_m(x)/\omega\epsilon_0} \right) - \frac{\partial E_x}{\partial y} = -j\omega\mu_0 H_z \quad (1c)$$

where the medium (soil) permeability is assumed to be that of free space, and its complex permittivity is:

$$\epsilon_s = \epsilon_0(\epsilon'_s - j\sigma_s/\omega\epsilon_0) \quad (2)$$

In general, ϵ'_s and σ_s are functions of frequency. The electric and magnetic PML conductivities $\sigma_e(x)$ and $\sigma_m(x)$ govern the rate of wave attenuation in the absorbing layers. For the continuous case in which the PML medium is impedance matched to the scattering space it terminates, $\sigma_e(x) = \sigma_m(x)$ and each increases with distance $x - x_{\max}$ from the scattering space. However, for finite difference computation, in which the E-fields and H-fields are calculated on interlocking grids, these conductivities are alternately sampled values of the continuously increasing function. For a typical eight grid cell PML layer, the conductivity profile is specified as a power function of position with the form [15]:

$$\sigma_{i-\frac{1}{2}} = \left(\frac{2i-1}{16} \right)^p \frac{S_{\max}}{\Delta}, \quad i = 1, \dots, 8 \quad (3a)$$

$$\sigma_i = \left(\frac{2i}{16} \right)^p \frac{S_{\max}}{\Delta}, \quad i = 1, \dots, 8 \quad (3b)$$

for a PML beginning at $i = 0$. Note that magnetic conductivity $\sigma_m((i - \frac{1}{2})\Delta)$ is associated with $\sigma_{i-\frac{1}{2}}$ values if the PML begins on an electric field point. For a PML terminating a free-space scattering region, quasi-exhaustive search studies in both the time and frequency domains have shown that the best values of p and S_{\max} are 3.1 and 0.021, respectively [6, 15]. With this choice, the maximum reflected signal for typical time pulse signals for incident angles from normal through 60° is -100 dB.

Viewing the PML as an anisotropic mapping of the normal coordinate (x , in the case above), it is clear

that regardless of the material characteristics of the scattering medium ϵ_s , the profile of PML conductivities is unchanged from those of free-space, Eqns. (3). While the actual conductivities of the individual grid cells within the PML will incorporate both the background conductivity of the soil and the PML conductivities, as long as the frequency domain TE curl equations are written and evaluated as in Eqns. (1), there is no need consider these actual values.

If instead of separate first-order curl equations, the FDFD computation makes use of Helmholtz equation – by substituting Eqns. (1a) and (1b) into (2) – the same approach applies:

$$\frac{1}{k^{\text{rel}}(x)} \frac{\partial}{\partial x} \frac{1}{k^{\text{rel}}(x)} \frac{\partial H_z}{\partial x} + \frac{\partial^2 H_z}{\partial y^2} + k_s^2 H_z = 0 \quad (4)$$

where $k^{\text{rel}}(x) = 1 - j\sigma_m(x)/\omega\epsilon_0$, for the continuous PML case. The complete scattering medium material characteristics are included in the wavenumber $k_s = \omega\sqrt{\mu_0\epsilon_s}$.

To terminate a parallel layered region in the frequency domain with a PML ABC, all that is required is to specify the free-space PML conductivity profile as the termination for each layer. Again using the mapped coordinate interpretation, the common transverse wavenumber along the air/soil interface (that is, normal to the PML), k_x maps to $k_x k^{\text{rel}}(x)$ in the PML which terminates both layers. The wavenumber normal to the air/soil interface, $k_y(x)$, for any of the i^{th} PML sublayers is the same as in the scattering space. As a result, the reflection and transmission properties across the air/soil interface are the same within the PML as they are in the scattering region, with only a relative wave attenuation normal to the PML boundary (and along the air/soil interface) applied to waves in all layers.

III. TIME DOMAIN PML THEORY FOR GENERAL LAYERED MEDIA

The relative elegance of the layered PML in the previous section is lost in conversion to the time domain. This happens because the material parameters of each cell in the PML must be specified explicitly. The background σ_s and ϵ'_s must be combined with the σ_e and σ_m of the PML for each layer.

The time domain version of Eqns. (1) is readily available in the literature in several forms, but the

most common splits the H-field into a part associated with the first term of Eqn (1c), H_{zx} , and another with the second term of Eqn (1c), H_{zy} . Thus, in preparation for converting to the time domain, Eqn (1c) splits into two equations:

$$-\frac{\partial E_y}{\partial x} = \mu_0 \left[j\omega + \frac{\sigma_m}{\epsilon_0} \right] H_{zx} \quad (5a)$$

$$\frac{\partial E_x}{\partial y} = j\omega\mu_0 H_{zy} \quad (5b)$$

Using Eqn. (2), Eqn. (1b) becomes:

$$-\frac{\partial H_z}{\partial x} = \epsilon_0 \left[j\omega\epsilon'_s + \frac{\sigma_s}{\epsilon_0} + \frac{\epsilon'_s\sigma_e}{\epsilon_0} - j\frac{\sigma_s\sigma_e}{\omega\epsilon_0^2} \right] E_y \quad (6)$$

Transforming Eqns. (1a, 6, 5a, 5b) yields the set:

$$\frac{\partial H_z}{\partial y} = \epsilon_0\epsilon'_s \left[\frac{\partial E_x}{\partial t} + \frac{E_x}{\tau_s} \right] \quad (7a)$$

$$-\frac{\partial H_z}{\partial x} = \epsilon_0\epsilon'_s \left[\frac{\partial E_y}{\partial t} + \left(\frac{1}{\tau_s} + \frac{1}{\tau_e} \right) E_y + \frac{\int E_y dt}{\tau_s\tau_e} \right] \quad (7b)$$

$$-\frac{\partial E_y}{\partial x} = \mu_0 \left[\frac{\partial H_{zx}}{\partial t} + \frac{H_{zx}}{\tau_m} \right] \quad (7c)$$

$$\frac{\partial E_x}{\partial y} = \mu_0 \frac{\partial H_{zy}}{\partial t} \quad (7d)$$

with $\tau_{(e)} = \epsilon_0/\sigma_{(e)}$, $\tau_s = \epsilon'_s\epsilon_0/\sigma_s$, and $H_z = H_{zx} + H_{zy}$. A similar set exists for the TM polarization.

If the PML terminates a scattering medium with frequency-dependent lossy permittivity, a separate dispersive FDTD model must be used. Recursive convolution [16], differential equation [17-19], and Z-transform methods [20] can be used for this purpose. The conventional Debye and Lorentz dispersion models attempt to match both the real and imaginary parts of the complex material permittivity at once. Although these model parameters exist for many soils, once the conductivity of the PML layers are included — as in Eqn (5a) — new model parameters must be determined for each value in the PML. A less complicated and more automatic approach is to use a dispersion model which matches conductivity separately, keeping the real part of the complex permittivity constant with frequency. Excellent agreement with this type of model for soils is possible [21]. In this case, the first two terms on the right hand side of Eqn (6) are not changed in the presence of PML conductivity, the third term is

merely a constant scaling of the profiled PML conductivity, and the fourth term is small enough to be ignored for typical soils and most of the conductivities in the PML profile. Thus, for the dispersive conductivity/constant dielectric constant model, the integration term in Eqn. (7b) is neglected, and the dispersive model for the scattering space is modified by the addition of simple frequency-independent constants.

The choice of conductivity profile in the PML at the air/soil interface follows the same argument in the time domain as previously for the FDFD case. The σ_e and σ_m values have the form given by Eqns. (3). Many trials have suggested that a simple parabolic profile with $p = 2$ and $S_{\max} = 0.0063$, gives the best absorption performance for dispersive layered soil media, so the *effective* conductivities of the progressive PML sub-layers (starting on an E-field point) are given by:

$$\sigma_m = \sigma_{s,i-\frac{1}{2}} = \frac{0.0063\epsilon'_s}{\Delta} \left(\frac{2i-1}{16} \right)^2, \quad i = 1, \dots, 8 \quad (8a)$$

$$\sigma_e = \sigma_{s,i} = \sigma_s(\omega) + \frac{0.0063\epsilon'_s}{\Delta} \left(\frac{2i}{16} \right)^2, \quad i = 1, \dots, 8 \quad (8b)$$

That is, the conventional PML is modified when terminating the lossy dispersive soil region by replacing the real permittivity ϵ_0 with that of the soil $\epsilon'_s\epsilon_0$, and using a conductivity profile with electric and magnetic conductivities given by Eqns. (8).

IV. NUMERICAL RESULTS

Numerical experiments were conducted to validate the theory presented above. Two scattering cases, representative of typical ground penetrating radar applications, were considered: a point-source above a lossy, uniform half-space of soil; and a plane wave normally incident on a soil half-space with a landmine-like rectangular target buried 4.5 cm below the interface. In both cases the soil parameters used are those of Puerto Rican clay loam, measured at 10% moisture with density 1.4 g/cc [22]. At a typical GPR center frequency of 960 MHz, this soil has dielectric constant $\epsilon' = 6.2$ and electrical conductivity $\sigma = 0.035$ S/m. The target has the dielectric properties of TNT: $\epsilon' = 2.9$, loss tangent 0.001, corresponding to $\sigma = 0.00015$ S/m at 960 MHz.

The FDFD modeling was performed in two dimensions, with field sampled in $1/20$ soil wavelength increments ($\Delta = 6.3$ mm). First, a point source, located at 14 points above the ground surface and 14 points to the left of the center of the scattering space (to examine symmetry), was simulated in a 61 by 41 point grid surrounded by a free-space PML on exterior boundaries of the upper half-plane, and a lossy medium PML for the lower half plane. The total, real part of the electric field H_z is displayed in Figure 1. Clearly, the left/right symmetry, relative to the source point indicates that there are very few numerical artifacts from the left and right boundaries. To further verify the reflectionless nature of the combined PML, a scattering region with twice the horizontal and vertical dimensions was examined. The resulting calculation of real electric field, Figure 2, includes the previous simulation as a subset centered about its origin. Since the agreement between the two simulations is very close over their common region, it is reasonable to conclude that the absorbing boundary surrounding the smaller region is not contributing significantly to the calculated field, even when this ABC is only 6 grid points (0.12λ) from the source point. Figure 3 presents explicitly the magnitude of the difference between the electric fields calculated with the two different size grids. The differences are normalized to the calculated electric field at the upper right corner (27,20). It is clear that the worst error occurs in this corner, where the wave from the source encounters the upper boundary with 82° grazing incidence angle. Even so, this error represents a reflection artifact of 0.17%, or about -55 dB.

The second case modelled by FDFD, is representative of target scattering by a buried 7.6cm by 4.4cm rectangular non-metallic mine-like target. For this calculation, first the unperturbed normally incident plane wave H_{unp} is determined analytically, using standard reflection/ transmission theory, with transmission coefficient given by [23]:

$$T = \frac{2}{1 + \sqrt{\epsilon' - j\sigma/\omega\epsilon_0}} \quad (9)$$

for free space permeability. Thus, for normal incidence,

$$H_{\text{unp}} = TE_0 \sqrt{\frac{\epsilon_s}{\mu_0}} e^{-jk_s(y_0-y)} \quad (10)$$

with E-field magnitude E_0 at the ground surface at $y = y_0$. The total field, $H_t = H_s + H_{\text{unp}}$ satisfies the Helmholtz equation:

$$[\nabla^2 + k^2(x, y)] H_t = 0 \quad (11)$$

for space-dependent wavenumber $k(x, y)$. Since the unperturbed magnetic field in the soil satisfies the Helmholtz equation with the constant scatterer-free wavenumber k_s , Eqn (11) can be separated into an inhomogeneous Helmholtz equation as:

$$[\nabla^2 + k^2(x, y)] H_s = -[k^2(x, y) - k_s^2] H_{\text{unp}} \quad (12)$$

where the right hand side is non-zero only over the support of buried target.

Using the combined PML, applied just to the scattered field, completes the specification of the FDFD calculation. The field scattered from the rectangular target buried in soil, added to the unperturbed reflected and transmitted plane wave was again computed across a smaller and a larger grid. The real part of this total field for the 61 by 41 grid is shown in Figure 4. The target occupies horizontal grid points $-18\Delta < x < -6\Delta$, and vertical points $-6\Delta < y < -13\Delta$. Once again, the field is symmetric with respect to the symmetric rectangular scatterer. The computation over the larger grid is presented in Figure 5, and the magnitude of the difference between the two computations divided by the computed field value where the largest error occurs at (-12,-20) is shown in Figure 6. The largest error is even lower than for the point source illumination case above, 0.018% (-75 dB), occurring in the lower left bottom boundary at the point closest to the target.

For time domain calculations, the PML performance is considerably worse. For the point source case, the excitation was chosen to be a gaussian pulse, modulated at 960 MHz, at the same position as for the FDFD example: (-14,14). The spatial sampling is also the same $\Delta = 6.3\text{mm}$, and the time step is selected to be well within the FDTD Courant stability condition to be $\Delta t = 10$ ps. The soil model parameters are those of Rappaport, *et. al.* [21]:

$$D(t) = \epsilon_{\text{AV}} E(t) \quad (13)$$

$$\sigma(Z) = \frac{b_0 + b_1 Z^{-1} + b_2 Z^{-2}}{1 + a_1 Z^{-1}} \quad (14)$$

where $Z = \exp(j\omega\Delta t)$, corresponding to a unit time delay in FDTD calculations. Parameter value which

match the measured values of Puerto Rican clay loam to within 10% from 30 MHz to 3840 MHz are: $\epsilon_{Av} = 1.171$, $b_0 = 4.386$, $b_1 = -8.637$, $b_2 = 4.251$, and $a_1 = -0.975$. Using Eqn. (14), the electric current density is related to the electric field in the time domain by:

$$J^n + a_1 J^{n-1} = b_0 E^n + b_1 E^{n-1} + b_2 E^{n-2} \quad (15)$$

where the superscript denote time step. Eqn. (15) can be used along with Eqn. (13) in the discretized Ampere's law for dispersive FDTD calculations [20].

For the point source case, at the time just after the time pulse peak has entirely penetrated the ground surface, the H-field pattern is fairly symmetric with respect to the line of symmetry passing through the source point, as shown in Figure 7. The error is calculated by subtracting the field values from this 61 by 41 cell grid from those calculated on a much bigger grid (361 by 341 cells, centered at the same point as the 61 by 41 cell grid). This difference, divided by the field value at the point of maximum error (-30,-18) is displayed in Figure 8. The largest error is 15% (-16 dB). Although this error is quite large, most of the reflection comes from the wall terminating the soil rather than from the air soil interface.

The buried rectangular TNT mine case was also examined using FDTD. Figure 9 shows the total H-field for the same parameters given above. the left/right symmetry is better than for the point source FDTD case. Again error is calculated by comparison with the larger grid. Figure 10 shows the difference between the sample grid calculation and the much larger reference calculation normalized to the value of H-field at the point of largest error (28,-40). The largest magnitude errors are at the corners corresponding to deepest soil locations, with a value of 20% (-14 dB).

IV. CONCLUSIONS

The theory of PML grid terminations for both FDFD and FDTD for an air/dispersive soil half space has been developed and analyzed. The frequency domain results are considerably better than the FDTD results, with local reflection errors of -55 dB compared to -14 dB respectively for an 8 layer parabolically profiled PML. The need to match the PML attenuation profile in air with that of soil at the

air/soil boundary decreases the FDTD PML absorption performance compared to that of a uniform scattering volume. Further work to determine the best PML conductivity for the air/soil media problem is well indicated. For many practical FDTD simulations, reasonable results are possible by enlarging the grid enough to prevent side and back grid termination reflections from reinteracting with the target region.

Analysis and Characterization of Ultrawide-Band Scalar Volume Sources and the Fields They Radiate: Part II—Square Pulse Excitation

Edwin A. Marengo, *Member, IEEE*, Anthony J. Devaney, *Member, IEEE*, and Ehud Heyman, *Senior Member, IEEE*

Abstract—In a previous paper [1], we studied transient radiation from scalar collimated volume source distributions subjected to impulsive excitation. In this paper, we extend our analysis and results to the case of nonimpulsive excitation, paying special attention to the parameterization of the radiation pattern of three-dimensional (3-D) ellipsoid source distributions driven by square pulses of finite duration. We study the role both of the source's space distribution and of the square pulse duration on the generation of well-collimated short-pulse fields. In particular, we explore the source's angular and range resolutions as functions of the transverse and longitudinal dimensions of the source (for a fixed source volume) and of the pulse duration.

Index Terms—Transient propagation.

I. INTRODUCTION

IN a previous paper [1] we investigated the radiation properties of scalar wave fields $U(\mathbf{r}, t)$ radiated by three-dimensional (3-D) sources to the scalar wave equation

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}\right) U(\mathbf{r}, t) = -4\pi Q(\mathbf{r}, t) \quad (1)$$

paying special attention to sources $Q(\mathbf{r}, t)$ having the space-time separable form of a "traveling wave"

$$Q(\mathbf{r}, t) = q_0(\mathbf{r})G(t - \hat{\mathbf{z}} \cdot \mathbf{r}/c) \quad (2)$$

where, without loss of generality, the main beam direction was chosen to be the positive z axis ($\hat{\mathbf{z}}$) and the space distribution $q_0(\mathbf{r})$ was normalized so that

$$\int d\mathbf{r}' q_0(\mathbf{r}') = 1. \quad (3)$$

In order to compare the radiation performance for different source parameters we have considered the source's volume V as invariant.

The class of sources defined in (2) represents a distribution of nondispersive isotropic point radiators, all of which radiate the same time signature $G(t)$ but with space-dependent

strength $q_0(\mathbf{r})$. The source defined in (2) could represent a discrete collection of point radiators (e.g., a 3-D antenna array of isotropic radiating elements) or a spatially continuous distribution of such radiators (note that in the discrete realization, the spectral shaping of the far field is also affected by the interelement spacings). A special case of such distribution is a uniformly distributed source wherein all point radiators are driven with the same strength: specific examples of uniform parallelepiped source distributions have been considered in [1].

In the present paper, we explore uniform ellipsoidal source distributions whose axis coincide with the z axis in (2) for which closed-form expressions can be obtained for all radiation directions and for all observation times. Furthermore, since the ellipsoidal shape may be continuously changed from a prolate to an oblate spheroidal shape, the closed-form results explain the different radiation characteristics of both elongated, quasi-linear traveling wave source distributions and quasi-planar broadside pulsed distributions, as well as those of 3-D sources with comparable longitudinal and transverse dimensions. Finally, while the analysis in [1] has concentrated on impulsive sources [i.e., $G(t) = \delta(t)$ in (2)], which generate near the beam axis singular field terms that cannot be parameterized, the emphasis here is placed on finite pulses (specifically on square pulses).

Our interest in the source distributions considered above arises from the fact that they yield highly collimated pulse beam fields with high degree of angular and range resolutions when they are driven by very short pulses $G(t)$ [1]. Motivation for the source structure in (2) is also provided by the possibility of building 3-D pulsed antenna arrays composed of identical electrically small photoconducting elements [2]–[4]. These antennas, made of III–V compound semiconductor wafers, radiate microwave pulses when triggered by short duration (e.g., picosecond) optical pulses. A 3-D array of such photoconducting elements can thus be realized using fiber optics and optical splitters, the latter to control the excitation strength associated with each element as dictated by $q_0(\mathbf{r})$ in (2) (the excitation strength can also be controlled by the voltage bias applied to each element [2], [3]). The progressive time delay in (2) can be controlled either by a delay network or simply by taking advantage of the propagation delay of the exciting optical wavefront along the z axis [5]. In addition, the antenna arrays described above are expected to have reduced microwave interelement coupling due to the short periods of photoconductivity associated with each element [5].

The source model defined in (2) can thus be viewed as an approximation to a 3-D distribution of electrically small (and thereby quasi-isotropic) photoconducting elements excited by a space-dependent amplitude $q_0(\mathbf{r})$ and with progressive time delay $\hat{\mathbf{z}} \cdot \mathbf{r}/c$ along the main beam direction $\hat{\mathbf{z}}$.

This paper generalizes our work in [1] by considering transient radiation from volume source distributions excited by finite duration square pulses. Our goal is to explore the role both of the excitation pulse duration W and of the length-to-width ratio $\ell \equiv L/a$ (where L and a are, respectively, the longitudinal and transverse dimensions of the source distribution) in establishing a highly collimated pulsed field with a high degree of angular and range resolutions. The angular resolution will be quantified from the directional properties of the *time-domain radiation pattern* $F(\hat{\mathbf{r}}, t)$ characterized by the peak amplitude and energy patterns while the range resolution will be determined from the pulse duration of $F(\hat{\mathbf{r}}, t)$. Special emphasis will be placed on the far-field properties near the main beam direction.

The work reported here encompasses that of Harmuth [6] where the peak amplitude, energy, and slope patterns of a linear (one-dimensional) array composed of elements that radiate far-field square pulses are derived using simple geometrical arguments. Also, the Radon transform radiation integral, which is the starting point of the present analysis, is a special case of the theory in [7] (formulated for electromagnetic sources) that applies to any time-dependent source distribution [not necessarily of the form in (2)]. We would also like to mention that even though we restrict our attention to ellipsoidal volume source distributions, the formulation presented here is rather general and can be applied to any 3-D source configuration of the form in (2). In what follows, we adopt the notation used in [1].

II. REVIEW OF THE GENERAL THEORY

The time-domain radiation pattern $F(\hat{\mathbf{r}}, t)$ is obtained by asymptotically evaluating the radiation field $U(\mathbf{r}, t)$ as $r \rightarrow \infty$, thus yielding [7], [8]

$$U(r\hat{\mathbf{r}}, t) \sim \frac{1}{r} F(\hat{\mathbf{r}}, t - r/c). \quad (4)$$

For the special case of the source in (2), $F(\hat{\mathbf{r}}, t)$ reduces to [1]

$$F(\hat{\mathbf{r}}, t) = G(t) * F_0(\hat{\mathbf{r}}, t) \quad (5)$$

where $*$ is used to denote temporal convolution and where the *time-domain pulsed-radiation pattern* $F_0(\hat{\mathbf{r}}, t)$ (e.g., the source's impulse response) is given by [1]

$$F_0(\hat{\mathbf{r}}, t) = \frac{c}{\xi} \bar{q}_0(\hat{\xi}, s) \Big|_{s=-ct/\xi} \quad (6)$$

where $\xi = \hat{\xi} \cdot \hat{\mathbf{r}} = \hat{\mathbf{r}} \cdot \hat{\mathbf{z}}$ (hence, $\xi = 2 \sin(\theta/2)$) and $\bar{q}_0(\hat{\xi}, s)$ is the Radon transform of $q_0(\mathbf{r})$ evaluated at the plane $\mathbf{r} \cdot \hat{\xi} = s$. Thus, for fixed $\hat{\mathbf{r}}$, the time-domain pulsed-radiation pattern $F_0(\hat{\mathbf{r}}, t)$ is defined by the projection of $q_0(\mathbf{r})$ onto the line directed along the unit vector $\hat{\xi}$.

A schematization of (6) is depicted in Fig. 1, which shows the planes $\mathbf{r} \cdot \hat{\xi} = s$ that lie perpendicular to the unit vector

Fig. 1. Schematization of (6). $\bar{q}_0(\hat{\xi}, s)$ is the Radon transform along the $\hat{\xi}$ axis obtained by integrating $q_0(\mathbf{r})$ on surfaces orthogonal to $\hat{\xi}$. The time-domain pulsed-radiation pattern $F_0(\hat{\mathbf{r}}, t)$ is related to \bar{q}_0 via the scaling in (6).

$\hat{\xi}$ along which the projection is computed. $\bar{q}_0(\hat{\xi}, s)$ is shown in the left portion of the figure as the plot of the area of q_0 computed along the planes $\mathbf{r} \cdot \hat{\xi} = s$ with s being a parameter along the $\hat{\xi}$ axis. The time-domain pulsed-radiation pattern is shown in the right portion of the figure and is obtained from $\bar{q}_0(\hat{\xi}, s)$ by mapping $s \rightarrow -ct/\xi$ and scaling the amplitude by c/ξ . Referring to Fig. 1, we see that if the source dimension in the $\hat{\xi}$ direction is $\Delta(\hat{\xi})$, then the pulse duration of $F_0(\hat{\mathbf{r}}, t)$ along the observation direction $\hat{\mathbf{r}}$ is

$$T(\hat{\mathbf{r}}) = \xi \Delta(\hat{\xi})/c. \quad (7)$$

Similarly, the temporal peak amplitude—defined as the maximum amplitude (over all time t) of the time-domain pulsed-radiation pattern $F_0(\hat{\mathbf{r}}, t)$ in a given direction—is given by

$$F_{0,\max}(\hat{\mathbf{r}}) = c|A_{\max}(\hat{\xi})|/\xi \quad (8)$$

where $A_{\max}(\hat{\xi})$ is the maximum projection of the source's space distribution $q_0(\mathbf{r})$ onto the $\hat{\xi}$ axis.

III. TIME-DOMAIN PULSED-RADIATION PATTERN: ELLIPSOID DISTRIBUTIONS

We consider uniform volume-source distributions $q_0(\mathbf{r})$ with the shape of an ellipsoid that has rotational symmetry with respect to the z axis and with radial and axial dimensions a and L , respectively. To comply with the source normalization in (3), the source's magnitude is taken to be

$$q_0(\mathbf{r}) = \begin{cases} 1/V, & \frac{x^2+y^2}{a^2} + \frac{z^2}{L^2} \leq \frac{1}{4} \\ 0, & \text{else} \end{cases} \quad (9)$$

with $V = \frac{\pi}{6} a^2 L$ being the source's volume. Henceforth, we shall express the source dimensions a and L in terms of the volume V and the length-to-width ratio $\ell \equiv L/a$. Thus, $a = (6/\pi)^{1/3} V^{1/3} \ell^{-1/3}$ and $L = (6/\pi)^{1/3} V^{1/3} \ell^{2/3}$. By doing this we may now compare sources with the same volume

Fig. 2. Peak amplitude pattern of ellipsoidal source distributions under impulsive excitation $F_{0,\max}$ as function of θ (in degrees) for $\ell = 0.2, 1, 5$.

V (and thereby the same input energy¹) for different values of the parameter ℓ . Furthermore, when comparing elongated sources ($\ell > 1$) with flat sources ($\ell < 1$), we shall consider, in particular, sources with the same maximum dimension defined as the diameter of the smallest sphere completely enclosing the source. Therefore, we shall compare the results for an elongated source with, say, $\ell = \ell_e > 1$ with those of a flat source with $\ell = \ell_e^{-2}$.

Using the general Radon transform relation in (6), it is found in the Appendix that the time signature of $F_0(\hat{r}, t)$ for the ellipsoidally shaped distribution in (9) has, at a given observation direction \hat{r} with polar angle θ , the shape of a parabola

$$F_0(\theta, t) = \begin{cases} \frac{3}{2T(\theta)} - \frac{6}{[T(\theta)]^3} t^2 & |t| \leq \frac{1}{2}T(\theta) \\ 0 & \text{else} \end{cases} \quad (10)$$

where

$$T(\theta) = c^{-1}(6/\pi)^{1/3}\ell^{-1/3}V^{1/3}\sin\theta\sqrt{1+\ell^2\tan^2(\theta/2)} \quad (11)$$

is the time duration of $F_0(\theta, t)$. The peak amplitude $F_{0,\max}(\theta)$ is readily seen from (10) to be (see Appendix)

$$F_{0,\max}(\theta) = \max_t[|F_0(\theta, t)|] = \frac{3}{2T(\theta)}. \quad (12)$$

Following the discussion in [1], we define the energy radiation pattern

$$S(\hat{r}) = \pi \int_{-\infty}^{\infty} dt |F(\hat{r}, t)|^2 = \int_0^{\infty} d\omega |f(\hat{r}, \omega)|^2 \quad (13)$$

where $f(\hat{r}, \omega)$ is the frequency-domain radiation pattern, i.e., the temporal Fourier transform of $F(\hat{r}, t)$. Thus, the energy radiation pattern of ellipsoid distributions subjected to impulsive excitation is found to be

$$S(\theta) = \frac{6\pi}{5T(\theta)} \quad (14)$$

¹ Valid for sources of the form (2) that are uniformly excited.

Fig. 3. Far-field pulse duration T of ellipsoidal source distributions under impulsive excitation versus θ (in radians) for $\ell = 0.2, 1, 5$.

hence, the peak amplitude radiation pattern $F_{0,\max}(\theta)$ and the energy radiation pattern $S(\theta)$ under impulsive excitation are identical within a multiplicative factor.

In the limit $\theta \rightarrow 0$ we obtain from (11)

$$T(\theta) \sim (6/\pi)^{1/3}V^{1/3}\ell^{-1/3}\theta/c \quad (15)$$

hence, $T(\theta)$ decreases monotonically with ℓ (for fixed $\theta \simeq 0$), while from (12), (14), (15), both $F_{0,\max}(\theta)$ and $S(\theta)$ increase monotonically with ℓ . Under impulsive excitation, elongated (large ℓ) sources thus produce far-field pulses of higher amplitude and shorter duration in the main-beam direction $\theta \simeq 0$.

Fig. 2 shows plots of the peak amplitude radiation pattern $F_{0,\max}(\theta)$ for ellipsoid source distributions with length-to-width ratios $\ell = 5, 1$, and 0.2 . These plots reveal that for a given $\theta \simeq 0$, higher radiated energy and peak amplitude (and thereby peak power) is available for larger ℓ (i.e., elongated distribution case). The presence of a secondary radiation lobe at $\theta = \pi$ for the small ℓ (planar source) case is also observed. Plots of the pulse duration $T(\theta)$ for the cases $\ell = 5, 1$, and 0.2 are shown in Fig. 3. We found that the θ dependence of the pulse duration is monotonic only for $\ell \leq 1$ and, more importantly, that the pulse duration for a fixed θ in the vicinity of the main-beam axis (i.e., $\theta \simeq 0$) is shorter for larger ℓ . For physical interpretation of the abovementioned effects, the interested reader is referred to [1].

IV. TIME-DOMAIN RADIATION PATTERN UNDER SQUARE-PULSE EXCITATION

In this section, we investigate the properties of the time-domain radiation pattern generated by scalar ellipsoid source distributions driven by unit amplitude square pulses having time duration W , i.e.,

$$G(t) = \begin{cases} 1, & 0 \leq t \leq W \\ 0, & \text{otherwise.} \end{cases} \quad (16)$$

We shall present the results in terms of the normalized pulse duration

$$\bar{W} = cW/V^{1/3}. \quad (17)$$

The time-domain radiation pattern $F(\hat{\mathbf{r}}, t)$ is now computed by convolving the square pulse $G(t)$ of (16) with the time-domain pulsed-radiation pattern $F_0(\theta, t)$ of (10) and (11). In performing the convolution, one identifies two distinct angular domains $\theta \leq \Theta_c(\ell, \bar{W})$ and $\theta \geq \Theta_c(\ell, \bar{W})$ where

$$\Theta_c(\ell, \bar{W}) = 2 \sin^{-1} \left[\frac{-1 + \sqrt{1 + (\pi/6)^{2/3} \ell^{2/3} (\ell^2 - 1) \bar{W}^2}}{2(\ell^2 - 1)} \right]^{1/2}. \quad (18)$$

For $(\pi/6)^{2/3} \ell^{2/3} (\ell^2 - 1) \bar{W}^2 \ll 1$ this expression yields

$$\Theta_c(\ell, \bar{W}) = 2 \sin^{-1} \left[\frac{1}{2} \left(\frac{\pi}{6} \right)^{1/3} \ell^{1/3} \bar{W} \right]. \quad (19)$$

This approximation also provides the limit of (18) at $\ell = 1$. Θ_c is defined by the condition that for $\theta < \Theta_c$, $T(\theta) < W$ while for $\theta > \Theta_c$, $T(\theta) > W$ where $T(\theta)$ is defined in (11). Accordingly, for $\theta < \Theta_c$ there is a time interval denoted as $T/2 < t < W - T/2$ where

$$G(t) * F_0(\theta, t) = \int dt F_0(\theta, t) = \int d\mathbf{r}' q_0(\mathbf{r}') = 1 \quad (20)$$

where we have also used the normalization in (3). By manipulating the convolution $G(t) * F_0(\theta, t)$ separately in these two angular regions we obtain (21), shown at the bottom of the page, for $\theta \leq \Theta_c$ and (22), shown at the bottom of the page, for $\theta \geq \Theta_c$. From (11), $T(\theta = 0) = 0$. Hence, from (21), $F(\theta = 0, t) = G(t)$ as expected.

A. Peak-Amplitude Pattern

The peak-amplitude radiation pattern $F_{\max}(\theta)$ is found from (21)–(22) to be

$$F_{\max}(\theta) = \max_t [|F(\theta, t)|] = \begin{cases} 1 & \theta \leq \Theta_c \\ \frac{3W}{2T(\theta)} - \frac{W^3}{2[T(\theta)]^3} & \theta \geq \Theta_c. \end{cases} \quad (23)$$

Note that in the small W limit, (23) yields $F_{\max}(\theta) \sim \frac{3W}{2T(\theta)}$, which agrees with the impulsive excitation result (12) (apart from the factor W arising from the fact that in the square pulse case $\int dt G(t) = W$).

Fig. 4(a)–(f) explores the combined role of the pulse width W and of the radiator shape on the peak amplitude radiation pattern $F_{\max}(\theta)$. The figure shows plots of $F_{\max}(\theta)$ for $\ell = 100, 10, 1$ (sphere), 0.1, and 0.01 and for various normalized

pulse durations \bar{W} [see (17)]. Note the angular region near the beam axis where $F_{\max} = 1$, which is more visible for the large W case. As expected, high directivity is obtained in the large or small ℓ limits. This result is related, of course, to the overall linear dimension of the source distribution (i.e., the diameter of the smallest sphere completely enclosing the source), which becomes increasingly larger for $\ell \gg 1$ and $\ell \ll 1$. The plots also provide insight into the need for excitation pulses of short duration (relative to the source's size) in order to achieve good angular resolution.

B. Peak-Amplitude Beamwidth: Θ_c

In order to explore the effect of ℓ and \bar{W} on the beamwidth, we shall refer to the angle Θ_c defined in (18). From (23) this angle is readily identified as the 0-dB beamwidth. We have also studied numerically the behavior of the 3-dB beamwidth of the peak-amplitude radiation pattern $F_{\max}(\theta)$, but the results (not shown) were similar to those obtained for Θ_c .

We consider first the limiting case $\bar{W} \ll 1$ (quasi-impulsive excitation). In this case, we obtain from (18)

$$\Theta_c(\ell, \bar{W})|_{\bar{W} \rightarrow 0} \sim (\pi/6)^{1/3} \ell^{1/3} \bar{W}. \quad (24)$$

For large planar sources ($\ell \ll 1$), this approximation is valid if $\ell \bar{W}^3 \ll 6/\pi$, while for large elongated sources ($\ell \gg 1$), it is valid if $\ell \bar{W}^{3/4} \ll (6/\pi)^{1/4}$. Thus, under these conditions the flat sources are seen to yield better peak amplitude directivity than the elongated ones. Note also that the impulsive excitation limit ($\bar{W} = 0$) yields $\Theta_c = 0$ independently of ℓ . This, of course, is in agreement with results reported in [1], where the normalized peak amplitude radiation patterns of elongated and planar sources were found to exhibit identical angular dependence in the vicinity of the main beam direction.

The condition in (24) applies for both elongated and flat sources as long as the excitation pulse is short enough as specified above. Another possible limit is for a large elongated source ($\ell \gg 1$) excited by a relatively long pulse such that $\ell \bar{W}^{3/4} \gg 1$. In this case (19) yields

$$\Theta_c(\ell, \bar{W}) \simeq \sqrt{2}(\pi/6)^{1/6} \ell^{-1/3} \bar{W}^{1/2} \quad (25)$$

which tends to zero as $\ell \rightarrow \infty$ subject to the condition $\ell \bar{W}^{3/4} \gg 1$.

Fig. 5 shows plots of Θ_c versus ℓ and parameterized by different values of \bar{W} . For a fixed \bar{W} , there is a value of ℓ (say ℓ_0) where Θ_c reaches a maximum and the angular resolution is poorest (for a source with a given volume and pulse length).

$$F(\theta, t) = \begin{cases} \frac{1}{2} + \frac{3}{2T}t - \frac{2}{T^3}t^3 & -T/2 \leq t \leq T/2 \\ \int dt F_0(\theta, t) = 1 & T/2 \leq t \leq W - T/2 \\ \frac{1}{2} + \frac{3}{2T}(W - t) - \frac{2}{T^3}(W - t)^3 & -T/2 + W \leq t \leq T/2 + W \end{cases} \quad (21)$$

$$F(\theta, t) = \begin{cases} \frac{1}{2} + \frac{3}{2T}t - \frac{2}{T^3}t^3 & -T/2 \leq t \leq W - T/2 \\ \frac{3W}{2T} - \frac{2}{T^3}(W^3 - 3W^2t + 3Wt^2) & W - T/2 \leq t \leq T/2 \\ \frac{1}{2} + \frac{3}{2T}(W - t) - \frac{2}{T^3}(W - t)^3 & T/2 \leq t \leq W + T/2 \end{cases} \quad (22)$$

Note also that for large \bar{W} 's, there is a range of ℓ where Θ_c reaches its maximal possible value π so that the source does not exhibit any peak-amplitude directivity.

We also explored analytically the variation of ℓ_0 with \bar{W} using (18), thus finding that ℓ_0 decreases monotonically with \bar{W} . Moreover, $\ell_0 \rightarrow \infty$ as $\bar{W} \rightarrow 0$ (quasi-impulsive case). Hence, optimal selection of the shape of the radiator is accomplished in the quasi-impulsive case ($\bar{W} \rightarrow 0$) by using the smallest possible value of ℓ (i.e., a planar source).

C. Energy and Correlation Patterns

Next, we shall explore the directional dependence both of the energy radiation pattern [defined in (13)] and of a radiation characterization we shall call the “correlation” or “matched filter” pattern $L(\theta)$, which we define as

$$L(\theta) = \frac{\max_t [|F(\theta, t) * F(\theta = 0, t)|]}{\max_t [|F(\theta = 0, t) * F(\theta = 0, t)|]} \quad (26)$$

where $*$ denotes temporal convolution. $L(\theta)$ provides a measure of the directional dependence of the (normalized) peak amplitude at the output of a matched filter tuned to the far-field pulse in the main-beam direction $F(\theta = 0, t) = G(t)$ (where a target or receiver may be expected to be located). This characterization thus simulates the angular resolution available in target detection or secure communication applications.

The normalized energy radiation pattern $\bar{S}(\theta) = S(\theta)/S(\theta = 0) = \frac{S(\theta)}{\pi \bar{W}}$ is obtained from (13), (21), and (22) and is given by

$$\bar{S}(\theta) = 1 - \frac{9}{35\bar{W}}T \quad (27)$$

for $\theta \leq \Theta_c$, where $T(\theta)$ is given in (11), and by

$$\bar{S}(\theta) = \frac{6}{5} \frac{W}{T} - \left(\frac{W}{T}\right)^3 + \frac{3}{5} \left(\frac{W}{T}\right)^4 - \frac{2}{35} \left(\frac{W}{T}\right)^6 \quad (28)$$

for $\theta \geq \Theta_c$. (We normalize S so as to be able to compare sources excited by pulses of different duration.)

The “correlation pattern” $L(\theta)$ is obtained from (26), (21), and (22), giving

$$L(\theta) = \begin{cases} 1 - \frac{3}{16\bar{W}}T(\theta), & \theta \leq \Theta_{cL} \\ \frac{3}{2T(\theta)}\bar{W} - \frac{1}{[T(\theta)]^3}W^3, & \theta \geq \Theta_{cL} \end{cases} \quad (29)$$

where Θ_{cL} is defined by $T(\Theta_{cL}) = 2W$.

1) *Special Case: Quasi-Impulsive Excitation:* Consider first the limit $\bar{W} \ll 1$. We examine this case using the small W limits of $\bar{S}(\theta)$ and $L(\theta)$ as computed using (27), (28), and (29). Here, $\Theta_c \ll 1$ as described in (24). We use the small θ approximations of $T(\theta)$ from (15). For $\theta \leq \Theta_c$ we therefore obtain from (27), with (15) and (24)

$$\bar{S}(\theta) \simeq 1 - \frac{9}{35} \left(\frac{6}{\pi}\right)^{1/3} \ell^{-1/3} \bar{W}^{-1} \theta = 1 - \frac{9}{35} \frac{\theta}{\Theta_c}. \quad (30)$$

This expression describes $\bar{S}(\theta)$ near the beam axis for $\theta \leq \Theta_c$ but, as follows from the second expression in (30), it does not describe the relevant range for $\theta > \Theta_c$ where $\bar{S}(\theta)$ may still be nonnegligible [note that $\bar{S}(\Theta_c)$ is about 0.75 of the value of \bar{S} at $\theta = 0$]. Hence, the effective beamwidth of the energy pattern

will be found from the analysis of \bar{S} in the region $\theta \geq \Theta_c$ where \bar{S} is described by (28). The leading term (in W) in this expression is given by $\bar{S}(\theta) \simeq \frac{6W}{5T} \simeq \frac{6}{5} \left(\frac{\pi}{6}\right)^{1/3} \ell^{1/3} \bar{W}^{-1} \theta$, where the second approximation follows from (15). The 3-dB beamwidth obtained by solving $\bar{S}(\theta) = \frac{1}{2}$ is therefore given by

$$\theta_{3\text{dB}} = \frac{12}{5} \left(\frac{\pi}{6}\right)^{1/3} \ell^{1/3} \bar{W} = \frac{12}{5} \Theta_c \quad (31)$$

and is smaller for flat sources (small ℓ). One therefore concludes that flat sources provide better energy focusing than elongated sources of comparable volume. Note in addition that since $S(\theta) = \pi W \bar{S}(\theta)$ we have $S(\theta)|_{W \rightarrow 0} \sim \frac{6\pi W^2}{5T}$, which is consistent with the impulsive source case in (14).

A similar analysis applies to the correlation pattern in (29). Thus, for small W and θ

$$L(\theta) \simeq \begin{cases} 1 - \frac{3}{16} \left(\frac{6}{\pi}\right)^{1/3} \ell^{-1/3} \bar{W}^{-1} \theta, & \theta < \Theta_{cL} \\ \frac{3}{2} \frac{W}{T(\theta)} \simeq \frac{3}{2} \left(\frac{\pi}{6}\right)^{1/3} \ell^{1/3} \bar{W}^{-1} \theta, & \theta > \Theta_{cL} \end{cases} \quad (32)$$

Thus, comparing (32) and (30) we note that the energy and correlation patterns exhibit a similar behavior in the vicinity of the main beam direction for sources with $\bar{W} \ll 1$.

In summary, the results above support the conclusion obtained in connection with the peak-amplitude pattern $F_{\max}(\theta)$, namely, that in the quasi-impulsive limit flat broadside sources provide narrower beamwidth than elongated sources.

2) *General Case: Simulation Results:* Plots of $\bar{S}(\theta)$ for the length-to-width ratios $\ell = 100, 10, 1, 0.1$, and 0.01 and for the normalized square-pulse durations $\bar{W} = 0.1$ and $\bar{W} = 1.0$ are shown in Fig. 6(a) and (b). These plots are also very similar to those of $L(\theta)$ (not shown here). Referring to Fig. 4, we also find that $\bar{S}(\theta)$ [and, thus, $L(\theta)$, too] depends on θ , \bar{W} , and ℓ essentially in the same manner as the peak-amplitude pattern considered in Fig. 4. Furthermore, the numerical study also revealed that the 3-dB beamwidths of both $\bar{S}(\theta)$ and $L(\theta)$ depend on ℓ and \bar{W} essentially in the same manner as the peak-amplitude beamwidth Θ_c considered in Fig. 5.

D. Pulse Duration and Range Resolution

The far-field pulse duration $\tau(\theta)$ is given by [see (21) and (22)]

$$\tau(\theta) = W + T(\theta) \quad (33)$$

where $T(\theta)$ of (11) is the pulse duration under impulsive excitation (i.e., $\tau|_{W=0} = T$). Plots of the normalized pulse duration $\bar{\tau}(\theta) \equiv \tau(\theta)c/V^{1/3}$ for various values of ℓ and \bar{W} are shown in Fig. 7. Note that near the main-beam direction $\bar{\tau}(\theta)$ is mainly controlled by \bar{W} . The shape of the radiator (i.e., ℓ) has, on the other hand, a significant effect away from the main direction (for example, one can easily show that away from the main direction, $\bar{\tau}$ varies monotonically with θ only for $\ell \geq 1$).

3) *Range Resolution for Highly Directive Sources:* For highly directive sources we may consider only the angular range near the beam axis. Specifically, we shall consider the angular range $\theta < \Theta_c$ where Θ_c is peak amplitude beamwidth in (18), which provides a reasonable figure of merit to the relevant angular domain.

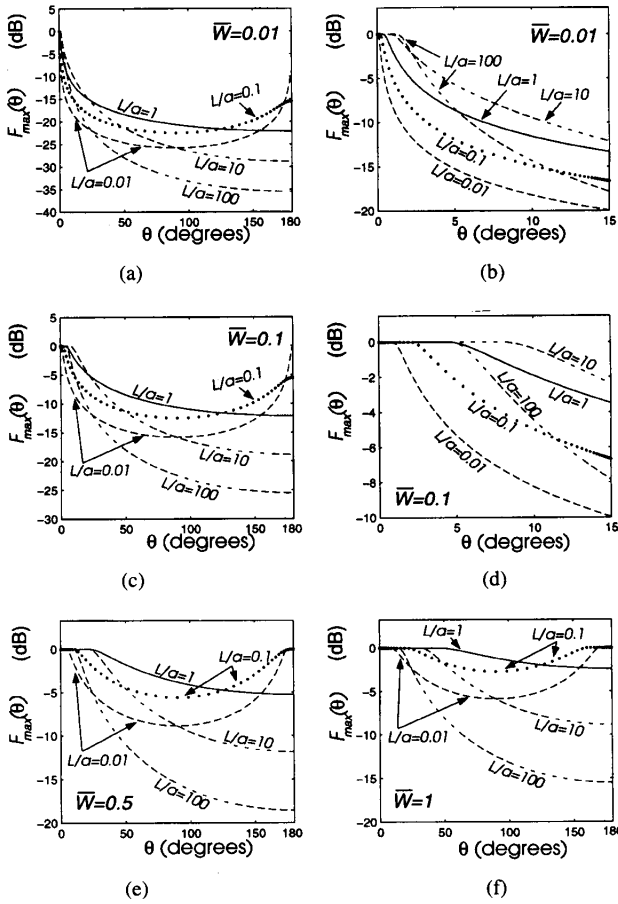

Fig. 4. Peak-amplitude pattern F_{\max} versus θ for $\ell = 0.01, 0.1, 1, 10, 100$, and for various values of \bar{W} . (a) $\bar{W} = 0.01$. (b) Small angles behavior of (a). (c) $\bar{W} = 0.1$. (d) Small angles behavior of (c). (e) $\bar{W} = 0.5$. (f) $\bar{W} = 1.0$.

Fig. 5. Θ_c versus ℓ and parameterized by \bar{W} .

Using (33) together with (15) and (24) for small θ and Θ_c , the normalized pulse duration reduces to

$$\bar{\tau}(\theta) \simeq \bar{W} + (6/\pi)^{1/3} \ell^{-1/3} \theta = \bar{W}(1 + \theta/\Theta_c). \quad (34)$$

Next, we calculate the average pulse duration within the main-

Fig. 6. Energy pattern \tilde{S} versus θ for $\ell = 0.01, 0.1, 1, 10, 100$, and for various values of \bar{W} . (a) $\bar{W} = 0.1$. (b) $\bar{W} = 1.0$.

Fig. 7. Normalized far-field pulse duration $\bar{\tau}$ versus θ for $\ell = 0.01, 0.1, 1, 10, 100$, and for various values of \bar{W} . (a) $\bar{W} = 0.1$. (b) $\bar{W} = 1.0$.

beam zone. Denoting this parameter as $\langle \bar{\tau} \rangle$ we find from (34)

$$\langle \bar{\tau} \rangle \equiv \frac{1}{\Theta_c} \int_0^{\Theta_c} d\theta \bar{\tau}(\theta) \simeq \frac{3}{2} \bar{W}. \quad (35)$$

Thus, for highly directive source distributions, $\langle \bar{\tau} \rangle$ is—apart from an unessential factor—equal to the normalized pulse width \bar{W} , thereby being independent of the source shape parameter ℓ .

A drawback of the above definition is that Θ_c depends both on ℓ and \bar{W} . Hence, the average value of the far-field pulse duration is computed within different angular regions for different source configurations. An alternative approach would be to measure the average of $\bar{\tau}$ within a fixed angular region $\theta \leq \theta_0$ where θ_0 is some fixed small angle in the vicinity of the main direction. Analytical and computer-simulated results obtained for this case (not shown here) revealed that elongated sources provide better range resolution than planar sources of comparable size in the quasi-impulsive excitation case.

Fig. 8. Cross section of an ellipsoid volume source distribution used to compute the time-domain pulsed-radiation pattern $F_0(\hat{\mathbf{r}}, t)$ analytically.

V. CONCLUSION

This two-part sequence has dealt with the (far-field) radiation characteristics of collimated pulsed-source distributions having the “traveling-wave” form in (2). We have parameterized the radiation properties for sources of this class in both frequency and time domains. The time-domain route is based on radiation integrals in the form of planar projections of the time-dependent source distributions along the observation directions, thereby providing simple analysis and optimization tools with direct physical (geometrical) interpretation.

The general analysis tools were developed in the first paper. In that paper, we also considered explicitly the radiation characteristics of canonical parallelepiped source distributions under impulsive excitation. Such sources produce, however, singular field solutions along the main beam axis and, therefore, cannot be properly parameterized. This paper has considered finite duration signals. We studied, analytically, canonical source distributions with the shape of an ellipsoid whose axis coincides with the main-beam direction. Furthermore, by changing the ellipsoidal shape from a prolate to an oblate, we have clarified the different radiation characteristics obtained by an elongated quasi-linear traveling-wave source distribution or by a quasi-planar broadside source distribution.

We have been mainly concerned with the role both of the width of the excitation pulse and of the length-to-width ratio ℓ of the source for fixed-source volume. The source’s focusing properties associated with the peak amplitude, energy, and “correlation” patterns were found to be strongly affected by both the excitation pulse width and the shape of the source. High directivity is achieved using either large planar ($\ell \ll 1$) or elongated ($\ell \gg 1$) sources and short-duration excitation pulses (such that $\bar{W} \ll 1$).

We also found that the angular dependence of all patterns studied (peak amplitude, energy, “correlation pattern,” etc.) and, of the pulse duration, is monotonic only for $\ell \geq 1$ and that this result is independent of the normalized excitation pulse width \bar{W} . Planar broadside sources thus generate undesirable backward radiation lobes, which are not produced by elongated endfire sources.

We also explored the role of the length-to-width ratio on the directivity of the source when the normalized pulse duration is kept fixed. It was found that there is a breakdown region (or point $\ell = \ell_0$) where the beamwidth reaches its maximum (keeping \bar{W} fixed). Optimal selection of the shape of the radiator is accomplished at any of the extremes $\ell \gg \ell_0$ or $\ell \ll \ell_0$ (i.e., choosing ℓ away from the breakdown region). Moreover, we have also investigated the variation of the suboptimal length-to-width ratio ℓ_0 as a function of the width of the excitation pulse. Interestingly, ℓ_0 was found to decrease *monotonically* with the normalized pulse width \bar{W} . Moreover, $\ell_0 \rightarrow \infty$ as $\bar{W} \rightarrow 0$. Hence, minimum beamwidth is accomplished in the quasi-impulsive excitation case by using the smallest possible value of ℓ (i.e., a planar source).

The range resolution in the neighborhood of the main-beam axis was found to be controlled mainly by the width of the excitation pulse. For highly directive sources (such as quasi-impulsively excited sources) the average range resolution as computed within the peak amplitude beam region $\theta \leq \theta_c$ was found to be independent of the shape of the radiator.

APPENDIX

We refer to the geometry in Fig. 8, which schematically shows a cross section of the source in the direction $\hat{\xi} = \cos \theta/2 \hat{x} - \sin \theta/2 \hat{z}$ where, without loss of generality, the $\hat{\xi}$ axis is taken to be in the (x, z) plane. Denoting the point of intersection of the cross-sectional plane with the x axis as x_0 and the cross-sectional area by $A(\theta; x_0)$, we obtain from (6)

$$F_0(\theta, t) = \frac{c}{\xi} q_0 A(\theta; x_0) |_{x_0 \cos \theta/2 = -ct/\xi} \quad (36)$$

where, from (3), $q_0 = 1/V = \frac{6}{\pi a^2 L}$ and $\xi = 2 \sin(\theta/2)$.

The line that delimits the cross section shown is a second-order polynomial with the shape of an ellipse with axes $d_{A-A'}$ and $d_{B-B'}$ given by

$$d_{A-A'} = \frac{L \sqrt{\mu(\theta) - 4x_0^2/a^2}}{\mu(\theta) \cos(\theta/2)} \quad (37)$$

$$d_{B-B'} = a \sqrt{\frac{\mu(\theta) - 4x_0^2/a^2}{\mu(\theta)}} \quad (38)$$

where $\mu(\theta) = 1 + \ell^2 \tan^2(\theta/2)$. The area of this ellipse is, therefore, given by

$$A(\theta; x_0) = \frac{\pi}{4} \frac{La[\mu(\theta) - 4x_0^2/a^2]}{[\mu(\theta)]^{3/2} \cos(\theta/2)} \quad (39)$$

Substituting (39) in (36) yields (10). The peak amplitude is calculated using (8) with $A_{\max} = q_0 A(\theta; x_0 = 0) =$

$\frac{\pi}{4} \frac{La}{\cos \theta/2 \sqrt{\mu(\theta)}}$, thus yielding

$$F_{0,\max}(\theta) = \frac{3c}{2\xi} \frac{1}{a \cos \theta/2 \sqrt{\mu(\theta)}}. \quad (40)$$

The pulse duration is calculated using (7). The quantity $\Delta(\hat{\xi})$ is obtained by finding the points Q and Q' in Fig. 8 where the ellipsoid is tangent to the plane $x = \tan \theta/2 z + x_0$ and later computing the projection of the distance $Q - Q'$ in the direction $\hat{\xi}$, giving $\Delta(\theta) = a \cos \theta/2 \sqrt{\mu(\theta)}$.

Estimation of Object Location from Wideband Scattering Data

George A. Tsihrintzis, Anthony J. Devaney, and Ehud Heyman

Abstract—We present a time domain algorithm for computation of the maximum likelihood estimate of the location of a known scattering object from wide-band scattering data acquired in a suite of scattering experiments. The algorithm consists of a three-step procedure: 1) data filtering, 2) time-domain backpropagation, and 3) coherent summation and is implemented via a number of forward and inverse Radon transforms integrated into a tomographic scheme. A computer simulation is included for illustration purposes.

Index Terms— Filtered backpropagation, inverse scattering, radon transform, tomography.

I. INTRODUCTION

Inverse scattering is the scientific discipline in which a scattering object is probed with incident waves in an attempt to estimate (reconstruct) its structure from scattered field measurements [1]. The scattering object is generally assumed to be embedded in a known, nonattenuating background medium and the objective is to quantitatively estimate the spatial distribution of its complex-valued index of refraction by inverting the mathematical mapping relating the probing wave, the refraction index, and the measurable total wave. This objective is nontrivial to achieve due to the inherent nonuniqueness and nonlinearity of the mapping from index of refraction to scattered field in any single scattering experiment [2]. The nonuniqueness issue can be partially addressed by employing a multiplicity of experiments, where the object is probed from several incident wave directions, and the full scattering data set is then available for the inversion. However, the issue of nonlinearity is significantly harder to address and, to date,

research has only produced mathematical results or computationally intensive iterative algorithms as opposed to practically implementable inversion algorithms.

Over the past 20 years, an alternative approach to the inverse scattering problem has been employed based on certain linearizing approximations [3]–[6]. This approach has led to an expanded discipline within the regime of tomography, known as *diffraction tomography* (DT), which has reached today the stage of being implemented in prototype commercial tomographic scanners for ultrasonic [7], [8], seismic [9], [10], and optical [11] imaging systems. The success of the DT algorithms depends critically, however, on the two assumptions of linearity and availability of multiple experiments and in many cases, the linearity assumption fails, while different constraints (economic, safety, operating, geometric, or physical) limit the number of scattering experiments that can be performed and/or provide low signal-to-noise ratio (SNR) data. As a result, DT based scatterer reconstruction algorithms often suffer from high noise levels, poor resolution, and artifacts, such as streaking and geometric distortion.

To overcome the limitations discussed above a more modest inverse scattering problem was addressed by the first two authors, originally within the framework of linearized [12] and later exact [13] scattering theory. The goal of this more modest inverse problem, which was motivated, in part, by earlier work on a related problem in X-ray computed tomography [14], was to estimate the location of a *known* scatterer having unknown central location from noisy scattered field data. It was found that for monochromatic plane-wave probing the optimum (in the maximum likelihood sense) location estimate could be obtained via a filtered backpropagation algorithm [3], in which partial images formed by filtering and backpropagating scattered field data for different probing directions were coherently summed. The algorithm yields an *image* of the log likelihood function of the object's location and can be used for target detection and classification as well as target location estimation. The location estimation is optimum for any given number of scattering experiments and can yield a good estimate even from a single experiment as long as the wavelength of the probing radiation is comparable with the typical dimensions of the target [12].

The work in [12] and [13] is formulated and solved within the frequency domain and can be directly applied to wideband probing wavefields using standard frequency-domain synthesis. However, in many wideband applications a time-domain algorithm can be computationally more efficient as is evidenced by the time-domain algorithm recently developed for the standard reconstruction problem of DT [15]. In this correspondence, we develop such a time-domain algorithm for the object location problem within the framework of exact scattering theory. In particular, the basic framework for the location estimation problem of DT developed in [13] and the more recent time-domain formulation of standard DT presented in [15] are unified to result in a time-domain algorithm for optimal estimation of the location of a known, nondispersive scattering object from a set of wideband scattering experiments. The theory and estimation algorithm are developed within the frameworks of exact scattering theory and maximum likelihood theory and have applicability to the problems of target detection and classification as well as to target location estimation.

II. CONFIGURATION AND SCATTERING EQUATIONS

We consider the data collection configuration illustrated in Fig. 1, where a known wide-band, plane-wave pulse propagating in the direction characterized by the unit propagation vector \mathbf{s}_0 is incident on a nondispersive (frequency independent) scattering object and the scattered wave is measured over a plane located outside the

Fig. 1. Configuration of scattering experiments.

object and perpendicular to the unit propagation vector \mathbf{s}_0 . We will denote a point on the measurement plane with the coordinate vector $\mathbf{r}_0 = \mathbf{r}_p + l\mathbf{s}_0$ where \mathbf{r}_p is a two-dimensional (2-D) coordinate vector and $l > 0$ is the distance of the measurement plane from the origin. The object is assumed to be embedded in a dispersionless, nonattenuating homogeneous medium of wave velocity c_0 and characterized by its frequency independent distribution of complex-valued index of refraction $n(\mathbf{r}) = c_0/c(\mathbf{r})$, where $c(\mathbf{r})$ is the wave velocity distribution inside the scatterer.

The interaction of the incident wave pulse with the object results in the formation of a time-dependent wavefield $\Psi(\mathbf{r}, t)$ whose Fourier amplitude $\psi(\mathbf{r}, \omega)$ satisfies the time-independent inhomogeneous Helmholtz equation

$$(\nabla^2 + k^2)\psi(\mathbf{r}, \omega) = -k^2 O(\mathbf{r})\psi(\mathbf{r}, \omega) \quad (2.1)$$

where $k = \frac{\omega}{c_0}$ is the wavenumber in the background medium and $O(\mathbf{r}) = n^2(\mathbf{r}) - 1$ is known as the *object function* and is the quantity whose determination is the ultimate goal of inverse scattering theory and DT. The solution of the Helmholtz equation (2.1) can be decomposed into the sum of the incident field and a scattered field in the form $\psi(\mathbf{r}, \omega) = \psi_0(\mathbf{r}, \omega) + \psi^s(\mathbf{r}, \omega)$ where the scattered field component is related to the object function and total field via the integral equation

$$\psi^s(\mathbf{r}, \omega) = k^2 \int d^3 r' O(\mathbf{r}') \psi(\mathbf{r}', \omega) G(\mathbf{r}, \mathbf{r}', \omega) \quad (2.2)$$

where $G(\mathbf{r}, \mathbf{r}', \omega) = \exp(ik|\mathbf{r} - \mathbf{r}'|)/[4\pi|\mathbf{r} - \mathbf{r}'|]$ is the outgoing wave Green function to the Helmholtz equation [16].

The scattered field satisfies a certain source/field translation property that is a key ingredient of the theory and results presented in [13]. In particular, consider an object function that results from some other object function $O_0(\mathbf{r})$ that is shifted to some location \mathbf{R}_c ; i.e., $O(\mathbf{r}; \mathbf{R}_c) = O_0(\mathbf{r} - \mathbf{R}_c)$. The source/field translation property proved in [13] relates the field $\psi^s(\mathbf{r}, \omega; \mathbf{R}_c)$ scattered by the shifted object function to the field $\psi^s(\mathbf{r}, \omega; 0)$ scattered by the centered object

function

$$\psi^s(\mathbf{r}, \omega; \mathbf{R}_c) = e^{ik\mathbf{s}_0 \cdot \mathbf{R}_c} \psi^s(\mathbf{r} - \mathbf{R}_c, \omega; 0). \quad (2.3)$$

Equation (2.3) states that the field scattered by a shifted object function is equal to the shifted field scattered by the centered object function multiplied by the phase shift factor $\exp(ik\mathbf{s}_0 \cdot \mathbf{R}_c)$. This equation, which holds within the framework of exact scattering theory, is the key result that allows the inverse problem of estimation of the location of a known object from scattered field data to be solved within exact scattering theory.

A. Time-Domain Plane-Wave Spectra of the Scattered Wave

In the frequency domain solution of the object location estimation problem presented in [13] the *plane wave expansion* of the scattered field plays a key role. In the work presented here we will make use of the time-domain equivalent of this plane wave expansion which was employed in [15] in obtaining the time-domain inversion algorithm for conventional diffraction tomography. We first review the standard frequency domain plane wave expansion which expresses the scattered field $\psi^s(\mathbf{r}, \omega)$ as a superposition of homogeneous and evanescent plane waves that propagate from the scatterer into any half-space lying outside the scatterer support. We will employ the notation used above and assume that the scatterer is located in the half-space $z = \mathbf{s}_0 \cdot \mathbf{r} < l$. Then the scattered field throughout the half-space $\mathbf{s}_0 \cdot \mathbf{r} > l$ is expressible in the plane wave expansion [3], [4]

$$\psi^s(\mathbf{r}, \omega) = \left(\frac{k}{2\pi}\right)^2 \int d^2\xi A(\xi, \omega) e^{ik(\xi \cdot \mathbf{r}_p + \zeta z)} \quad (2.4)$$

where $\mathbf{r} = \mathbf{r}_p + z\mathbf{s}_0$ with \mathbf{r}_p being a 2-D coordinate vector in the plane passing through the origin and perpendicular to \mathbf{s}_0 . The quantity ζ is given by

$$\zeta = \begin{cases} \sqrt{1 - |\xi|^2}, & \text{if } |\xi| \leq 1 \\ i\sqrt{|\xi|^2 - 1}, & \text{else.} \end{cases} \quad (2.5)$$

The plane wave expansion equation (2.4) decomposes the scattered wavefield $\psi^s(\mathbf{r}, \omega)$ into a superposition of propagating (corresponding to $|\xi| \leq 1$) and evanescent (corresponding to $|\xi| > 1$) plane waves. Because the evanescent waves decay exponentially with distance from the scatterer their contribution to the scattered field becomes negligible at distances greater than a few wavelengths from the scatterer location. Thus, the integration region in equation (2.4) is effectively limited to the homogeneous region $|\xi| \leq 1$ at all field points located more than a few wavelengths from the scatterer.

The plane wave amplitude $A(\xi, \omega)$ can be expressed directly via a spatial Fourier transform of the boundary value field $\psi(\mathbf{r}, \omega)$ over any plane $z \geq l$. In particular, we find using (2.4) that

$$A(\xi, \omega) = e^{-ik\zeta z} \tilde{\psi}_z^s(k\xi, \omega) \quad (2.6)$$

where

$$\tilde{\psi}_z^s(\mathbf{K}_p, \omega) = \int d^2r_p e^{-i\mathbf{K}_p \cdot \mathbf{r}_p} \psi^s(\mathbf{r}, \omega)|_z$$

is the 2-D spatial Fourier transform of the scattered field on the z plane. It follows immediately from (2.6) that the spatial Fourier transform of the scattered field over any two planes, z_1, z_2 satisfies the translation property

$$e^{-ik\zeta z_1} \tilde{\psi}_{z_1}^s(k\xi, \omega) = e^{-ik\zeta z_2} \tilde{\psi}_{z_2}^s(k\xi, \omega).$$

By making use of the source/field translation property (2.3) and the above result we can relate the spatial Fourier transform of the field scattered by a shifted object function $O_0(\mathbf{r} - \mathbf{R}_c)$ to that of an unshifted object function $O_0(\mathbf{r})$. In particular, the spatial Fourier

transforms of these two fields over the measurement plane $z = l$ are related through the equation

$$\tilde{\psi}_l^s(k\xi, \omega; \mathbf{R}_c) = e^{ik[(1-\zeta)\mathbf{s}_0 - \xi] \cdot \mathbf{R}_c} \tilde{\psi}_l^s(k\xi, \omega; 0) \quad (2.7)$$

where $\tilde{\psi}_l^s(k\xi, \omega; \mathbf{R}_c)$ is the transform of the scattered field generated by the shifted object function and $\tilde{\psi}_l^s(k\xi, \omega; 0)$ the transform of the field scattered by the unshifted object function.

The plane wave expansion equation (2.4) and the associated equations (2.6) and (2.7) have time-domain equivalents. In particular, the time-domain plane-wave amplitude of the wavefield is defined as the temporal Fourier transform of the frequency domain plane wave amplitude, viz,

$$A(\xi, \tau) = \frac{1}{2\pi} \int d\omega A(\xi, \omega) e^{-i\omega\tau}. \quad (2.8)$$

On making use of (2.6), we can express the time-domain plane wave amplitude $A(\xi, \tau)$ in terms of the time-domain scattered field over the plane $z = l$ in the form

$$\begin{aligned} A(\xi, \tau) &= \frac{1}{2\pi} \int d\omega \int d^2r_p \psi^s(\mathbf{r}, \omega)|_{z=l} e^{-i\omega(\tau + \frac{\xi \cdot \mathbf{r}_p}{c_0} + \frac{\zeta}{c_0}l)} \\ &= \int d^2r_p \psi^s\left(\mathbf{r}, \tau + \frac{\xi \cdot \mathbf{r}_p}{c_0} + \frac{\zeta}{c_0}l\right)\Big|_{z=l}. \end{aligned} \quad (2.9)$$

Equation (2.9) is recognized as a Radon transform [17] of the boundary value of the wavefield $\psi^s(\mathbf{r}, t)$ in the three-dimensional (3-D) space (\mathbf{r}_p, t) and has, thus, been termed a slant-stack transform [15].

III. ESTIMATION OF OBJECT LOCATION

We consider a scatterer described by the shifted object function $O(\mathbf{r}; \mathbf{R}_c) = O_0(\mathbf{r} - \mathbf{R}_c)$ where O_0 is a known function and \mathbf{R}_c is an unknown scatterer location. The object is probed in a set of scattering experiments where, in each experiment, the incident wave is a wideband plane-wave pulse propagating in the direction \mathbf{s}_0 and the scattered field is measured over a measurement plane as illustrated in Fig. 1. We assume that in each experiment the scattered field measurements are corrupted by additive white Gaussian noise (AWGN) according to the signal model:

$$Y(\mathbf{r}_p, t, \mathbf{s}_0) = X(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{R}_c) + N(\mathbf{r}_p, t, \mathbf{s}_0) \quad (3.1)$$

where

$$X(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{R}_c) = F(\mathbf{r}_p, t, \mathbf{s}_0) \odot \Psi_l^s(\mathbf{r}_p + l\mathbf{s}_0, t, \mathbf{s}_0; \mathbf{R}_c) \quad (3.2)$$

is the time-dependent scattered field Ψ_l^s on the measurement plane $z = l$ filtered by the space-time convolutional (measurement) filter $F(\mathbf{r}_p, t, \mathbf{s}_0)$. In (3.1), $N(\mathbf{r}_p, t, \mathbf{s}_0)$ is a zero-mean white Gaussian noise process¹ in the variables \mathbf{r}_p, t , and \mathbf{s}_0 , i.e.,

$$\mathcal{E}\{N(\mathbf{r}_p, t, \mathbf{s}_0)N(\mathbf{r}'_p, t', \mathbf{s}'_0)\} = \sigma_N^2 \delta(\mathbf{r}_p - \mathbf{r}'_p) \delta(t - t') \delta_{\mathbf{s}_0, \mathbf{s}'_0}. \quad (3.3)$$

The inverse problem that we address is that of estimating the unknown parameter vector (object location) \mathbf{R}_c from the measurements filtered and noisy measurements of the scattered field $Y(\mathbf{r}_p, t, \mathbf{s}_0)$.

¹Gaussian noise of arbitrary color can be handled by expanding the algorithm of this section to include a proper whitening filter.

Fig. 2. Measured scattered field at $(x = 0, z = 5)$ for time $0 < t < 16$ and different noise levels.

A. Log Likelihood Function

The maximum likelihood estimate (MLE) of the object location vector \mathbf{R}_c is obtained by maximizing the *log likelihood function* [18]

$$L(\mathbf{r}_c) = \sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} dt \int d^2 r_p Y(\mathbf{r}_p, t, \mathbf{s}_0) \tilde{X}(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c) - \frac{1}{2} \sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} dt \int d^2 r_p |\tilde{X}(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c)|^2 \quad (3.4)$$

with respect to test location \mathbf{r}_c . We have the following theorem.

Theorem 1: In the absence of evanescent plane waves the second term in (3.4) is independent of object location \mathbf{r}_c and can be dropped from the log likelihood function.

We first make use of Parseval's theorem to write

$$\sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} dt \int d^2 r_p |\tilde{X}(\mathbf{r}_p, t, \mathbf{s}_0; \mathbf{r}_c)|^2 = \left(\frac{1}{2\pi} \right)^3 \sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} d\omega k^2 \int_{|\xi| \leq 1} d^2 \xi |\tilde{X}(k\xi, \omega, \mathbf{s}_0; \mathbf{r}_c)|^2 \quad (3.5)$$

where $k = \omega/c_0$ is the wavenumber and $\tilde{X}(k\xi, \omega, \mathbf{s}_0; \mathbf{r}_c)$ denotes the space-time Fourier transform of the filtered scattered field data. Making use of (2.7) we have that

$$\tilde{X}(k\xi, \omega, \mathbf{s}_0; \mathbf{r}_c) = e^{ik[(1-\zeta)\mathbf{s}_0 - \xi] \cdot \mathbf{r}_c} \tilde{X}(k\xi, \omega, \mathbf{s}_0; 0) \quad (3.6)$$

which, when substituted into (3.5) establishes the theorem since the quantity $(1-\zeta)\mathbf{s}_0 - \xi$ is purely real over the homogeneous region $|\xi| \leq 1$.

Theorem 2: In the absence of evanescent plane waves the log likelihood function can be expressed in the form

$$L(\mathbf{r}_c) = -\frac{1}{(2\pi c_0)^2} \sum_{\mathbf{s}_0} \int_{|\xi| \leq 1} d^2 \xi \frac{\partial^2}{\partial \tau^2} \times [\hat{Y}(\xi, \tau, \mathbf{s}_0) \hat{X}(\xi, \tau, \mathbf{s}_0; 0)] \Big|_{\tau = -\frac{[(1-\zeta)\mathbf{s}_0 - \xi] \cdot \mathbf{r}_c}{c_0}} \quad (3.7)$$

where

$$\hat{X}(\xi, \tau; \mathbf{s}_0; 0) = \int d^2 r_p \tilde{X}\left(\mathbf{r}_p, \tau + \frac{\xi \cdot \mathbf{r}_p}{c_0}; \mathbf{s}_0; 0\right) \\ \hat{Y}(\xi, \tau, \mathbf{s}_0) = \int d^2 r_p Y\left(\mathbf{r}_p, \tau + \frac{\xi \cdot \mathbf{r}_p}{c_0}, \mathbf{s}_0\right)$$

are the slant stacks of $\tilde{X}(\mathbf{r}_p, \tau, \mathbf{s}_0; 0)$ and $Y(\mathbf{r}_p, \tau, \mathbf{s}_0)$ [cf., (2.9)].

We again start with Parseval's theorem to find that the log likelihood function, in the absence of the second term, can be expressed in the form

$$L(\mathbf{r}_c) = \left(\frac{1}{2\pi} \right)^3 \sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} d\omega k^2 \int_{|\xi| \leq 1} d^2 \xi \tilde{Y}(k\xi, \omega, \mathbf{s}_0) \\ \times \tilde{X}(k\xi, \omega, \mathbf{s}_0; \mathbf{r}_c) \\ = \frac{1}{(2\pi)^3 c_0^2} \sum_{\mathbf{s}_0} \int_{-\infty}^{\infty} d\omega \int_{|\xi| \leq 1} d^2 \xi \omega^2 \tilde{Y}(k\xi, \omega, \mathbf{s}_0) \\ \times \tilde{X}(k\xi, \omega, \mathbf{s}_0; 0) e^{-i\omega \frac{[(1-\zeta)\mathbf{s}_0 - \xi] \cdot \mathbf{r}_c}{c_0}} \quad (3.8)$$

where we have put $k = \omega/c_0$ and made use of (3.6). The quantity

$$\tilde{Y}(\xi, \tau; \mathbf{s}_0) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \tilde{Y}(k\xi, \omega, \mathbf{s}_0) e^{-i\omega \tau} \\ = \int d^2 r_p \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega y(\mathbf{r}_p, \omega; \mathbf{s}_0) e^{-i\omega(\tau + \frac{\xi \cdot \mathbf{r}_p}{c_0})} \\ = \int d^2 r_p Y\left(\mathbf{r}_p, \tau + \frac{\xi \cdot \mathbf{r}_p}{c_0}, \mathbf{s}_0\right)$$

is recognized as being the slant stack of the measured field data on the measurement plane where we have denoted the time Fourier transform of the measured field data by $y(\mathbf{r}_p, \omega; \mathbf{s}_0)$. Similarly,

$$\hat{X}(\xi, \tau; \mathbf{s}_0) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \tilde{X}(k\xi, \omega, \mathbf{s}_0; 0) e^{-i\omega \tau}$$

is the slant stack of $\tilde{X}(\mathbf{r}_p, t; \mathbf{s}_0; 0)$. It then follows, again using Parseval's theorem, that

$$\frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega \omega^2 \tilde{Y}(k\xi, \omega, \mathbf{s}_0) \tilde{X}(k\xi, \omega, \mathbf{s}_0; 0) e^{-i\omega \frac{[(1-\zeta)\mathbf{s}_0 - \xi] \cdot \mathbf{r}_c}{c_0}} \\ = \int_{-\infty}^{\infty} d\tau \frac{\partial^2}{\partial \tau^2} [\hat{Y}(\xi, \tau; \mathbf{s}_0) \hat{X}(\xi, \tau; \mathbf{s}_0; 0)] \\ \times \delta\left[\tau + \frac{[(1-\zeta)\mathbf{s}_0 - \xi] \cdot \mathbf{r}_c}{c_0}\right] \\ = \frac{\partial^2}{\partial \tau^2} [\hat{Y}(\xi, \tau; \mathbf{s}_0) \hat{X}(\xi, \tau; \mathbf{s}_0; 0)] \Big|_{\tau = -\frac{[(1-\zeta)\mathbf{s}_0 - \xi] \cdot \mathbf{r}_c}{c_0}}$$

Finally, on substituting the above expression into (3.8) we obtain the desired result.

Equation (3.7) can be interpreted as follows: For each incident wave pulse, the scattered field data are Radon-transformed with respect to their space-time coordinates, filtered in Radon space, and inverse Radon-transformed (one inverse Radon transform per value of $\mathbf{s}_0 \cdot \mathbf{r}_c$) into object space to form partial images of the log likelihood function. The Radon-space filter consists of the complex conjugate of the time-domain plane-wave spectra of the field scattered by the centered object $O_0(\mathbf{r})$. Finally, the partial images are coherently superimposed.

IV. COMPUTER ILLUSTRATION

We consider a single scattering experiment in a 2-D geometry in which a scatterer lies in the (x, z) -plane and is infinitely long and uniform along the y -axis. The probing pulse is incident along the direction of the positive z -axis and data are measured along the line $(x, z = l)$. The field scattered by the centered scatterer (corresponding to the object located at the origin) is the pulse

$$w_0^s(\mathbf{r}, t) = \frac{\sigma^2}{c_0^2} \frac{q\left(t - \frac{|\mathbf{r}|}{c_0}\right)}{\sqrt{|\mathbf{r}|}} \quad (4.1)$$

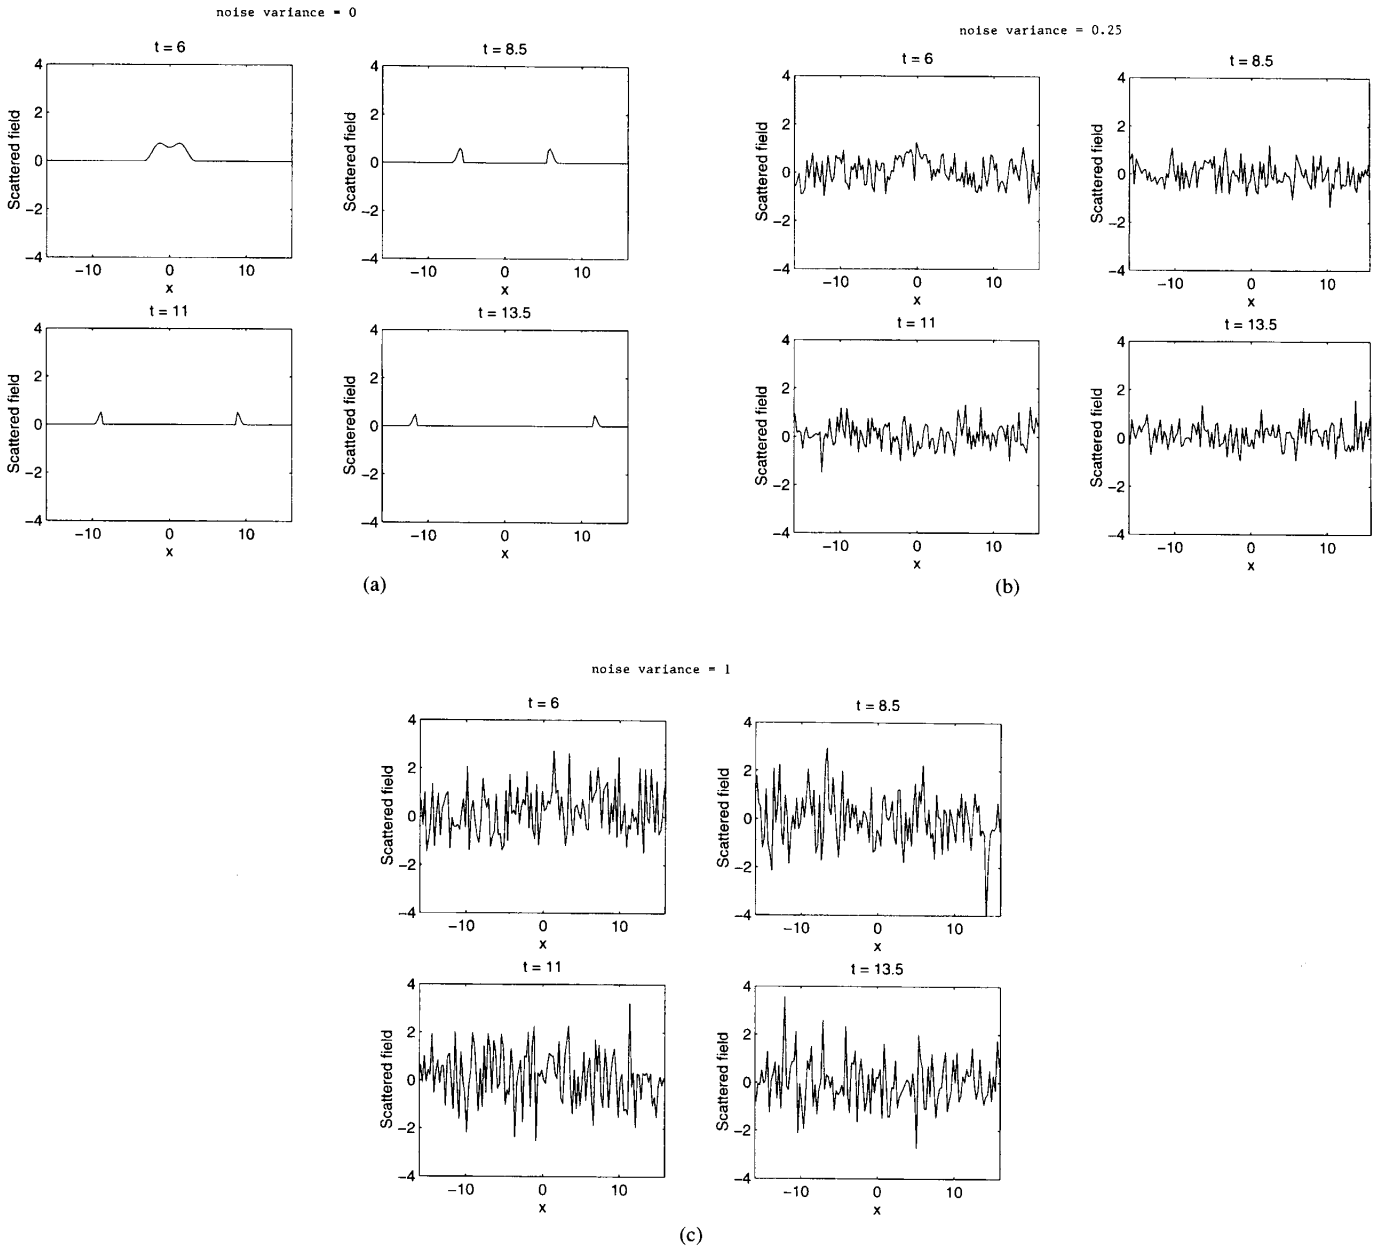

Fig. 3. Snapshots of scattered field along the measurement line $(x, z = 5)$ for times $t = 0, t = 8.5, t = 11,$ and $t = 13.5$. (a) Noise variance = 0. (b) Noise variance = 0.25. (c) Noise variance = 1.

where $\mathbf{r} = (x, z)$ denotes a point in the (x, z) plane and σ^2 is the scatterer cross section and

$$q(t) = \begin{cases} \frac{2\beta}{T} [\cos(\beta t^2) [1 + 2\beta t^2] - 1], & \text{if } 0 < t < T \\ 0, & \text{else.} \end{cases} \quad (4.2)$$

Equation (4.1) is an approximation of the field scattered by a line scatterer of cross section σ^2 when probed with a plane-wave pulse. The scattered field generated by a shifted line scatterer is obtained using (2.3).

We assume the scatterer to be located at the origin of the (x, z) -plane and chose the parameters $\sigma^2 = 1, c_0 = 1, \beta = 1, T = 1,$ and $l = 5$. For the additive Gaussian noise, we examined three different cases with corresponding variances 0, 0.25, and 1. In Fig. 2, we show the scattered pulse at $(x = 0, z = 5)$ for time $0 < t < 16$ for the three noise levels. Fig. 3 shows four snapshots of the field along

the measurement line $(x, z = 5)$ taken at times $t = 6, t = 8.5, t = 11,$ and $t = 13.5$ for the three noise levels. Finally, the likelihood functions computed via (3.7) are shown in Fig. 4 for the three noise levels.

V. SUMMARY, CONCLUSIONS, AND FUTURE WORK

In this correspondence, we established that the log likelihood function for estimation of the location of a known scattering object from noisy wideband scattering data can be computed via a time-domain, filtered backpropagation algorithm consisting of a sequence of direct and inverse Radon transforms of the space-time measurements. Target classification/identification can also be performed via a similar algorithm, in which a bank is employed of filters matched to various target signatures. A computer simulation of a single scattering experiment was performed to illustrate the procedure, which revealed high algorithm performance even

Fig. 4. Log likelihood functions for estimation of object location. (a) Noise variance = 0. (b) Noise variance = 0.25. (c) Noise variance = 1.

in the case of low SNR. Further performance improvements can be achieved if a multiplicity of scattering experiments are utilized.

Related research issues to be addressed in the future include the derivation of proper location estimation algorithms for the cases of measurement planes that remain fixed from scattering experiment to experiment. This is the case in geophysical surveys in which the sensor array is fixed in space and several scattering experiments are performed, each with a different probing plane-wave pulse [19]. Another avenue of future research is the derivation of nonparametric algorithms for detection, location estimation, and classification of stochastic scattering objects.

ABSTRACT

We present a statistically-based method for the enhancement and detection of mines and mine-like targets, in multi-channel imagery. Standard approaches to such multi-channel image processing take advantage of the correlation across channels within a pixel, but typically do not exploit the spatial dependency between pixels. This work aims to construct appropriate spatial statistical models for multi-channel mine imagery and apply these models to allow both image enhancement as well as direct and improved detection of anomalies (i.e., targets) in such data.

We base the method on a Markov Random Field (MRF) model that incorporates a priori information about both the target's and the background's spatial characteristics. In particular, we find a Maximum A Posteriori (MAP) detector of mine targets in background under the prior assumption target pixels are locally spatially dependent. We implement our algorithm on polarimetric and thermal data obtained from the Remote Minefield Detection System (REMIDS), with favorable results compared to a Maximum Likelihood (ML) detector that performs detections on a pixel-by-pixel basis, i.e. without spatial correlation.

Keywords: mine, MRF, multispectral, polarimetric, thermal, statistical, spatial, REMIDS, UXO, detection

1. INTRODUCTION

The need for mine and unexploded ordnance (UXO) detection and removal is growing in both military and humanitarian applications. In places like Cambodia, the threat of mines to the general populace is overwhelming. Since the end of the Cold War, there has been a growth in smaller, regional conflicts where threats are often not from high-tech weaponry, but from inexpensive ordnance. Bosnia is just one example. Mines are one of the least expensive weapons available, and their threat often far outlasts the conflict for which they are emplaced. Mine detection is therefore necessary in two roles: detecting minefield obstacles for military intelligence and detecting individual mines for eventual removal.

One specific subject of mine detection involves wide-area surveillance. In one case, military forces need to chart possible impediments to ground movement accurately over broad swaths of territory. In humanitarian applications, surveyors examining terrain for mine clearance can limit the area searched with wide-area surveillance. For both situations, it is highly desirable to conduct mine searches from the air to minimize the danger to personnel. Unfortunately, ground penetrating radar and quasistatic electromagnetic approaches are somewhat limited in range.

Optical techniques can meet many of the requirements of wide-area minefield detection. One area of much interest is polarimetric sensing. In the near infrared domain, mines have a highly polarizing characteristic. While this feature alone is inadequate to detect mines, it can be a powerful tool when combined with multispectral information, such as thermal imaging or imaging spectrometers. For all-weather capabilities, an active infrared sensor in combination with a thermal sensor is nearly ideal.

However, while polarization and multispectral capabilities, when fused in a rational, statistical manner, can go a long way toward perfecting mine detection from an airborne platform, they can fail under some conditions. For example, during diurnal crossover periods or other situations of low thermal contrast, polarization methods alone cannot make up for the lost information from the thermal channel. Under these conditions, we may require other sources of information to obtain good detection rates while restricting false alarms. In fact, mine detection rates are high using only polarization information, but reducing the false alarm rate is a harder problem, requiring that we apply additional information. Statistical spatial models of prior knowledge can help reduce false alarm rates in a reasonable, quantifiable way. By encoding prior spatial information, such as shape, smoothness, or pattern, in a

statistical form, we can fuse that information with the available data to improve the mine detection process under a wide range of operational conditions.

2. BACKGROUND

2.1. Sensor

Our data consist of three infrared imagery channels generated by the U.S. Army Engineer Waterways Experiment Station's Remote Minefield Detection System (REMIDS).^{1,2} The first two channels are imaged using an active infrared system at the $1.05\ \mu\text{m}$ wavelength. One channel is percent polarization, $(P - S)/(P + S)$, and the other channel is total reflectance, $(P + S)$, where P is reflectance in parallel polarization and S is reflectance in cross polarization. The third channel is a passive thermal infrared channel operating over the $8\text{--}12\ \mu\text{m}$ range. The sensor is mounted on an airborne platform, represented in Figure 1. The data that we use for this study has a resolution

Figure 1. REMIDS Thematic Representation

of 2-3 inches per pixel, although later system upgrades have increased this resolution.

Several researchers have shown that polarization characteristics are advantageous in the mine detection process.^{1,3,4} Man-made objects such as mines and other unexploded ordnance (UXO) are significant near infrared polarizers compared to natural backgrounds, which tend to be random polarizers. REMIDS only uses linear polarization features, but the same algorithmic techniques can be extended to circular polarization as well. Additionally, thermal data alone is sensitive to weather and time of day, especially diurnal thermal crossover.

The active near-IR sensor used in REMIDS is capable of all-weather imaging, but this all-weather capability comes at the price of a laser source, its power supply, and other support equipment. A passive polarization sensor could be implemented cheaply, but would have weather-dependent detection and false alarm rates. An alternative system is a passive hyperspectral polarimetric imager,³ but this again increases the system cost.

2.2. Algorithms

Because detecting individual mines from the air is often prone to false alarms, many researchers have concentrated on detecting minefields, which is to say a collection of mines that can be grouped in some way. Some have used collinearity,⁵ and some have used Poisson point models⁶⁻⁸ as a basis for detecting minefields. However, collinearity is useful only when studying patterned minefields, and Poisson point models are limited by their preprocessor's ability to screen out false detections of individual mines. To obtain better minefield detection, a clear solution is to either improve the detection of individual mines or reduce the number of individual mine false alarms, or both. A good mine detection model can then be combined with a minefield detection model with the end result being improved detection of both mines and minefields.

One way to improve the individual mine detection process is to model the system statistically. Statistical model-based approaches can provide many advantages. Bayesian approaches provide a rational framework in which to model and fuse both information and its uncertainty. Statistical models frequently provide confidence measures of results.

They make fusion of information from disparate sources, especially prior information, a reasonable and quantifiable process.

One appropriate system for detecting mines in background is a Maximum A Posteriori (MAP) detector. With x being the image where each pixel can take on two states, mine or background, and y being the multichannel data image, the formula for determining the values of x is:

$$\hat{x} = \operatorname{argmax}_x p(x|y) = \operatorname{argmax}_x p(y|x)p(x) \quad (1)$$

where $p(x|y)$ is the posterior probability distribution of the mine location image conditioned on the multichannel data image, $p(y|x)$ is the likelihood of the data image conditioned on the mine locations, and $p(x)$ is the prior probability distribution of the mine location image. Thus, we just need three things: an observation probability model, a prior probability model, and an algorithm for maximizing over all possible mine location images x .

3. METHOD

For our observation model, we assume that each pixel of data, y_i , is conditionally independent of all other data pixels, conditioned on knowledge of mine presence at that pixel, x_i . Formally,

$$p(y|x) = p(y_1, \dots, y_N | x_1, \dots, x_N) = \prod_{i=1}^N p(y_i | x_i) \quad (2)$$

where N is the number of pixels in the image. We also assume that each pixel is an identically distributed Gaussian random 3-vector, with one element for each of the three channels: percent polarization, total reflectance, and thermal,

$$p(y_i | x_i) = \frac{1}{|2\pi\Sigma_{x_i}|} \exp \left\{ -\frac{1}{2} (y_i - \mu_{x_i})^T \Sigma_{x_i}^{-1} (y_i - \mu_{x_i}) \right\} \quad (3)$$

where μ_{x_i} and Σ_{x_i} are the mean and the covariance, respectively, of the observation variable, given that the observation is of type x_i . This type can be either mine or background, which we will denote as 1 and 0, respectively. For the purposes of this paper, we have assumed that the mean and covariance are known for both background and mines, and we have estimated the mean and a full covariance matrix for both mines and background directly from the data. In practice, we would need to estimate these parameters from the data, possibly by using a tool such as the Expectation-Maximization algorithm.

For our prior model, we have chosen to introduce spatial correlation of mine or background using a Markov Random Field (MRF) model.⁹ Some previous work has been done on using MRFs in mine detection and classification problems.^{10,11} In one case, the focus was on detecting boundaries using an MRF boundary structure model. In another case, the author based his approach on detecting deviations from an autoregressive (MRF) model that he computed from the data. Neither of these studies dealt with the problem of wide-area surveillance. We have chosen to use a type of discrete “smoothness,” or region-based, model, under the assumption that the mines we are detecting extend over multiple pixels and thus any pixel with a mine will be near several other pixels containing mines:

$$p(x) = \frac{1}{\mathcal{Z}} \prod_{k=1}^N \exp \left\{ -\alpha \sum_{j \in \mathcal{N}_k} (x_k - x_j)^2 \right\} \quad (4)$$

The \mathcal{Z} term is a normalizing constant given by,

$$\mathcal{Z} = \sum_x \prod_{k=1}^N \exp \left\{ -\alpha \sum_{j \in \mathcal{N}_k} (x_k - x_j)^2 \right\} \quad (5)$$

and \mathcal{N}_k is the set of four nearest neighbors around pixel k , as shown in Figure 2. Those familiar with statistical mechanics may recognize this as a variant form of the Ising magnet model. In simpler terms, Equation 4 states that each pixel has a higher probability of being the same as its neighbors than of looking different. We can then combine

Figure 2. Neighborhood Structure of the Spatial Model

these two models into a function proportional to the posterior distribution with α as a weighting constant between the prior and likelihood distributions:

$$p(x|y) \propto e^{-H(x|y)} \quad (6)$$

where

$$H(x|y) = \sum_{k=1}^N \left[\alpha \sum_{j \in \mathcal{N}_k} (x_k - x_j)^2 + \frac{1}{2} (y_k - \mu_{x_k})^T \Sigma_{x_k}^{-1} (y_k - \mu_{x_k}) \right] \quad (7)$$

The last thing we need is a means to maximize this joint distribution, and hence the posterior distribution, for all x . We have chosen to implement this maximization using a simulated annealing algorithm because the distribution of x is discrete.¹² Thus, we introduce a “temperature” parameter to the distribution:

$$p(x|y) \propto e^{-H(x|y)/T} \quad (8)$$

To obtain an optimal solution, T should start at a sufficiently high temperature and be reduced slowly according to a logarithmic cooling schedule. However, to reduce the number of computations necessary, we chose to initialize the system at a relatively low temperature with a pixel-by-pixel Maximum Likelihood (ML) solution using the likelihoods given in Equation 3. We then reduced the temperature with an exponential cooling schedule:

$$\frac{1}{T} = \gamma e^{\beta k} \quad k = 1, 2, \dots \quad (9)$$

While this approach is not guaranteed to achieve a globally optimal solution, the initialization makes this algorithm unlikely to do worse than the ML solution and the exponential cooling schedule gives fast convergence. Because only local interactions are involved in this processing and the number of local operations required are small, this technique is well-suited to massive parallelization, either on multiple processors or on application specific ICs.

4. RESULTS

For our test we had access to only two data sets, both from 1991 test flights of REMIDS over Fort Drum, New York. The first flight was conducted at 9 am on an overcast day, resulting in a complete lack of thermal contrast between mines and background. The second flight was conducted at 3 pm on a sunny day. Representative segments of all channels of both scenes are shown in Figures 3 and 4. The mines in these images are surface patterned anti-tank mines, but note that our technique does not use any pattern based information, so it is equally applicable to scatterable mines as long as sufficient spatial resolution is available.

The good thermal and percent polarization contrast in the sunny imagery made near perfect detection possible with simple techniques, such as thresholding the three images separately and combining them with boolean operations, so this data will not be considered here. However, the cloudy imagery removed the advantages conveyed by the thermal channel. A likelihood ratio test based on a Gaussian model for each hypothesis, mine and background, produced a very high false alarm rate (Figure 5) Using the MAP estimator with its a priori “smoothness” model

significantly reduced the false alarms, as demonstrated in Figure 6. An empirically determined ROC curve appears in Figure 7. We computed this ROC by taking the total number of false alarms in a 710×9000 pixel ($166\text{ft} \times 2100\text{ft}$) image as the x-axis and the ratio of detected mines to actual mines as the probability of correct detection on the y-axis. A detection (both correct detection and false alarms) was any continuously 4-connected region of mine pixels.

We found that we could also achieve good minefield detection simply by counting the number of detections in a processed block. In each case where a minefield was present in a block of the cloudy day data, the number of individual mine detections significantly exceeded some threshold between 4 and 10, as shown in Table 1. This result

	Block 1	Block 2	Block 3	Block 4	Block 5	Block 6	Block 7	Block 8	Block 9
ML	299	260	522	44	433	233	174	183	341
MAP	2	0	1	0	11	12	12	0	3
True	0	0	0	0	11	11	11	0	0

Table 1. Number of Mine Detections in Each Data Block

shows that we have found a simple tool for minefield detection that does not depend on patterned minefield layouts. In addition, our method can still be combined with other statistical models of mine layouts, to further improve both minefield and individual mine detection.

Note that the only ground truth available to us at the time of this writing comes from human evaluation of the data. Note also that our algorithms, both the ML and the MAP detectors, detected every individual mine. The only errors in these results arose from false alarms. Because of the small data set, however, it would not be prudent to attempt to estimate true error rates from these data.

Processing a $710 \times 1000 \times 3$ data block through twenty iterations in MATLAB using non-optimized code required approximately 2.5 minutes on a Sun Ultra 1. Large speedups are possible by going to native compiled code rather than interpreted code and by implementing this algorithm in a massively parallel environment.

5. CONCLUSIONS

We have demonstrated the incorporation of a spatial correlation structure in a mine detector using a statistical approach to fuse a priori spatial knowledge with multichannel imagery. We implemented this approach on three channel data from the REMIDS sensor, comprised of percent polarization and total reflectance from an active sensor in the near infrared domain and a single passive thermal infrared channel. This MAP formulation resulted in a noticeable improvement over an ML hypothesis test under reasonably common conditions where the thermal channel provided little or no discriminating information. Limited data availability precluded a more thorough evaluation of performance measures.

This approach required no information about the pattern of the minefield or the shape of the mines. We only required the information that mines form multi-pixel regions. Hence, there is no reason why this approach would not work equally well on scatterable mines. In addition, because we formulated this algorithm as a statistical model, we can fuse the results of this detection process with other sources of information in a rational way. For example, we could have included a global statistical model of the mine locations in a minefield to better detect minefields. In future work, we aim to examine the buried minefield problem.

6. ACKNOWLEDGMENTS

We would like to thank Ricky Goodson and Ernesto Cespedes of the US Army Corps of Engineers Waterways Experimental Station's Environmental Laboratory for graciously sharing their REMIDS data. This work is partially supported by the Army Research Office under Grant ARO DAAG55-97-1-0013, the Air Force Office of Scientific Research under Grant F49620-96-1-0028, and the National Institutes of Health under Grant NINDS 1 R01 NS34189.

Time-dependent plane wave and multipole expansions of the electromagnetic field

Edwin A. Marengo^{a)} and Anthony J. Devaney

*Center for Electromagnetics Research, Northeastern University,
Boston, Massachusetts 02115*

(Received 24 November 1997; accepted for publication 8 April 1998)

A new and conceptually simple derivation is presented of the time-dependent multipole expansion of the electromagnetic field radiated by a time-varying, localized, volume charge-current distribution. The analysis is based on a new time-dependent plane wave representation of the electromagnetic field (i.e., an “angular spectrum expansion” in the time domain), also derived in the paper. Expressions are given for the time-dependent plane wave spectra in terms of a fourfold Radon transform representation of the transverse current distribution. Two alternative expressions for the time-dependent multipole moments are derived; the first gives them in terms of the spectral amplitude vectors of the corresponding time-dependent plane wave representation while the second gives them in terms of a weighted radial-temporal average of the current distribution. Thus the analysis also sheds light on the relationship between the time-dependent plane wave and multipole expansions in their common domains of validity. © 1998 American Institute of Physics.

I. INTRODUCTION

In describing transient wave phenomena, descriptions directly in space-time domain (where the sources and fields are well-localized) are usually more efficient and insightful than their conventional, frequency domain counterparts. Examples include the pulsed beams (PBs) and the focus wave modes (FWMs), among others.^{1,2} This investigation is concerned with the time domain analogs of more traditional (frequency-domain-based) representations, namely, the plane wave and multipole expansions. Thus, the electromagnetic field radiated by a time-varying (e.g., pulsed), localized, volume charge-current distribution is expressed as a sum of time-dependent spherical (multipole) wave functions. We also obtain, via analytic signal representation, a new time-dependent plane wave representation of the electromagnetic field (i.e., an “angular spectrum expansion” in the time domain). The relationship between the expansion coefficients (moments) of the time-dependent plane wave and multipole expansions in their common domains of validity is also examined. The work reported here is an extension to the electromagnetic field case of the time domain multipole theory for scalar fields developed in Ref. 3. It is also an extension to the time domain of the frequency domain plane wave representations and multipole expansions of the electromagnetic field developed in Ref. 4.

Time-dependent multipolelike (spherical wave) expansions of electromagnetic radiation fields are not new. Early work in this area is associated with the names of Granzow,⁵ Davidon⁶ and Campbell *et al.*⁷ More recent contributions include those of Heyman and Devaney,³ where a scalar time-dependent multipole theory for volume source distributions is developed and Hansen,⁸ where time-dependent multipole fields are applied to address theoretical aspects of spherical near field scanning. However, even though work in this field is not new, both the procedure we use to derive our results as well as many of the results are new. For instance, the time domain multipole theories in Refs. 6 and 7 originate from the Debye-potential formalism⁴ while ours originates from the time-dependent plane wave representation, also derived in the paper. Granzow's⁵ and Hansen's⁸ focus is on the diffraction problem for prescribed field data over a boundary while ours is on the radiation problem for volume current distributions. Furthermore, our formulation is conceptually

^{a)}Electronic mail: emarengo@cdsp.neu.edu

simple and insightful in describing the relationship between the time-dependent expansion coefficients (moments) of the time-dependent plane wave and multipole expansions in their common domains of validity. Aspects of our time-dependent plane wave representations of the electromagnetic field have also appeared before in connection with time domain planar near field scanning.⁹ Our formulation, however, is given in terms of charge-current distributions (i.e., radiation problem), unlike those in Ref. 9, which are given in terms of fields prescribed over a boundary (i.e., diffraction problem). More importantly, our analysis not only corroborates those of previous contributions but also yields new, alternative expressions for both types of expansions.

Frequency domain plane wave and multipole expansions of scalar and electromagnetic fields have played a key role in classical and quantum-mechanical theories of wave radiation, propagation and diffraction and in defining fundamental limits in antenna theory.^{10,11} Thus, in analogy to their frequency domain counterparts, the time-dependent expansion schemes considered here could be useful in treating canonical radiation and scattering problems directly in the time domain. They could also be of interest in diffraction problems formulated in terms of near or far field data (e.g., time domain near field scanning⁸ and inverse diffraction from far field data⁴). Furthermore, they could also help in elucidating transient radiation phenomena (e.g., fundamental limitations of antennas driven by short pulses) and—by doing so—also in defining relevant figures of merit for transient radiation.

The remainder of the paper is organized as follows. Section II reviews known results on plane wave and multipole expansions for scalar fields. We examine, in analytic signal representation, the Weyl expansion (or angular spectrum expansion) of the scalar field generated by a localized scalar source distribution that is turned on at some initial time (say $t=0$). We then derive, again in analytic signal representation, a time domain multipole expansion of the scalar field based on the corresponding time-dependent plane wave representation. Methodologically, we Fourier invert to the time domain the corresponding frequency domain multipole expansion. The final form of the time-dependent multipole expansion is given explicitly in terms of real signals using the real spherical harmonics $S_{\ell,m}^{(1)}(\theta, \phi)$ and $S_{\ell,m}^{(2)}(\theta, \phi)$ (also known as tesseral harmonics¹²), defined, respectively, by the real and imaginary parts of the ordinary spherical harmonic of degree ℓ and order m , $Y_{\ell,m}(\theta, \phi)$. An alternative form of the time-dependent multipole expansion in which the time-dependent multipole moments are expressed as a weighted radial-temporal average of the source distribution is also derived.

The main contribution of the paper is contained in Sec. III. There we extend the theory developed in Sec. II for scalar fields to the electromagnetic field case, with the vector spherical harmonics in the latter case playing a role analogous to that of the ordinary spherical harmonics in the scalar case. In Sec. III A we derive, in analytic signal representation, a new time-dependent plane wave representation of the electromagnetic field generated by a time-varying, localized, volume charge-current distribution. The time-dependent plane wave spectra are given in terms of a fourfold Radon transform representation of the transverse current distribution. Later, we derive, following lines analogous to those of the scalar field treatment in Sec. II, a new form of time-dependent multipole expansion of the electromagnetic field; the spherical-wave expansion functions used are the vector analogs of the real spherical harmonics. However, unlike in Sec. II, our electromagnetic field case manipulations in Sec. III are carried out in the time domain. Two alternative expressions for the time-dependent multipole moments (i.e., the expansion coefficients) are derived; the first gives them in terms of the spectral amplitude vectors of the corresponding time-dependent plane wave representation while the second gives them in terms of a weighted radial-temporal average of the current distribution. Emphasis is placed on real spherical harmonics, hence our expansion involves only real time-dependent multipole wave functions and moments.

Notation: We define the temporal and spatial-temporal Fourier transforms, $q(\mathbf{r}, \omega)$ and $\tilde{q}(\mathbf{K}, \omega)$, respectively, of a scalar source $Q(\mathbf{r}, t)$ of finite energy [i.e., square-integrable in (\mathbf{r}, t)] via

$$q(\mathbf{r}, \omega) = \int_{-\infty}^{\infty} dt' e^{i\omega t'} Q(\mathbf{r}, t') \quad (1)$$

where

$$Q(\mathbf{r}, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} d\omega' e^{-i\omega' t} q(\mathbf{r}, \omega'), \quad (2)$$

and

$$\tilde{q}(\mathbf{K}, \omega) = \int_{-\infty}^{\infty} dt' e^{i\omega t'} \int d\mathbf{r}' e^{-i\mathbf{K} \cdot \mathbf{r}'} Q(\mathbf{r}', t') \quad (3)$$

where

$$Q(\mathbf{r}, t) = \frac{1}{(2\pi)^4} \int_{-\infty}^{\infty} d\omega' e^{-i\omega' t} \int d\mathbf{K}' e^{i\mathbf{K}' \cdot \mathbf{r}} \tilde{q}(\mathbf{K}', \omega'). \quad (4)$$

Thus the spatial-temporal Fourier transform $\tilde{q}(\mathbf{K}, \omega)$ of $Q(\mathbf{r}, t)$ is simply the spatial Fourier transform of $q(\mathbf{r}, \omega)$. We shall refer to $q(\mathbf{r}, \omega)$ as being the source spectrum.

Unless otherwise stated, we shall subsequently use lowercase and uppercase letters to denote frequency and time domain quantities, respectively. Unless otherwise stated, a tilde (\sim) over a constituent will denote a spatial-frequency domain constituent. A caret ($\hat{}$) over a vector will denote a unit vector, e.g., $\hat{\mathbf{r}} \equiv \mathbf{r}/|\mathbf{r}|$.

We shall denote the Cartesian coordinates of \mathbf{r} (configuration space) and \mathbf{K} (momentum space) as (x, y, z) and (K_x, K_y, K_z) , respectively. The corresponding spherical coordinates will be denoted as (r, θ, ϕ) and (K, α, β) , respectively. We also define the \mathbf{K} -space unit vector $\mathbf{s} \equiv \mathbf{K}/K$.

In order to simplify the manipulations time-dependent quantities will be manipulated first in analytic signal representation. For example, we define the analytic source distribution $Q^+(\mathbf{r}, t)$ corresponding to a real, square-integrable source distribution $Q(\mathbf{r}, t)$ by

$$Q^+(\mathbf{r}, t) = \frac{1}{2\pi} \int_0^{\infty} d\omega' e^{-i\omega' t} q(\mathbf{r}, \omega') \quad (5)$$

so that, for real t ,

$$Q(\mathbf{r}, t) = 2\Re\{Q^+(\mathbf{r}, t)\}, \quad (6)$$

where \Re denotes the real part. The quantity $Q^+(\mathbf{r}, t)$ defined by Eq. (5) is an analytic function in the lower-half plane of the complex t plane.¹³ Of particular interest to us is the real- t limit of $Q^+(\mathbf{r}, t)$, which defines the real, physical source distribution $Q(\mathbf{r}, t)$ via Eq. (6). Subsequently a plus sign (+) in the upper-right of a constituent will denote its analytic extension.

To simplify notation we also define a temporal integration operator ∂_t^{-1} such that

$$\partial_t^{-1} Q(\mathbf{r}, t) \equiv \int_{-\infty}^t dt' Q(\mathbf{r}, t'). \quad (7)$$

The corresponding n th-order temporal integration will be denoted as ∂_t^{-n} .

II. REVIEW OF THE THEORY FOR SCALAR FIELDS

This section reviews time-dependent plane wave and multipole expansions for scalar fields $U(\mathbf{r}, t)$ radiated by scalar sources $Q(\mathbf{r}, t)$ to the inhomogeneous wave equation

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \right) U(\mathbf{r}, t) = -4\pi Q(\mathbf{r}, t). \quad (8)$$

We will assume that the source $Q(\mathbf{r}, t)$ is a square-integrable, continuous and continuously differentiable function of (\mathbf{r}, t) , is confined to within a spherical volume about the origin [such that $Q(\mathbf{r}, t) = 0$ for $r > a$], and is turned on at some initial time, say $t = 0$ [such that $Q(\mathbf{r}, t) = 0$ for $t < 0$]. The radiated field $U(\mathbf{r}, t)$ is the causal solution to Eq. (8), given by¹⁴

FIG. 1. The α -contours of integration C_+ and C_- in complex α space.

$$U(\mathbf{r}, t) = \int_0^\infty dt' \int_{r' \leq a} d\mathbf{r}' \frac{Q(\mathbf{r}', t') \delta\left(t' - t + \frac{|\mathbf{r} - \mathbf{r}'|}{c}\right)}{|\mathbf{r} - \mathbf{r}'|}, \quad (9)$$

where $\delta(\cdot)$ is Dirac's delta function.

A. Plane wave expansion of scalar fields in the time domain

It is well known that the radiated field $U(\mathbf{r}, t)$ at points \mathbf{r} within any half-space $|z| \geq a$ can be written as a superposition of monochromatic homogeneous and inhomogeneous (evanescent) plane waves; in particular,¹⁵

$$U(\mathbf{r}, t) = 2\Re\{U^+(\mathbf{r}, t)\} = 2\Re\left\{\frac{ic}{(2\pi)^2} \int_0^\infty \frac{\omega}{c} d\left(\frac{\omega}{c}\right) \int_{-\pi}^\pi d\beta \int_{C_\pm} d\alpha \sin \alpha f(\mathbf{s}, \omega) e^{[i(\omega/c)(\mathbf{s} \cdot \mathbf{r} - ct)]}\right\} \quad (10)$$

where \mathbf{s} is the unit vector having Cartesian components (in general complex) $(\sin \alpha \cos \beta, \sin \alpha \sin \beta, \cos \alpha)$ while the contours of integration C_\pm in the complex α plane are those shown in Fig. 1, where C_+ is used if $z \geq a$ and C_- if $z \leq -a$. The real-axis portion of the contours C_\pm contributes to the propagating spectrum, describing homogeneous plane waves propagating into the half-space $z \geq a$ or $z \leq -a$. The complex portion of the contours C_\pm corresponds, on the other hand, to the evanescent spectrum, describing evanescent plane waves that decay exponentially in amplitude along the z axis (i.e., in $\hat{\mathbf{z}}$ if $z \geq a$ and in $-\hat{\mathbf{z}}$ if $z \leq -a$). The spectral amplitude function $f(\mathbf{s}, \omega)$ in (10) is related to the source spectrum $q(\mathbf{r}, \omega)$ by¹⁵

$$f(\mathbf{s}, \omega) = \tilde{q}(\mathbf{K}, \omega)|_{\mathbf{K}=(\omega/c)\mathbf{s}} = \int_{r' \leq a} d\mathbf{r}' e^{-i(\omega/c)\mathbf{s} \cdot \mathbf{r}'} q(\mathbf{r}', \omega). \quad (11)$$

It is noted that since we require $q(\mathbf{r}, \omega)$ to be continuous and compactly supported in space, it follows that $\tilde{q}(\mathbf{K}, \omega)$ is, for fixed frequency ω , the boundary value, on the real K_x, K_y, K_z axes, of an entire analytic function of three complex variables K_x, K_y, K_z . Thus, for fixed frequency ω ,

$f(\mathbf{s}, \omega)$ is given by the value of the spatial Fourier transform $\tilde{q}(\mathbf{K}, \omega)$, and its analytic continuation into the complex \mathbf{K} plane, of the source spectrum $q(\mathbf{r}, \omega)$ evaluated at $\mathbf{K} = (\omega/c)\mathbf{s}$.

By performing the ω integration in (10) and using (5) we obtain

$$U^+(\mathbf{r}, t) = -\frac{1}{2\pi c} \frac{\partial}{\partial t} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha F^+(\mathbf{s}, t - \mathbf{s} \cdot \mathbf{r}/c), \quad (12)$$

where from Eq. (11)

$$F^+(\mathbf{s}, t) \equiv \frac{1}{2\pi} \int_0^{\infty} d\omega' e^{-i\omega' t} f(\mathbf{s}, \omega') = \int_{r' \leq a} d\mathbf{r}' Q^+(\mathbf{r}', t + \mathbf{s} \cdot \mathbf{r}'/c). \quad (13)$$

Equations (12) and (13) define the time-dependent plane wave representation of the analytic signal $U^+(\mathbf{r}, t)$ corresponding to the real, physical field $U(\mathbf{r}, t)$.

Equation (13) is the time domain analog of (11). The operation defined by the integral on the right-hand side of Eq. (13), sometimes referred to as “slant-stack transform” of the analytic source distribution $Q^+(\mathbf{r}, t)$, has been studied in recent years by Heyman.¹⁶ It involves spatial Radon projection of $Q^+(\mathbf{r}, t)$ evaluated at planes normal to the spectral propagation direction \mathbf{s} and stacking them with a progressive time delay $\mathbf{s} \cdot \mathbf{r}/c$ associated with a wave front propagating at the speed of light along this direction. Mathematically, $F^+(\mathbf{s}, t)$ is given by the value of the fourfold Radon transform, and its analytic continuation for complex \mathbf{s} ,¹⁷ of the analytic source distribution evaluated at the hyperplane $ct - \mathbf{s} \cdot \mathbf{r} = 0$ in a four-dimensional space-time domain (ct, \mathbf{r}) .

The real, physical field $U(\mathbf{r}, t)$ is recovered from $U^+(\mathbf{r}, t)$ via Eqs. (6) and (5). In the far radiation zone¹⁴

$$U(r\hat{\mathbf{r}}, t)|_{r \rightarrow \infty} \sim \frac{1}{r} F(\mathbf{s}, \tau)|_{\mathbf{s}=\hat{\mathbf{r}}} \quad (14)$$

with $\tau = t - r/c$. Thus the time domain radiation pattern is from Eq. (14), the propagating portion of the time-dependent plane-wave spectrum. The evanescent spectrum can be recovered by analytic continuation of the time domain radiation pattern to complex-valued observation directions.¹⁷ The individual contributions of the propagating and evanescent spectra to the total field have been examined in detail by Heyman,¹⁶ who has shown that the contribution from the evanescent spectrum vanishes after a certain time t_E that may be determined *a priori* for a given field point; in regions of space where t_E occurs prior to the causal arrival time of the field, the latter is describable only by its propagating spectrum within the causal time window while noncausal contributions due to both propagating and evanescent spectra cancel out prior to the causal arrival time.

B. Multipole theory in the frequency domain

The multipole expansion of the radiated field spectrum $u(\mathbf{r}, \omega)$ is readily obtained by expanding the spectral amplitudes $f(\mathbf{s}, \omega)$ of the (frequency domain) angular spectrum expansion

$$u(\mathbf{r}, \omega) = \frac{i\omega/c}{2\pi} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha f(\mathbf{s}, \omega) e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}} \quad (15)$$

into a series of spherical harmonics $Y_{\ell, m}(\alpha, \beta)$ (see Appendix A for a review) so that

$$f(\mathbf{s}, \omega) = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} (-i)^{\ell} \tilde{a}_{\ell, m}(\omega) Y_{\ell, m}(\alpha, \beta) \quad (16)$$

where

$$\tilde{a}_{\ell, m}(\omega) = i^{\ell} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha f(\mathbf{s}, \omega) Y_{\ell, m}^*(\alpha, \beta). \quad (17)$$

By substituting from Eqs. (16) and (17) into Eq. (15) while interchanging orders of integration and summation one readily finds

$$u(\mathbf{r}, \omega) = \frac{i\omega}{c} \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} \tilde{a}_{\ell,m}(\omega) \Pi_{\ell,m}(\mathbf{r}, \omega), \quad (18)$$

where

$$\Pi_{\ell,m}(\mathbf{r}, \omega) = (-i)^{\ell} \frac{1}{2\pi} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha Y_{\ell,m}(\alpha, \beta) e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}} \quad (19)$$

is precisely the angular spectrum representation of the scalar multipole field of degree ℓ and order m , i.e.,⁴

$$\Pi_{\ell,m}(\mathbf{r}, \omega) = h_{\ell}^{(1)}\left(\frac{\omega}{c} r\right) Y_{\ell,m}(\theta, \phi). \quad (20)$$

In Eq. (20), $h_{\ell}^{(1)}(\cdot)$ is the spherical Hankel function of the first kind of order ℓ (as defined in Ref. 14). Even though Eqs. (18) and (20) were derived for $\omega > 0$, they apply to all real ω . This fact is implicit in our time-dependent multipole treatment (Sec. II C). For example, the operator $\mathcal{L}_{\ell}^{(r,t)}$ in Eq. (24) applies to both analytic and real signals.

The multipole expansion Eq. (18) is valid for $r \geq a$ while the plane wave expansion Eq. (15) is valid for $|z| \geq a$. However, it is obvious that as long as \mathbf{r} is outside the source, one can always decompose the radiated field spectrum $u(\mathbf{r}, \omega)$ in the form Eq. (15) by a suitable choice of coordinates.¹⁶

An alternative expression for the multipole moments $\tilde{a}_{\ell,m}(\omega)$ is obtained by substituting (11) on (17) and interchanging orders of integration so as to yield⁴

$$\tilde{a}_{\ell,m}(\omega) = 4\pi \int_{r' \leq a} d\mathbf{r}' q(\mathbf{r}', \omega) \Lambda_{\ell,m}^*(\mathbf{r}', \omega) \quad (21)$$

with

$$\Lambda_{\ell,m}(\mathbf{r}, \omega) \equiv j_{\ell}\left(\frac{\omega}{c} r\right) Y_{\ell,m}(\theta, \phi) = (-i)^{\ell} \frac{1}{4\pi} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha Y_{\ell,m}(\alpha, \beta) e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}}, \quad (22)$$

where $j_{\ell}(\cdot)$ is the spherical Bessel function of the first kind and order ℓ (as defined in Ref. 4).

The multipole expansion enjoys several advantages over the angular spectrum expansion. First of all, we see from Eq. (17) that the multipole moments $\tilde{a}_{\ell,m}(\omega)$ are defined only by the real \mathbf{s} (propagating) spectral amplitudes $f(\mathbf{s}, \omega)$. Thus, in contrast to the angular spectrum expansion—which requires analytic continuation—the multipole expansion requires no analytic continuation of $f(\mathbf{s}, \omega)$ for complex values of the polar angle α . In addition, unlike the plane waves $e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}}$, the multipole fields $\Pi_{\ell,m}(\mathbf{r}, \omega)$ obey Sommerfeld's radiation condition. Hence, the multipole expansion is, unlike the angular spectrum expansion, a true mode expansion of the radiation field spectrum. This can be of interest if one wishes to approximate the radiated field either by truncating the series (18) or by limiting the (α, β) region of integration in (15). In the former case the approximation will obey Sommerfeld's radiation condition while in the latter it will not. These advantages are obtained, however, at the expense of the increased complexity of the spherical wave fields $\Pi_{\ell,m}(\mathbf{r}, \omega)$ as compared to the plane waves $e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}}$.

C. Time-dependent multipole expansion of the scalar field

Next we obtain a time domain multipole expansion for the scalar field $U(\mathbf{r}, t)$ following the lines of Ref. 3. Our starting point is the result [see Ref. 18, Eq. (10.1.16)]

$$\frac{1}{2\pi} \int_0^\infty d\omega e^{-i\omega t} h_\ell^{(1)}\left(\frac{\omega}{c} r\right) \tilde{a}_{\ell,m}(\omega) = -(-i)^\ell \frac{c}{r} \partial_t^{-1} \mathcal{L}_{\ell}^{(r,t)} a_{\ell,m}^+(t), \quad (23)$$

where

$$a_{\ell,m}^+(t) = \frac{1}{2\pi} \int_0^\infty d\omega e^{-i\omega t} \tilde{a}_{\ell,m}(\omega)$$

and

$$\mathcal{L}_{\ell}^{(r,t)} a_{\ell,m}^+(t) = \sum_{n=0}^{\ell} \frac{(\ell+n)!}{n!(\ell-n)!} \left(\frac{2r}{c}\right)^{-n} \partial_t^{-n} a_{\ell,m}^+(\tau). \quad (24)$$

In Eqs. (23) and (24) $\tau = t - r/c$ (as before) and ∂_t^{-n} denotes n th-order temporal integration [recall (7)].

By Fourier inverting Eq. (18) over positive frequencies while using Eqs. (20) and (23) we obtain

$$U^+(\mathbf{r}, t) = \frac{1}{r} \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} (-i)^\ell Y_{\ell,m}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} a_{\ell,m}^+(t). \quad (25)$$

The analytic time-dependent multipole moments $a_{\ell,m}^+(t)$ are obtained by Fourier inverting over positive frequencies both sides of Eq. (17), thus giving

$$a_{\ell,m}^+(t) = i^\ell \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha F^+(\mathbf{s}, t) Y_{\ell,m}^*(\alpha, \beta). \quad (26)$$

Thus, for fixed t , the analytic time-dependent multipole moments $a_{\ell,m}^+(t)$ are, apart from the factor i^ℓ , given by projections of the analytic time-dependent plane wave spectrum $F^+(\mathbf{s}, t)$ [see Eq. (13)] onto the set of spherical harmonics $Y_{\ell,m}(\alpha, \beta)$. Note, however, that—as expected from our discussion in Eq. (17)—only the real- \mathbf{s} , propagating plane wave spectral components enter into play in Eq. (26).

An alternative form of Eq. (25) due to Hansen and Norris¹⁹ is obtained using (see Ref. 19 and references therein)

$$h_\ell^{(1)}\left(\frac{\omega}{c} r\right) Y_{\ell,m}(\theta, \phi) = i^{-\ell} \tilde{P}_{\ell,m}^\omega \frac{e^{i(\omega/c)r}}{i(\omega/c)r}, \quad (27)$$

where

$$\tilde{P}_{\ell,m}^\omega = (-1)^m \sqrt{\frac{(2\ell+1)(\ell-m)!}{4\pi(\ell+m)!}} \left(\frac{1}{i(\omega/c)} \frac{\partial}{\partial x} + i \frac{1}{\omega} \frac{\partial}{\partial y} \right)^m P_\ell^{(m)} \left(\frac{1}{i} \frac{\omega}{c} \frac{\partial}{\partial z} \right), \quad m \geq 0, \quad (28)$$

where $P_\ell^{(m)}(\cdot)$ is the m th derivative of the Legendre polynomial and for $m < 0$, $\tilde{P}_{\ell,-m}^\omega = (-1)^m \tilde{P}_{\ell,m}^{\omega*}$. On substituting from Eqs. (27) and (28) into Eqs. (18) and (20) while using the complex-point source field expansion of the real-point source field [see Eq. (16) in Ref. 19]

$$\frac{e^{i(\omega/c)r}}{4\pi r} = \frac{1}{4\pi j_0(i(\omega/c)\rho)} \int_{-\pi}^{\pi} d\phi' \int_0^{\pi} d\theta' \sin \theta' \frac{e^{i(\omega/c)\xi(\theta', \phi')}}{4\pi \xi(\theta', \phi')}, \quad (29)$$

where $\xi = |\mathbf{r} - i\rho \hat{\mathbf{r}}'| = \xi_r + i\xi_i$ is the complex length having real and imaginary parts ξ_r and ξ_i , respectively, where $\rho \leq a$ is a positive constant (such that $\xi_r \geq 0$ and $-\rho \leq \xi_i \leq \rho$), and transforming to the time domain one obtains

$$U^+(\mathbf{r}, t) = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} (-i)^{\ell} \int_{-\pi}^{\pi} d\phi' \int_0^{\pi} d\theta' \sin \theta' \tilde{L}_0 \tilde{P}_{\ell m}^t \frac{a_{\ell, m}^+(t - \xi(\theta', \phi')/c)}{4\pi \xi(\theta', \phi')}, \quad (30)$$

where \tilde{L}_0 is a time domain operator whose frequency domain representation is $1/j_0((i\omega/c)\rho)$ [see Eq. (37) in Ref. 19] while $\tilde{P}_{\ell m}^t$ is the time domain analog of $\tilde{P}_{\ell m}^{\omega}$. Equation (30) is the result Eq. (59) in Ref. 19; it is an analytic field expansion in terms of time-dependent multipoles with complex-source locations. Unlike in Eq. (25), in Eq. (30) the basis functions are directionally localized; hence they are of interest in well-collimated wave radiation and propagation (see, e.g., Heyman and Felsen¹). However, the real-signal counterpart of the analytic complex-source multipole expansion Eq. (30) is complicated and involves convolutions; in contrast, the real-signal version of Eq. (25) is straightforward and can be written in terms of the operator $\mathcal{L}_{\ell}^{(r, t)}$. This is done below.

We use (25) to recover the real, physical field $U(\mathbf{r}, t) = 2\Re\{U^+(\mathbf{r}, t)\}$. In order to evaluate the real part of expression (25) we consider the real spherical harmonics $S_{\ell, m}^{(j)}$, with $\ell = 0, 1, \dots, m = 0, 1, \dots, \ell$ (see Appendix A). They obey the following orthogonality and completeness properties:³

$$\int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha S_{\ell, m}^{(j)}(\alpha, \beta) S_{\ell', m'}^{(j')}(\alpha, \beta) = \delta_{\ell, \ell'} \delta_{m, m'} \delta_{j, j'} \frac{1}{c_m}, \quad (31)$$

where $c_m = 1$ or 2 for $m = 0$ or $m \geq 1$, respectively, and

$$\sum_{\ell=1}^{\infty} \sum_{m=0}^{\ell} \sum_{j=1,2} c_m S_{\ell, m}^{(j)}(\alpha, \beta) S_{\ell', m'}^{(j')}(\alpha', \beta') = \frac{1}{\sin \alpha} \delta(\beta - \beta') \delta(\alpha - \alpha') \equiv \delta(\mathbf{s} - \mathbf{s}'). \quad (32)$$

[In Eq. (32), α' and β' are, respectively, the polar and azimuthal coordinates of the unit vector \mathbf{s}' .]

By taking the real part to both sides of Eq. (25) while using Eqs. (26), (32), and (31) one obtains (see derivation in Appendix B)

$$U(\mathbf{r}, t) = \frac{1}{r} \sum_{\ell=0}^{\infty} \sum_{m=0}^{\ell} \sum_{j=1,2} c_m S_{\ell, m}^{(j)}(\theta, \phi) \mathcal{L}_{\ell}^{(r, t)} q_{\ell, m}^{(j)}(t), \quad (33)$$

where we have introduced the new (real) multipole moments $q_{\ell, m}^{(j)}(t)$, defined via

$$q_{\ell, m}^{(j)}(t) = \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha F(\mathbf{s}, t) S_{\ell, m}^{(j)}(\alpha, \beta). \quad (34)$$

On comparing Eqs. (14) and (33) with $\mathcal{L}_{\ell}^{(r, t)}$ given by Eq. (24), the far field is seen to correspond to the lowest order term (i.e., $n = 0$) in the series expansion Eq. (24) corresponding to $\mathcal{L}_{\ell}^{(r, t)}$. Thus from Eq. (24) $\mathcal{L}_{\ell}^{(r, t)} q_{\ell, m}^{(j)}(t)|_{r \rightarrow \infty} \sim q_{\ell, m}^{(j)}(\tau)$. Using this result in Eq. (33) yields

$$U(\mathbf{r}, t)|_{r \rightarrow \infty} \sim \frac{1}{r} \sum_{\ell=0}^{\infty} \sum_{m=0}^{\ell} \sum_{j=1,2} c_m S_{\ell, m}^{(j)}(\theta, \phi) q_{\ell, m}^{(j)}(\tau). \quad (35)$$

Also, from (14) and (35), the time domain radiation pattern reduces to

$$F(\hat{\mathbf{r}}, t) = \sum_{\ell=0}^{\infty} \sum_{m=0}^{\ell} \sum_{j=1,2} c_m S_{\ell, m}^{(j)}(\theta, \phi) q_{\ell, m}^{(j)}(t). \quad (36)$$

Since the multipole moments $q_{\ell, m}^{(j)}(t)$ define via Eq. (33) the field everywhere outside the source, it follows from Eq. (34) that the time domain radiation pattern $F(\hat{\mathbf{r}}, t)$ also determines the field everywhere outside the source (problem of inverse diffraction from far field data^{3,4}).

Equation (34) defines the real time-dependent multipole moments $q_{\ell, m}^{(j)}(t)$ as projections of the time-dependent plane wave spectrum onto the set of real spherical harmonics. An alternative

formula for $q_{\ell,m}^{(j)}(t)$ based on a radially dependent weighted time average of $Q(\mathbf{r},t)$ follows readily from the time domain analog of Eq. (21). The remainder of this section is based on Eq. (21) and the following result:³

$$j_{\ell}(z) = \frac{(z/2)^{\ell}}{2^{\ell}\ell!} \int_{-1}^1 d\eta (1-\eta^2)^{\ell} e^{iz\eta}. \quad (37)$$

We begin by substituting from Eq. (37) into Eq. (21), thus obtaining

$$\tilde{a}_{\ell,m}(\omega) = \frac{4\pi c^{-\ell} \omega^{\ell}}{\ell! 2^{\ell+1}} \int_{r \leq a} d\mathbf{r} q(\mathbf{r}, \omega) Y_{\ell,m}^*(\theta, \phi) r^{\ell} \int_{-1}^1 d\eta (1-\eta^2)^{\ell} e^{-i\omega r \eta/c}. \quad (38)$$

The analytic time-dependent multipole moments $a_{\ell,m}^{+}(t)$ are obtained by Fourier inverting $\tilde{a}_{\ell,m}(\omega)$ as given by Eq. (38) over positive frequencies. This procedure yields

$$a_{\ell,m}^{+}(t) = \frac{1}{2\pi} \int_0^{\infty} d\omega e^{-i\omega t} \tilde{a}_{\ell,m}(\omega) = i^{\ell} \int_{-\pi}^{\pi} d\phi \int_0^{\pi} d\theta \sin \theta Y_{\ell,m}^*(\theta, \phi) F_{\ell}^{+}(\hat{\mathbf{r}}, t), \quad (39)$$

where

$$F_{\ell}^{+}(\hat{\mathbf{r}}, t) = \frac{4\pi c^{-\ell}}{\ell! 2^{\ell+1}} \int_{r \leq a} dr r^{\ell} \int_{-1}^1 d\eta (1-\eta^2)^{\ell} \frac{\partial^{\ell}}{\partial t^{\ell}} Q^{+}(\mathbf{r}, t + r\eta/c). \quad (40)$$

The real time-dependent multipole moments $q_{\ell,m}^{(j)}(t)$ follow from Eqs. (39) and (40) with $q_{\ell,m}^{+}(t) = (-i)^{\ell} a_{\ell,m}^{+}(t)$:

$$q_{\ell,m}^{(j)}(t) = \int_{-\pi}^{\pi} d\phi \int_0^{\pi} d\theta \sin \theta S_{\ell,m}^{(j)}(\theta, \phi) F_{\ell}(\hat{\mathbf{r}}, t), \quad (41)$$

where

$$F_{\ell}(\hat{\mathbf{r}}, t) = \frac{4\pi c^{-\ell}}{\ell! 2^{\ell+1}} \int_{r \leq a} dr r^{\ell} \int_{-1}^1 d\eta (1-\eta^2)^{\ell} \frac{\partial^{\ell}}{\partial t^{\ell}} Q(\mathbf{r}, t + r\eta/c). \quad (42)$$

The time-dependent real multipole moments $q_{\ell,m}^{(j)}(t)$ are now given from Eqs. (41) and (42) by the projection of an ℓ -dependent (effective) time domain radiation pattern $F_{\ell}(\hat{\mathbf{r}}, t)$ onto the set of real spherical harmonics. This latter quantity is computed using a two-step procedure described below.

The first step is that of η integration in (42). It involves radially dependent weighted time averaging of the ℓ th time derivative of the source distribution, $(\partial^{\ell}/\partial t^{\ell})Q(\mathbf{r}, t)$ (η integration plays the role of temporal integration). The term $(1-\eta^2)^{\ell}$ in Eq. (42) acts as weighting kernel. The η -integration limits in Eq. (42) define the time window $t \pm r/c$ within which weighted time averaging of $(\partial^{\ell}/\partial t^{\ell})Q(\mathbf{r}, t)$ is carried out. This first step acts on both the temporal and radial dependence of the source. The temporal nature of the source enters into play here through both time derivation and time averaging. On the other hand, both ℓ and r (and, therefore, also the source's radius a) control the effective time averaging window.

The second step is that of radial integration. It acts only on the radial dependence of the source. Thus it plays a role in controlling the relative relevance of the outer versus the inner source's structure in defining $q_{\ell,m}^{(j)}(t)$.

III. TIME-DEPENDENT PLANE WAVE AND MULTIPOLE EXPANSIONS OF ELECTROMAGNETIC FIELDS

In Gaussian systems of units, the time-dependent electric and magnetic field vectors $\mathcal{E}(\mathbf{r}, t)$ and $\mathcal{H}(\mathbf{r}, t)$, respectively, generated in free space by a time-dependent current distribution $\mathcal{J}(\mathbf{r}, t)$, are the causal solutions to the vector wave equations¹⁴

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}\right) \mathcal{E}(\mathbf{r}, t) = -4\pi \left[-\frac{1}{c^2} \frac{\partial}{\partial t} + \partial_t^{-1} \nabla \cdot \right] \mathcal{T}(\mathbf{r}, t), \quad (43)$$

$$\left(\nabla^2 - \frac{1}{c^2} \frac{\partial^2}{\partial t^2}\right) \mathcal{H}(\mathbf{r}, t) = -4\pi \frac{1}{c} \nabla \times \mathcal{T}(\mathbf{r}, t),$$

where, again, ∂_t^{-1} denotes integration over time [see Eq. (7)]. Here and henceforth it is assumed that $\mathcal{T}(\mathbf{r}, t)$ is a square-integrable, continuous and continuously differentiable function of (\mathbf{r}, t) , is confined to a finite region of radius a around the origin, and is turned on at some initial time $t = 0$. In Secs. III A and III B we derive new time-dependent plane wave and multipole expansions for $\mathcal{E}(\mathbf{r}, t)$ and $\mathcal{H}(\mathbf{r}, t)$ in terms of $\mathcal{T}(\mathbf{r}, t)$.

A. Plane wave expansion of electromagnetic fields in the time domain

It follows from (43) that each Cartesian component of the electromagnetic field vectors $\mathcal{E}(\mathbf{r}, t)$, $\mathcal{H}(\mathbf{r}, t)$ satisfies an inhomogeneous scalar wave equation of the form Eq. (8). Therefore, the results of Sec. II are applicable to each Cartesian component of $\mathcal{E}(\mathbf{r}, t)$ and $\mathcal{H}(\mathbf{r}, t)$. Thus, we introduce the analytic field vectors $\mathcal{E}^+(\mathbf{r}, t) = (1/2\pi) \int_0^\infty d\omega e^{-i\omega t} \mathbf{E}(\mathbf{r}, \omega)$, $\mathcal{H}^+(\mathbf{r}, t) = (1/2\pi) \int_0^\infty d\omega e^{-i\omega t} \mathbf{H}(\mathbf{r}, \omega)$, where $\mathbf{E}(\mathbf{r}, \omega)$ and $\mathbf{H}(\mathbf{r}, \omega)$ are, respectively, the electric and magnetic field spectrum. They are related to the analytic current distribution $\mathcal{T}^+(\mathbf{r}, t) = (1/2\pi) \int_0^\infty d\omega e^{-i\omega t} \mathbf{J}(\mathbf{r}, \omega)$ by Eq. (43) with \mathcal{E} , \mathcal{H} and \mathcal{T} substituted by \mathcal{E}^+ , \mathcal{H}^+ and \mathcal{T}^+ , respectively.

By applying to Eq. (43) the scalar case result Eq. (12) one obtains

$$\mathcal{E}^+(\mathbf{r}, t) = -\frac{1}{2\pi c} \frac{\partial}{\partial t} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha \mathbf{F}_E^+(\mathbf{s}, t - \mathbf{s} \cdot \mathbf{r}/c), \quad (44)$$

$$\mathcal{H}^+(\mathbf{r}, t) = -\frac{1}{2\pi c} \frac{\partial}{\partial t} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha \mathbf{F}_H^+(\mathbf{s}, t - \mathbf{s} \cdot \mathbf{r}/c),$$

where from Eq. (13)

$$\mathbf{F}_E^+(\mathbf{s}, t) = \int_{r' \leq a} d\mathbf{r}' \left[-\frac{1}{c^2} \frac{\partial}{\partial t} + \partial_t^{-1} \nabla' \cdot \right] \mathcal{T}^+(\mathbf{r}', t + \mathbf{s} \cdot \mathbf{r}'/c), \quad (45)$$

$$\mathbf{F}_H^+(\mathbf{s}, t) = \frac{1}{c} \int_{r' \leq a} d\mathbf{r}' \nabla' \times \mathcal{T}^+(\mathbf{r}', t + \mathbf{s} \cdot \mathbf{r}'/c),$$

with ∇' operating on \mathbf{r}' (∇' does not act on $t + \mathbf{s} \cdot \mathbf{r}'/c$). The results Eqs. (44) and (45) above define a new time-dependent plane wave representation for electromagnetic fields whose interpretation is analogous to that of its scalar counterpart Eqs. (12) and (13).

Next we would like to express Eq. (45) more compactly in terms of the slant-stack transform

$$\hat{\mathcal{T}}^+(\mathbf{s}, t) = \int_{r' \leq a} d\mathbf{r}' \mathcal{T}^+(\mathbf{r}', t + \mathbf{s} \cdot \mathbf{r}'/c) \quad (46)$$

of the analytic time-dependent current distribution \mathcal{T}^+ . By manipulating the integrals of Eq. (45) while using (46) we obtain (see derivation in Appendix C)

$$\mathbf{F}_E^+(\mathbf{s}, t) = \frac{1}{c^2} \frac{\partial}{\partial t} \{ \mathbf{s} \times [\mathbf{s} \times \hat{\mathcal{T}}^+(\mathbf{s}, t)] \}, \quad (47)$$

$$\mathbf{F}_H^+(\mathbf{s}, t) = -\frac{1}{c^2} \frac{\partial}{\partial t} [\mathbf{s} \times \hat{\mathcal{T}}^+(\mathbf{s}, t)].$$

We see from Eq. (47) that $\mathbf{F}_E^+(\mathbf{s}, t)$ and $\mathbf{F}_H^+(\mathbf{s}, t)$ are defined by the transverse part (relative to \mathbf{s})—and its analytic continuation to complex \mathbf{s} —of $\hat{\mathcal{T}}^+(\mathbf{s}, t)$. We see also from Eq. (47) that

$$\mathbf{s} \cdot \mathbf{F}_E^+(\mathbf{s}, t) = \mathbf{s} \cdot \mathbf{F}_H^+(\mathbf{s}, t) = 0, \quad (48)$$

$$\mathbf{F}_E^+(\mathbf{s}, t) = -\mathbf{s} \times \mathbf{F}_H^+(\mathbf{s}, t).$$

Hence, the terms in the integrands of (44) represent—for each \mathbf{s} —electromagnetic plane waves, as expected.

We conclude this section by applying the scalar case result Eq. (14) to each Cartesian component of the field vectors, thus obtaining from (47) the far zone approximations

$$\mathcal{E}(r\hat{\mathbf{r}}, t)|_{r \rightarrow \infty} \sim \frac{1}{r} \mathbf{F}_E(\hat{\mathbf{r}}, \tau)|_{r \rightarrow \infty} = \frac{1}{c^2 r} \frac{\partial}{\partial t} \{ \hat{\mathbf{r}} \times [\hat{\mathbf{r}} \times \hat{\mathcal{T}}(\hat{\mathbf{r}}, \tau)] \}, \quad (49)$$

$$\mathcal{H}(r\hat{\mathbf{r}}, t)|_{r \rightarrow \infty} \sim \frac{1}{r} \mathbf{F}_H(\hat{\mathbf{r}}, \tau)|_{r \rightarrow \infty} = -\frac{1}{c^2 r} \frac{\partial}{\partial t} [\hat{\mathbf{r}} \times \hat{\mathcal{T}}(\hat{\mathbf{r}}, \tau)]$$

where, as before, $\tau = t - r/c$. Expressions (49) have been derived before in connection with questions of realizability of time domain radiation patterns¹⁷ and in time domain antenna characterization.²⁰

B. Time-dependent multipole expansion of the electromagnetic field

Next we will obtain an expansion of the analytic time-dependent electric and magnetic field vectors $\mathcal{E}^+(\mathbf{r}, t)$ and $\mathcal{H}^+(\mathbf{r}, t)$ in terms of vector spherical wave functions. Methodologically, first we will expand the analytic time-dependent plane wave spectra $[\mathbf{F}_E^+(\mathbf{s}, t)$ and $\mathbf{F}_H^+(\mathbf{s}, t)]$ into a series of the two sets of vector functions $\mathbf{Y}_{\ell, m}(\alpha, \beta)$ and $\mathbf{s} \times \mathbf{Y}_{\ell, m}(\alpha, \beta)$; later we will substitute the vector spherical harmonics expansions for $\mathbf{F}_E^+(\mathbf{s}, t)$ and $\mathbf{F}_H^+(\mathbf{s}, t)$ into the time-dependent plane wave expansions—Eq. (44). The first step above yields

$$\begin{aligned} \mathbf{F}_E^+(\mathbf{s}, t) &= \sum_{\ell=1}^{\infty} \sum_{m=-\ell}^{\ell} (-i)^{\ell} [a_{\ell, m}^+(t) \mathbf{s} \times \mathbf{Y}_{\ell, m}(\alpha, \beta) + b_{\ell, m}^+(t) \mathbf{Y}_{\ell, m}(\alpha, \beta)], \\ \mathbf{F}_H^+(\mathbf{s}, t) &= \sum_{\ell=1}^{\infty} \sum_{m=-\ell}^{\ell} (-i)^{\ell} [-a_{\ell, m}^+(t) \mathbf{Y}_{\ell, m}(\alpha, \beta) + b_{\ell, m}^+(t) \mathbf{s} \times \mathbf{Y}_{\ell, m}(\alpha, \beta)]. \end{aligned} \quad (50)$$

It is noted that the forms of the expansions above are consistent with Eq. (48).

By making use of the orthogonality condition of the vector spherical harmonics, Eq. (A8), we obtain from Eq. (50)

$$\begin{aligned} a_{\ell, m}^+(t) &= -\frac{i^{\ell}}{\ell(\ell+1)} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha \mathbf{F}_H^+(\mathbf{s}, t) \cdot \mathbf{Y}_{\ell, m}^*(\alpha, \beta), \\ b_{\ell, m}^+(t) &= \frac{i^{\ell}}{\ell(\ell+1)} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha \mathbf{F}_E^+(\mathbf{s}, t) \cdot \mathbf{Y}_{\ell, m}^*(\alpha, \beta). \end{aligned} \quad (51)$$

Thus the analytic time-dependent multipole moments $a_{\ell, m}^+(t)$ and $b_{\ell, m}^+(t)$ are defined by the projections of $\mathbf{F}_H^+(\mathbf{s}, t)$ and $\mathbf{F}_E^+(\mathbf{s}, t)$, respectively, onto the set of vector spherical harmonics.

The time-dependent multipoles can also be expressed directly in terms of the slant-stack transform of the current distribution by substituting from Eq. (47) into Eq. (51), thus giving

$$a_{\ell,m}^+(t) = \frac{i^\ell c^{-2}}{\ell(\ell+1)} \frac{\partial}{\partial t} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha [\mathbf{s} \times \hat{\mathcal{T}}^+(\mathbf{s}, t)] \cdot \mathbf{Y}_{\ell,m}^*(\alpha, \beta), \quad (52)$$

$$b_{\ell,m}^+(t) = \frac{i^\ell c^{-2}}{\ell(\ell+1)} \frac{\partial}{\partial t} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha \{ \mathbf{s} \times [\mathbf{s} \times \hat{\mathcal{T}}^+(\mathbf{s}, t)] \} \cdot \mathbf{Y}_{\ell,m}^*(\alpha, \beta).$$

Next we insert the series expansions Eq. (50) into the time-dependent plane wave expansions of the field vectors $\mathcal{E}(\mathbf{r}, t)$ and $\mathcal{H}(\mathbf{r}, t)$ [refer to Eq. (44)] and interchange orders of summation and integration, thus finding

$$\begin{aligned} \mathcal{E}^+(\mathbf{r}, t) = & -\frac{1}{2\pi c} \frac{\partial}{\partial t} \sum_{\ell=1}^{\infty} \sum_{m=-\ell}^{\ell} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha (-i)^\ell [a_{\ell,m}^+(t - \mathbf{s} \cdot \mathbf{r}/c) \mathbf{s} \times \mathbf{Y}_{\ell,m}(\alpha, \beta) \\ & + b_{\ell,m}^+(t - \mathbf{s} \cdot \mathbf{r}/c) \mathbf{Y}_{\ell,m}(\alpha, \beta)], \quad (53) \\ \mathcal{H}^+(\mathbf{r}, t) = & -\frac{1}{2\pi c} \frac{\partial}{\partial t} \sum_{\ell=1}^{\infty} \sum_{m=-\ell}^{\ell} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha (-i)^\ell [-a_{\ell,m}^+(t - \mathbf{s} \cdot \mathbf{r}/c) \mathbf{Y}_{\ell,m}(\alpha, \beta) \\ & + b_{\ell,m}^+(t - \mathbf{s} \cdot \mathbf{r}/c) \mathbf{s} \times \mathbf{Y}_{\ell,m}(\alpha, \beta)]. \end{aligned}$$

Next we shall solve the integrals over \mathbf{s} above so as to obtain the sought-after time-dependent multipole expansion of the electromagnetic field. For this purpose we will use the vector counterpart of Eqs. (19) and (20), given by⁴

$$\frac{(-i)^\ell}{2\pi} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha \mathbf{Y}_{\ell,m}(\alpha, \beta) e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}} = h_{\ell}^{(1)}\left(\frac{\omega}{c} r\right) \mathbf{Y}_{\ell,m}(\theta, \phi). \quad (54)$$

Furthermore, by applying the curl operator $\nabla \times$ to both sides of (54) while using $\nabla e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}} = i(\omega/c) \mathbf{s} e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}}$ and $\nabla \times \mathbf{Y}_{\ell,m}(\alpha, \beta) = 0$, one readily obtains⁴

$$\frac{(-i)^\ell}{2\pi} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha \mathbf{s} \times \mathbf{Y}_{\ell,m}(\alpha, \beta) e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}} = \frac{-ic}{\omega} \nabla \times \left[h_{\ell}^{(1)}\left(\frac{\omega}{c} r\right) \mathbf{Y}_{\ell,m}(\theta, \phi) \right]. \quad (55)$$

The following results follow readily from Eqs. (54) and (55) and Eqs. (23) and (24):

$$\begin{aligned} & \frac{(-i)^\ell}{2\pi} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha a_{\ell,m}^+(t - \mathbf{s} \cdot \mathbf{r}/c) \mathbf{Y}_{\ell,m}(\alpha, \beta) \\ &= \frac{1}{2\pi} \int_0^{\infty} d\omega e^{-i\omega t} \tilde{a}_{\ell,m}(\omega) h_{\ell}^{(1)}\left(\frac{\omega}{c} r\right) \mathbf{Y}_{\ell,m}(\theta, \phi) \\ &= -(-i)^\ell \frac{c}{r} \mathbf{Y}_{\ell,m}(\theta, \phi) \partial_t^{-1} \mathcal{L}_{\ell}^{(r,t)} a_{\ell,m}^+(t) \end{aligned} \quad (56)$$

and, similarly,

$$\begin{aligned} & \frac{(-i)^\ell}{2\pi} \int_{-\pi}^{\pi} d\beta \int_{C_{\pm}} d\alpha \sin \alpha a_{\ell,m}^+(t - \mathbf{s} \cdot \mathbf{r}/c) \mathbf{s} \times \mathbf{Y}_{\ell,m}(\alpha, \beta) = \frac{1}{2\pi} \int_0^{\infty} d\omega e^{-i\omega t} \tilde{a}_{\ell,m}(\omega) \left\{ \frac{-ic}{\omega} \right. \\ & \quad \left. \times \nabla \left[h_{\ell}^{(1)}\left(\frac{\omega}{c} r\right) \mathbf{Y}_{\ell,m}(\theta, \phi) \right] \right\} = (-i)^\ell \frac{c^2}{r} \partial_t^{-2} \nabla \times [\mathbf{Y}_{\ell,m}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} a_{\ell,m}^+(t)]. \end{aligned} \quad (57)$$

By substituting from Eqs. (56) and (57) into Eq. (53) we obtain

$$\begin{aligned}
\mathcal{E}^+(\mathbf{r}, t) &= \sum_{\ell=1}^{\infty} \sum_{m=-\ell}^{\ell} \frac{1}{r} (-i)^{\ell} \{ -c \partial_t^{-1} \nabla \times [\mathbf{Y}_{\ell,m}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} a_{\ell,m}^+(t)] \\
&\quad + \mathbf{Y}_{\ell,m}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} b_{\ell,m}^+(t) \} \\
\mathcal{H}^+(\mathbf{r}, t) &= \sum_{\ell=1}^{\infty} \sum_{m=-\ell}^{\ell} \frac{1}{r} (-i)^{\ell} \{ -\mathbf{Y}_{\ell,m}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} a_{\ell,m}^+(t) \\
&\quad - c \partial_t^{-1} \nabla [\mathbf{Y}_{\ell,m}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} b_{\ell,m}^+(t)] \}.
\end{aligned} \tag{58}$$

Furthermore, we can now express the real electric and magnetic fields using the real vector spherical harmonics (refer to Appendix A for a review) following lines analogous to those used for scalar fields in Sec. II C. By analogy with our treatment of the scalar field we begin by introducing the new (real) multipole moments

$$\begin{aligned}
c_{\ell,m}^{(j)}(t) &= -\frac{1}{\ell(\ell+1)} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha \mathbf{F}_H(\mathbf{s}, t) \cdot \mathbf{S}_{\ell,m}^{(j)}(\alpha, \beta), \\
d_{\ell,m}^{(j)}(t) &= \frac{1}{\ell(\ell+1)} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha \mathbf{F}_E(\mathbf{s}, t) \cdot \mathbf{S}_{\ell,m}^{(j)}(\alpha, \beta).
\end{aligned} \tag{59}$$

We can also express $c_{\ell,m}^{(j)}(t)$ and $d_{\ell,m}^{(j)}(t)$ in terms of the slant-stack transform of the current distribution by substituting from Eq. (47) into Eq. (59). This procedure yields

$$\begin{aligned}
c_{\ell,m}^{(j)}(t) &= \frac{c^{-2}}{\ell(\ell+1)} \frac{\partial}{\partial t} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha [\mathbf{s} \times \hat{\mathcal{T}}(\mathbf{s}, t)] \cdot \mathbf{S}_{\ell,m}^{(j)}(\alpha, \beta), \\
d_{\ell,m}^{(j)}(t) &= \frac{c^{-2}}{\ell(\ell+1)} \frac{\partial}{\partial t} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha \{ \mathbf{s} \times [\mathbf{s} \times \hat{\mathcal{T}}(\mathbf{s}, t)] \} \cdot \mathbf{S}_{\ell,m}^{(j)}(\alpha, \beta),
\end{aligned} \tag{60}$$

in analogy to its analytic signal counterpart Eq. (52). Both forms of time-dependent multipole moments defined above [i.e., Eqs. (59) and (60)] appear to be new.

By employing the vector counterpart of the procedure used to derive Eq. (33) from Eq. (25) (see Appendix B), we obtain from Eq. (58) the sought-after time-dependent multipole representation for the real, physical fields:

$$\begin{aligned}
\mathcal{E}(\mathbf{r}, t) &= \sum_{\ell=1}^{\infty} \sum_{m=0}^{\ell} \sum_{j=1,2} c_m \frac{1}{r} \{ -c \partial_t^{-1} \nabla \times [\mathbf{S}_{\ell,m}^{(j)}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} c_{\ell,m}^{(j)}(t)] + \mathbf{S}_{\ell,m}^{(j)}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} d_{\ell,m}^{(j)}(t) \}, \\
\mathcal{H}(\mathbf{r}, t) &= \sum_{\ell=1}^{\infty} \sum_{m=0}^{\ell} \sum_{j=1,2} c_m \frac{1}{r} \{ -\mathbf{S}_{\ell,m}^{(j)}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} c_{\ell,m}^{(j)}(t) - c \partial_t^{-1} \nabla \times [\mathbf{S}_{\ell,m}^{(j)}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} d_{\ell,m}^{(j)}(t)] \},
\end{aligned} \tag{61}$$

where, as before, $c_m = 1$ or 2 if $m = 0$ or $m \geq 1$, respectively. Equation (61) is, to the authors' knowledge, also new. Note also that Eq. (59) gives the real electric and magnetic multipole moments in terms of the far electric and magnetic fields while Eq. (60) gives them in terms of the transverse part of the slant-stack transform of the current distribution. Thus, Eq. (61) yields solutions to the radiation problem as well as to the inverse diffraction problem from time domain far field data. The theory above also corroborates, in the time domain, the well-known result that the radiation pattern uniquely determines the radiated field everywhere outside the source, as is evident from Eqs. (61) and (59).

In analogy to our treatment of the scalar field in Sec. II, we conclude this section with alternative expressions for the real time-dependent multipole moments $c_{\ell,m}^{(j)}(t)$ and $d_{\ell,m}^{(j)}(t)$. The corresponding derivation follows by analogy with the procedure used in Sec. II.

We conveniently rewrite $a_{\ell,m}^+(t)$ as defined in Eq. (52) as

$$a_{\ell,m}^+(t) = -\frac{i^\ell c^{-1}}{\ell(\ell+1)} \int_{r \leq a} d\mathbf{r} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha [\nabla \times \mathcal{T}^+(\mathbf{r}, t + \mathbf{s} \cdot \mathbf{r}/c)] \cdot \mathbf{Y}_{\ell,m}^*(\alpha, \beta). \quad (62)$$

The result above was obtained by using (see Appendix C)

$$\mathbf{s} \times \hat{\mathcal{T}}^+(\mathbf{s}, t) = -c \partial_t^{-1} \int d\mathbf{r} \nabla \times \mathcal{T}^+(\mathbf{r}, t + \mathbf{s} \cdot \mathbf{r}/c). \quad (63)$$

A convenient expression for $b_{\ell,m}^+(t)$ is obtained, on the other hand, by substituting from Eq. (46) into Eq. (52) and interchanging orders of \mathbf{r} and \mathbf{s} integration, thus giving

$$b_{\ell,m}^+(t) = -\frac{i^\ell c^{-2}}{\ell(\ell+1)} \frac{\partial}{\partial t} \int_{r \leq a} d\mathbf{r} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha \mathcal{T}^+(\mathbf{r}, t + \mathbf{s} \cdot \mathbf{r}/c) \cdot \mathbf{Y}_{\ell,m}(\alpha, \beta), \quad (64)$$

where we have made use of $\mathbf{s} \times \mathbf{s} \times \mathbf{S}_{\ell,m}^{(j)}(\alpha, \beta) = -\mathbf{S}_{\ell,m}^{(j)}(\alpha, \beta)$ and the well-known vector identity $\mathbf{a} \cdot (\mathbf{b} \times \mathbf{c}) = \mathbf{b} \cdot (\mathbf{c} \times \mathbf{a}) = \mathbf{c} \cdot (\mathbf{a} \times \mathbf{b})$.

Next we make use of the vector counterpart of Eq. (22):⁴

$$\frac{(-i)^\ell}{4\pi} \int_{-\pi}^{\pi} d\beta \int_0^{\pi} d\alpha \sin \alpha \mathbf{Y}_{\ell,m}(\alpha, \beta) e^{i(\omega/c)\mathbf{s} \cdot \mathbf{r}} = j_\ell \left(\frac{\omega}{c} r \right) \mathbf{Y}_{\ell,m}(\theta, \phi). \quad (65)$$

By substituting from (65) into Eqs. (63) and (64) we obtain after some manipulations

$$\begin{aligned} a_{\ell,m}^+(t) &= -\frac{i^\ell c^{-1}}{\ell(\ell+1)} \frac{4\pi c^{-\ell}}{\ell! 2^{\ell+1}} \int_{-\pi}^{\pi} d\phi \int_0^{\pi} d\theta \sin \theta \mathbf{Y}_{\ell,m}^*(\theta, \phi) \cdot \left\{ \int_{r \leq a} dr r^\ell [\nabla \times \mathbf{I}^+(\mathbf{r}, t)] \right\}, \\ b_{\ell,m}^+(t) &= -\frac{i^\ell c^{-2}}{\ell(\ell+1)} \frac{4\pi c^{-\ell}}{\ell! 2^{\ell+1}} \frac{\partial}{\partial t} \int_{-\pi}^{\pi} d\phi \int_0^{\pi} d\theta \sin \theta \mathbf{Y}_{\ell,m}^*(\theta, \phi) \cdot \left[\int_{r \leq a} dr r^\ell \mathbf{I}^+(\mathbf{r}, t) \right], \end{aligned} \quad (66)$$

with

$$\mathbf{I}^+(\mathbf{r}, t) = \int_{-1}^1 d\eta (1 - \eta^2)^\ell \frac{\partial^\ell}{\partial t^\ell} \mathcal{T}^+(\mathbf{r}, t + r\eta/c). \quad (67)$$

Equation (66) has been derived before from the Debye representation;^{6,7} here it has been obtained from the time-dependent plane wave representation.

Finally, the real time-dependent electric and magnetic multipole moments $c_{\ell,m}^{(j)}(t)$ and $d_{\ell,m}^{(j)}(t)$ are readily obtained from Eqs. (66) and (67) by recalling that $c_{\ell,m}^+(t) = (-i)^\ell a_{\ell,m}^+(t)$ and $d_{\ell,m}^+(t) = (-i)^\ell b_{\ell,m}^+(t)$. We obtain

$$\begin{aligned} c_{\ell,m}^{(j)}(t) &= -\frac{c^{-1}}{\ell(\ell+1)} \frac{4\pi c^{-\ell}}{\ell! 2^{\ell+1}} \int_{-\pi}^{\pi} d\phi \int_0^{\pi} d\theta \sin \theta \mathbf{S}_{\ell,m}^{(j)}(\theta, \phi) \cdot \left\{ \int_{r \leq a} dr r^\ell [\nabla \times \mathbf{I}(\mathbf{r}, t)] \right\}, \\ d_{\ell,m}^{(j)}(t) &= -\frac{c^{-2}}{\ell(\ell+1)} \frac{4\pi c^{-\ell}}{\ell! 2^{\ell+1}} \frac{\partial}{\partial t} \int_{-\pi}^{\pi} d\phi \int_0^{\pi} d\theta \sin \theta \mathbf{S}_{\ell,m}^{(j)}(\theta, \phi) \cdot \left[\int_{r \leq a} dr r^\ell \mathbf{I}(\mathbf{r}, t) \right], \end{aligned} \quad (68)$$

with

$$\mathbf{I}(\mathbf{r}, t) = \int_{-1}^1 d\eta (1 - \eta^2)^\ell \frac{\partial^\ell}{\partial t^\ell} \mathcal{T}(\mathbf{r}, t + r\eta/c). \quad (69)$$

Equations (68) and (69) are the electromagnetic case counterparts of Eqs. (41) and (42) and their interpretation is analogous to that of Eqs. (41) and (42).

APPENDIX A: ORDINARY AND VECTOR SPHERICAL HARMONICS

We use the standard definition of the spherical harmonics:¹⁴

$$Y_{\ell,m}(\theta, \phi) = y_{\ell,m} P_{\ell}^m(\cos \theta) e^{im\phi} \quad (\text{A1})$$

with

$$y_{\ell,m} = \sqrt{\frac{(2\ell+1)(\ell-m)!}{4\pi(\ell+m)!}}, \quad (\text{A2})$$

where $\ell = 0, 1, 2, \dots$, $m = 0, \pm 1, \dots, \pm \ell$, and $P_{\ell}^m(x)$ are the associated Legendre polynomials, defined by means of the Rodrigues formula

$$P_{\ell}^m(x) = \frac{(-1)^m}{2^{\ell} \ell!} (1-x^2)^{m/2} \left(\frac{d}{dx} \right)^{\ell+m} (x^2-1)^{\ell}. \quad (\text{A3})$$

The spherical harmonics obey the orthogonality and closure properties¹⁴

$$\int_{-\pi}^{\pi} d\phi \int_0^{\pi} d\theta \sin \theta Y_{\ell,m}^*(\theta, \phi) Y_{\ell',m'}(\theta, \phi) = \delta_{\ell,\ell'} \delta_{m,m'}, \quad (\text{A4})$$

$$\sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} Y_{\ell,m}(\theta, \phi) Y_{\ell,m}^*(\theta', \phi') = \frac{1}{\sin \theta} \delta(\theta - \theta') \delta(\phi - \phi') \equiv \delta(\hat{\mathbf{r}} - \hat{\mathbf{r}}'). \quad (\text{A5})$$

The real spherical harmonics $S_{\ell,m}^{(1)}(\theta, \phi) \equiv \Re\{Y_{\ell,m}(\theta, \phi)\}$ and $S_{\ell,m}^{(2)}(\theta, \phi) \equiv \Im\{Y_{\ell,m}(\theta, \phi)\}$, where $\ell = 0, 1, 2, \dots$, and $m = 0, 1, \dots, \ell$, obey, on the other hand, the orthogonality and closure properties of Eqs. (31) and (32).³

The vector spherical harmonic $\mathbf{Y}_{\ell,m}(\theta, \phi)$ is defined by^{14,21}

$$\mathbf{Y}_{\ell,m}(\theta, \phi) = \mathbf{L} Y_{\ell,m}(\theta, \phi), \quad (\text{A6})$$

where

$$\mathbf{L} = -i\mathbf{r} \times \nabla = -i \left(\mathbf{u}_{\phi} \frac{\partial}{\partial \theta} - \frac{1}{\sin \theta} \mathbf{u}_{\theta} \frac{\partial}{\partial \phi} \right). \quad (\text{A7})$$

In Eq. (A7), \mathbf{u}_{θ} and \mathbf{u}_{ϕ} are, respectively, the unit vectors in the positive θ and ϕ directions. The $\mathbf{Y}_{\ell,m}(\theta, \phi)$'s are defined for $\ell = 1, 2, \dots$, and $m = 0, \pm 1, \dots, \pm \ell$. The value $\ell = 0$ is excluded since $Y_{0,0} = 1/\sqrt{4\pi}$, hence from Eqs. (A6) and (A7) $\mathbf{Y}_{0,0} = 0$.

The vector spherical harmonics $\mathbf{Y}_{\ell,m}(\theta, \phi)$ are everywhere tangential to the unit sphere [such that $\hat{\mathbf{r}} \cdot \mathbf{Y}_{\ell,m}(\theta, \phi) = 0$]. They satisfy the orthogonality condition^{14,21}

$$\int_{-\pi}^{\pi} d\phi \int_0^{\pi} d\theta \sin \theta \mathbf{Y}_{\ell,m}^*(\theta, \phi) \cdot \mathbf{Y}_{\ell',m'}(\theta, \phi) = \ell(\ell+1) \delta_{\ell,\ell'} \delta_{m,m'}. \quad (\text{A8})$$

They also form, together with the associated vector functions $\hat{\mathbf{r}} \times \mathbf{Y}_{\ell,m}(\theta, \phi)$, a complete orthogonal set in terms of which all well-behaved vector functions $\mathbf{F}(\hat{\mathbf{r}})$ with $\hat{\mathbf{r}} \cdot \mathbf{F}(\hat{\mathbf{r}}) = 0$ can be expanded.^{14,21}

We define the real vector spherical harmonics $\mathbf{S}_{\ell,m}^{(j)}$ via

$$\mathbf{S}_{\ell,m}^{(1)}(\theta, \phi) = \mathcal{I}\{\mathbf{Y}_{\ell,m}(\theta, \phi)\} = -i\mathbf{L}S_{\ell,m}^{(1)}, \quad (\text{A9})$$

$$\mathbf{S}_{\ell,m}^{(2)}(\theta, \phi) = \mathcal{R}\{\mathbf{Y}_{\ell,m}(\theta, \phi)\} = i\mathbf{L}S_{\ell,m}^{(2)},$$

so that, from (31) and $L^2 Y_{\ell,m} = \ell(\ell+1)Y_{\ell,m}$ (see Refs. 14 and 21),

$$\int_{-\pi}^{\pi} d\phi \int_0^{\pi} d\theta \sin \theta \mathbf{S}_{\ell,m}^{(j)}(\theta, \phi) \cdot \mathbf{S}_{\ell',m'}^{(j')}(\theta, \phi) = \ell(\ell+1) \delta_{\ell,\ell'} \delta_{m,m'} \delta_{j,j'} \frac{1}{c_m}. \quad (\text{A10})$$

They also form, together with the vector functions $\hat{\mathbf{r}} \times \mathbf{S}_{\ell,m}^{(j)}(\theta, \phi)$ a complete orthogonal set in terms of which all well-behaved vector functions $\mathbf{F}(\hat{\mathbf{r}})$ with $\hat{\mathbf{r}} \cdot \mathbf{F}(\hat{\mathbf{r}}) = 0$ can be expanded.

APPENDIX B: DERIVATION OF EQ. (33)

A key step in deriving (33) will consist in showing that

$$2\Re \left\{ \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} (-i)^{\ell} Y_{\ell,m}^m(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} a_{\ell,m}^+(t) \right\} = \sum_{\ell=0}^{\infty} \sum_{m=0}^{\ell} \sum_{j=1,2} c_m S_{\ell,m}^{(j)}(\theta, \phi) \mathcal{L}_{\ell}^{(r,t)} q_{\ell,m}^{(j)}(t) \quad (\text{B1})$$

with $a_{\ell,m}^+(t)$ and $q_{\ell,m}^{(j)}(t)$ given by (26) and (34), respectively, and where $c_m = 1$ or 2 for $m = 0$ or $m \geq 1$, respectively. To simplify the manipulations we will use Dirac bra-ket notation.²¹ Thus we represent the spherical and real spherical harmonics $Y_{\ell,m}$ and $S_{\ell,m}^{(j)}$, respectively, by the vectors (kets) $|\ell, m\rangle$ and $|\ell, m, j\rangle$, where²¹

$$Y_{\ell,m}(\theta, \phi) \equiv \langle \mathbf{r} | \ell, m \rangle, \quad (\text{B2})$$

$$S_{\ell,m}^{(j)}(\theta, \phi) \equiv \langle \mathbf{r} | \ell, m, j \rangle. \quad (\text{B3})$$

In Dirac bra-ket notation, the orthogonality and closure properties defined in Eqs. (A4) and (A5) and Eqs. (31) and (32) translate into

$$\langle \ell, m | \ell', m' \rangle = \delta_{\ell,\ell'} \delta_{m,m'}, \quad (\text{B4})$$

$$\sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} |\ell, m\rangle \langle \ell, m| = I, \quad (\text{B5})$$

$$\langle \ell, m, j | \ell', m', j' \rangle = \frac{1}{c_m} \delta_{\ell,\ell'} \delta_{m,m'} \delta_{j,j'}, \quad (\text{B6})$$

$$\sum_{\ell=0}^{\infty} \sum_{m=0}^{\ell} \sum_{j=1,2} c_m |\ell, m, j\rangle \langle \ell, m, j| = I, \quad (\text{B7})$$

where I is the identity operator. We introduce, conveniently, the new analytic multipole moments

$$q_{\ell,m}^+(t) \equiv (-i)^{\ell} a_{\ell,m}^+(t), \quad (\text{B8})$$

which are the ordinary spherical harmonic counterpart of $q_{\ell,m}^{(j)}(t)$. By substituting from (B8) into (25) and (26) while using Dirac bra-ket notation we obtain

$$U(\mathbf{r}, t) = \frac{1}{r} 2\Re \left\{ \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{\ell} \langle \mathbf{r} | \ell, m \rangle \mathcal{L}_{\ell}^{(r,t)} \langle \ell, m | F^+(t) \rangle \right\}. \quad (\text{B9})$$

By inserting the identity operator right after the term $\langle \ell, m |$ in Eq. (B9) while making use of Eqs. (B5) and (B7) and interchanging orders of summation one readily finds

$$U(\mathbf{r}, t) = \frac{1}{r} \sum_{\ell'=0}^{\infty} \sum_{m'=0}^{\ell'} \sum_{j'=1,2} c_{m'} \langle \mathbf{r} | \ell', m', j' \rangle \mathcal{L}_{\ell'}^{(r,t)} \langle \ell', m', j' | F(t) \rangle. \quad (\text{B10})$$

Finally, we complete our derivation of Eq. (33) by substituting expression (B3) and $q_{\ell', m'}^{(j')}(t) = \langle \ell', m', j' | F(t) \rangle$ [this follows from Eq. (34)] in Eq. (B10).

APPENDIX C: DERIVATION OF EQS. (47)

Consider a four-dimensional (4D) space-time with Cartesian coordinates ($x_0 = ct$, $x_1 = x$, $x_2 = y$, $x_3 = z$) and denote the coordinate vector in space-time as \mathbf{x} . The Radon transform $R\mathbf{f}(\mathbf{v}, \xi)$ of a rather arbitrary vector function $\mathbf{f}(\mathbf{x})$ is defined as

$$R\mathbf{f}(\mathbf{v}, \xi) = \int d\mathbf{x} \mathbf{f}(\mathbf{x}) \delta(\xi - \mathbf{v} \cdot \mathbf{x}), \quad (\text{C1})$$

where \mathbf{v} is a unit vector in 4D Radon domain and ξ is a scalar. We will use the property [see Ref. 22, Eq. (6.7)]

$$R(\mathcal{H}\mathbf{f}) = \mathcal{H} \left(v_1 \frac{\partial}{\partial \xi}, \dots, v_n \frac{\partial}{\partial \xi} \right) R\mathbf{f}, \quad (\text{C2})$$

where x_k is the k th Cartesian component of \mathbf{x} , v_k is the k th Cartesian component of the unit vector \mathbf{v} and $\mathcal{H}(\partial/\partial x_1, \dots, \partial/\partial x_n)$ is a linear operator with constant coefficients.

By putting $\mathbf{f}^+(\mathbf{x}) \equiv \mathcal{F}^+(\mathbf{r}, t = x_0/c)$, Eq. (46) and the various definitions above yield

$$\hat{\mathcal{F}}^+(\mathbf{s}, t) = \frac{1}{\sqrt{2}} R\mathbf{f}^+(\mathbf{v}_s, ct/\sqrt{2}), \quad (\text{C3})$$

where $\mathbf{v}_s = (1/\sqrt{2})(1, -\mathbf{s})$ is the unit vector whose Cartesian components are ($x_0 = (1/\sqrt{2})$, $x_1 = -(1/\sqrt{2})$, $x_2 = -(1/\sqrt{2})$, $x_3 = -(1/\sqrt{2})$).

By substituting into Eq. (45) from Eqs. (C1)–(C3) we obtain

$$\mathbf{F}_E^+(\mathbf{s}, t) = \frac{1}{\sqrt{2}} R \left\{ \left[-\frac{1}{c^2} \frac{\partial}{\partial t} + \partial_t^{-1} \nabla \nabla \cdot \right] \mathbf{f}^+ \right\} (\mathbf{v}_s, ct/\sqrt{2}) \quad (\text{C4})$$

and

$$\mathbf{F}_H^+(\mathbf{s}, t) = \frac{1}{c\sqrt{2}} R \{ \nabla \times \mathbf{f}^+ \} (\mathbf{v}_s, ct/\sqrt{2}). \quad (\text{C5})$$

Using Eqs. (C2) and (C3) one can easily show that

$$\begin{aligned} R \{ \nabla \nabla \cdot \mathbf{f} \} (\mathbf{v}_s, ct/\sqrt{2}) &= \frac{1}{c^2} \frac{\partial^2}{\partial t^2} [\mathbf{s} \mathbf{s} \cdot R\mathbf{f}(\mathbf{v}_s, ct/\sqrt{2})], \\ R \{ \nabla \times \mathbf{f} \} (\mathbf{v}_s, ct/\sqrt{2}) &= -\frac{1}{c} \frac{\partial}{\partial t} [\mathbf{s} \times R\mathbf{f}(\mathbf{v}_s, ct/\sqrt{2})]. \end{aligned} \quad (\text{C6})$$

The final step consists of applying the results (C6)–(C3) to Eqs. (C4)–(C5) and substituting into the result thus obtained from Eq. (C3).

Buried Object Detection and Location Estimation from Electromagnetic Field Measurements

George A. Tsihrintzis, Peter Meincke Johansen,
and Anthony J. Devaney

Abstract—A translation property is derived describing the field scattered from a known buried object placed at distinct locations. The result is used to derive the optimum algorithm for detecting the known buried object and estimating its location from noisy scattered electromagnetic field measurements.

Index Terms—Ground penetrating radar, Lippmann–Schwinger equation, object detection, wave scattering.

I. INTRODUCTION

The problem of detecting known buried objects and estimating their location from electromagnetic field measurements is relevant in many technological areas such as demining, buried waste clean up, excavation planning, and archaeological investigations. In all of the above applications, serious challenges arise, mainly due to physical limitations such as: 1) significant losses due to moist soil that limit the signal-to-noise ratio; 2) presence of a large number of randomly distributed unwanted objects, returns from which obscure the return from the object of interest (volume clutter); and 3) random roughness of the air/soil interface that results in incoherent (random) returns (surface clutter). As a result of these limitations, standard threshold detection algorithms [1] may not successfully address the buried object detection problem, especially when the object is small and the return signal weak.

The signal processing strategy with the highest potential to address the buried object detection problem is the one that utilizes field models for the air/soil/object environment. Due to the complicated nature of this environment, however, certain simplifications need to be made, namely the assumption of a planar air/soil interface and of no interactions between the object of interest and the distribution of unwanted objects. These assumptions allow, as illustrated in this letter, the solution to the buried object detection problem within the framework of exact electromagnetic field scattering theory and the derivation of a computationally efficient optimum detection algorithm. More specifically, the letter is organized as follows. Section II is devoted to statement of the basic field equations governing the interaction of probing fields with the air/soil/object environment and derivation of a field translation property. Section III addresses the buried object detection problem and presents the maximum likelihood algorithm for the solution to it. Finally, Section IV is a discussion of the results of the letter with suggestions for possible future research avenues.

II. CONFIGURATION AND SCATTERING EQUATIONS

Consider the configuration in Fig. 1 in which a planar interface separates air (medium 1) from soil (medium 2). The orthogonal coordinate system $\mathbf{r} = \mathbf{x} + \hat{z}z$ is defined, with \mathbf{x} indicating a two-dimensional (2-D) coordinate on the interface and the z axis directed so that $z > 0$ is air and $z < 0$ is soil. Buried in the soil is a known target object, but its coordinates $\mathbf{r}_c = \mathbf{x}_c + \hat{z}z_c$ with $z_c \leq 0$ are unknown. A monochromatic plane wave with electric field $\mathbf{E}^i(\mathbf{r}) = \mathbf{E}_0 e^{i\mathbf{k}_1 \cdot \mathbf{r}}$ and wavevector \mathbf{k}_1 is incident upon the planar interface. As the incident field reaches the interface, it partially reflects back into air and partially refracts into the soil where it interacts with the buried object. The interaction produces a scattered field, part of which refracts back into air where it is measured.

The total field $\mathbf{E}(\mathbf{r}; \mathbf{r}_c)$ at position \mathbf{r} is given by

$$\mathbf{E}(\mathbf{r}; \mathbf{r}_c) = \mathbf{E}^b(\mathbf{r}) + \mathbf{E}^s(\mathbf{r}; \mathbf{r}_c) \quad (1)$$

where $\mathbf{E}^b(\mathbf{r})$ is the electric field in the absence of the buried object (background field) consisting of the incident and the reflected field in air and the refracted field in soil and $\mathbf{E}^s(\mathbf{r}; \mathbf{r}_c)$ is the scattered field due to the presence of the buried object at the unknown location \mathbf{r}_c .

$$\mathbf{E}^s(\mathbf{r}; \mathbf{r}_c) = \begin{cases} \mathbf{E}_2^s(\mathbf{r}; \mathbf{r}_c) \equiv \int_{z' < 0} \bar{\mathbf{G}}_{22}(\mathbf{r}, \mathbf{r}') \cdot [\mathbf{E}^b(\mathbf{r}') + \mathbf{E}_2^s(\mathbf{r}'; \mathbf{r}_c)] O(\mathbf{r}'; \mathbf{r}_c) d^3 r', & z < 0 \text{ (soil)} \\ \mathbf{E}_1^s(\mathbf{r}; \mathbf{r}_c) \equiv \int_{z' < 0} \bar{\mathbf{G}}_{12}(\mathbf{r}, \mathbf{r}') \cdot [\mathbf{E}^b(\mathbf{r}') + \mathbf{E}_2^s(\mathbf{r}'; \mathbf{r}_c)] O(\mathbf{r}'; \mathbf{r}_c) d^3 r', & z > 0 \text{ (air)}. \end{cases} \quad (2)$$

In (2), the object function $O(\mathbf{r}; \mathbf{r}_c)$ is defined as

$$O(\mathbf{r}; \mathbf{r}_c) = k^2(\mathbf{r}; \mathbf{r}_c) - k_2^2 \quad (3)$$

where $k(\mathbf{r}; \mathbf{r}_c)$ is the complex wavenumber at point \mathbf{r} and k_2 is the complex wavenumber of the soil. Equation (2) is the Lippmann–Schwinger equation for the scattering problem and maps the object function to the corresponding scattered field nonlinearly.

The dyadic Green functions $\bar{\mathbf{G}}_{12}$ and $\bar{\mathbf{G}}_{22}$ are defined for the source point in soil and the observation point in air and soil, respectively. Explicit expressions for them can be found in [2]; however, the critical information for this context is that both Green

Fig. 1. Configuration of the buried object detection problem in which a plane wave is impinging upon the air/soil interface. From scattered field measurements above the interface, an estimate of the location of the known object is searched for.

functions satisfy the property $\bar{\mathbf{G}}(\mathbf{r}, \mathbf{r}') = \bar{\mathbf{G}}(\mathbf{x} - \mathbf{x}', z, z')$. Express now the object function $O(\mathbf{r}; \mathbf{r}_c)$ as

$$O(\mathbf{r}; \mathbf{r}_c) = O_0(\mathbf{r} - \mathbf{r}_c) \quad (4)$$

describing the known buried object $O_0(\mathbf{r})$ located at $\mathbf{r}_c = \mathbf{x}_c + \hat{z}z_c$. The scattered field in soil satisfies the upper branch in (2) or, equivalently, as algebraic manipulation shows

$$\begin{aligned} & e^{-i\mathbf{K} \cdot \mathbf{x}_c} \mathbf{E}_2^s(\mathbf{r} + \mathbf{x}_c; \mathbf{r}_c) \\ &= \int_{z' < 0} \bar{\mathbf{G}}_{22}(\mathbf{x} - \mathbf{x}', z, z') \cdot [\mathbf{E}^b(\mathbf{r}') \\ &+ e^{-i\mathbf{K} \cdot \mathbf{x}_c} \mathbf{E}_2^s(\mathbf{r}' + \mathbf{x}_c; \mathbf{r}_c)] O_0(\mathbf{r}' - \hat{z}z_c) d^3 r' \end{aligned} \quad (5)$$

where $\mathbf{K} = \mathbf{k}_1 - \hat{z}\hat{z} \cdot \mathbf{k}_1$ is the horizontal component of \mathbf{k}_1 .

The key step is now to observe that the scattered field $\mathbf{E}_2^s(\mathbf{r}; \hat{z}z_c)$ due to the object centered at $\hat{z}z_c$, satisfies the same equation as does the quantity $e^{-i\mathbf{K} \cdot \mathbf{x}_c} \mathbf{E}_2^s(\mathbf{r} + \mathbf{x}_c; \mathbf{r}_c)$ in (5). Hence, from the uniqueness of the solution to the Lippmann-Schwinger equation (2), it is readily concluded that

$$\mathbf{E}_2^s(\mathbf{r}; \mathbf{r}_c) = e^{i\mathbf{K} \cdot \mathbf{x}_c} \mathbf{E}_2^s(\mathbf{r} - \mathbf{x}_c; \hat{z}z_c); \quad z < 0. \quad (6)$$

Similarly, from (6) and the lower branch in (2), it is seen that

$$\mathbf{E}_1^s(\mathbf{r}; \mathbf{r}_c) = e^{i\mathbf{K} \cdot \mathbf{x}_c} \mathbf{E}_1^s(\mathbf{r} - \mathbf{x}_c; \hat{z}z_c); \quad z > 0. \quad (7)$$

Equations (6) and (7) state that the scattered field at position \mathbf{r} due to an object located at \mathbf{r}_c is related through a phase factor to the scattered field at position $\mathbf{r} - \mathbf{x}_c$ due to the same object located at $\hat{z}z_c$. Therefore, these equations are the two-layer background medium equivalent to the homogeneous background medium field translation property first derived by Tsirintzis and Devaney in [3]. The main difference is that in the homogeneous background case, the field translation property also applies to vertical translations of the object. In the two-layer background case, however, vertical object translations do not result in simple, closed-form field translations such as (6) and (7), due to the nonlinearity associated with the multiple interactions between the object and the air/soil interface.

III. OBJECT LOCATION ESTIMATION

Consider now noisy signal measurements V of the scattered electric field \mathbf{E}_1^s on a plane $\mathbf{r}_p = \mathbf{x}_p + \hat{z}l$ parallel to the interface at a height l above the ground

$$\begin{aligned} V(\mathbf{x}_p) &= \alpha(\mathbf{x}_p; \mathbf{r}_c) + n(\mathbf{x}_p) \\ &\equiv \mathbf{h}(\mathbf{x}_p) \otimes_{\mathbf{x}_p} \mathbf{E}_1^s(\mathbf{x}_p + \hat{z}l; \mathbf{r}_c) + n(\mathbf{x}_p). \end{aligned} \quad (8)$$

Herein, $\mathbf{h}(\mathbf{x}_p)$ is a measurement filter comprising dot multiplication and convolution and $n(\mathbf{x}_p)$ is additive white Gaussian measurement noise. The problem is to estimate the unknown location \mathbf{r}_c of the buried object from the noisy measurements $V(\mathbf{x}_p)$. The desired estimate $\hat{\mathbf{r}}_c$ is computed by minimizing the squared error between the measured data and synthetic data computed for the object at a test location \mathbf{r}_t , i.e.,

$$\hat{\mathbf{r}}_c = \arg \min_{\mathbf{r}_t} \int |V(\mathbf{x}_p) - \alpha(\mathbf{x}_p; \mathbf{r}_t)|^2 d^2 x_p. \quad (9)$$

Under the additive white Gaussian noise assumption, the estimate thus returned is the maximum likelihood estimate [1]. The parameter \mathbf{r}_c of interest enters the signal model in a nonlinear manner; therefore, no unbiased estimate exists that achieves the lower (Cramér-Rao) bound¹ on error variance [1]. However, the likelihood function to be presented below in (11) and (13) contains the same information as the full set of measurements V for the estimation of the parameter \mathbf{r}_c and, therefore, constitutes a sufficient statistic for this problem. Additionally, the maximum likelihood estimate is asymptotically unbiased and optimum in the sense that it becomes unbiased and of minimum error variance as the data measurement procedure is repeated a large number of times [1].

To derive a computationally more efficient procedure for calculating $\hat{\mathbf{r}}_c$, (9) is rewritten in two steps. First, after expanding the square in (9), it is found that the estimate $\hat{\mathbf{r}}_c$ is equivalently obtained via maximization as

$$\hat{\mathbf{r}}_c = \arg \max_{\mathbf{r}_t} L(\mathbf{r}_t) \quad (10)$$

where $L(\mathbf{r}_t)$ is the log likelihood function [1] defined as

$$\begin{aligned} L(\mathbf{r}_t) &= \Re \left\{ \int V(\mathbf{x}_p) \alpha^*(\mathbf{x}_p; \mathbf{r}_t) d^2 x_p \right\} \\ &- \frac{1}{2} \int |\alpha(\mathbf{x}_p; \mathbf{r}_t)|^2 d^2 x_p. \end{aligned} \quad (11)$$

In (11), $*$ denotes the complex conjugate and $\Re\{\cdot\}$ the real part. The second term in (11) is independent of the data and, thus, can be precomputed as a function (image) of the variable \mathbf{r}_t and stored. Moreover, as can be seen from (7), it is independent of \mathbf{x}_t , the component of \mathbf{r}_t on the interface and, thus, needs only be computed for the range of values of interest of z_t . Second, using the field translation property (7) derived in Section II, Parseval's theorem, and the shift property of the Fourier transform, the first term in (11) becomes

$$\begin{aligned} & \int V(\mathbf{x}_p) \alpha^*(\mathbf{x}_p; \mathbf{r}_t) d^2 x_p \\ &= e^{-i\mathbf{K} \cdot \mathbf{x}_t} \int V(\mathbf{x}_p) \alpha^*(\mathbf{x}_p - \mathbf{x}_t; \hat{z}z_t) d^2 x_p \\ &= \frac{e^{-i\mathbf{K} \cdot \mathbf{x}_t}}{(2\pi)^2} \int e^{i\mathbf{K}_p \cdot \mathbf{x}_t} \tilde{V}(\mathbf{K}_p) \tilde{\alpha}^*(\mathbf{K}_p; \hat{z}z_t) d^2 K_p \end{aligned} \quad (12)$$

¹The Cramér-Rao bound for the estimation problem can be computed following a procedure similar to the one outlined in [4].

where $\hat{V}(\mathbf{K}_p) = \int e^{-i\mathbf{K}_p \cdot \mathbf{x}_p} V(\mathbf{x}_p) d^2x_p$ is the 2-D spatial Fourier transform of the signal measurements $V(\mathbf{x}_p)$. Substituting (12) into (11), the log likelihood function becomes

$$L(\mathbf{r}_t) = \frac{1}{(2\pi)^2} \cdot \Re \left\{ e^{-i\mathbf{K} \cdot \mathbf{x}_t} \int e^{i\mathbf{K}_p \cdot \mathbf{x}_t} \hat{V}(\mathbf{K}_p) \hat{\alpha}^*(\mathbf{K}_p; \hat{z}_t) d^2K_p \right\} - \frac{1}{2} \int |\alpha(\mathbf{x}_p; \mathbf{r}_t)|^2 d^2x_p. \quad (13)$$

Equations (10) and (13) define an algorithm that employs a bank of parallel procedures with each branch corresponding to a different test depth. In each branch of the bank, the data are convolutionally filtered (using for example a fast Fourier transform algorithm) and multiplied by the exponential factor $e^{-i\mathbf{K} \cdot \mathbf{x}_t}$. The filter in each branch is the one matched to signal measurements of the scattered field due to the object at zero horizontal location and at the corresponding depth. The algorithm returns a bank of images, the highest maximum of which gives the horizontal location estimate and the branch at which this occurs specifies the depth estimate. The algorithm of (10) and (13) can be readily generalized to the case where a multiplicity of scattering experiments are performed in each of which the wavevector \mathbf{k}_1 of the probing wave is varied in direction and/or temporal frequency. The maximum likelihood estimate is returned via maximization of the likelihood function obtained as the superposition of the expressions (13) computed for all probing wavevectors \mathbf{k}_1 .

IV. DISCUSSION AND FUTURE WORK

First, in this letter, a translation property was derived describing the field scattered by a known buried object placed at distinct locations in the soil. Next, the property was used to derive the maximum likelihood algorithm for detection and estimation of the location of a known buried object from noisy scattered electromagnetic field

measurements. It was shown that the algorithm attained the form (13), which could be efficiently implemented with use of a fast Fourier transform algorithm. Even though the case of a two-layer background medium was considered, the critical information for the derivations in the letter is that the Green functions in the Lippmann-Schwinger equation (2) satisfy the property $\overline{\mathbf{G}}(\mathbf{r}, \mathbf{r}') = \overline{\mathbf{G}}(\mathbf{x} - \mathbf{x}', z, z')$. The same property is satisfied by the Green functions for arbitrary background media that vary only in the vertical direction. Therefore, both the field translation property (7) and the expression in (13) for the likelihood function are valid for such background media.

Further research in this area seems appropriate. Issues to be addressed in the future include the derivation of proper detection and location estimation algorithms for the cases of probing with arbitrary (nonplane) waves and arbitrary measurement configurations. Another avenue of future research is in the direction of efficient time-domain algorithms for underground probing with electromagnetic pulses of very short duration. For such pulses, frequency-domain algorithms such as the one proposed in this letter may not exploit the entire data spectrum efficiently and direct time-domain may lead to more efficient implementations. This and related research is currently pursued and its results will be announced shortly.

Higher-Order (Nonlinear) Diffraction Tomography: Reconstruction Algorithms and Computer Simulation

George A. Tsihrintzis, *Member, IEEE*, and Anthony J. Devaney, *Member, IEEE*

Abstract—The usual propagation transform of diffraction tomography is generalized into higher-order (nonlinear) propagation transforms via use of the Born series as the data-generating model in scattering experiments. Nonlinear tomographic reconstruction algorithms are developed for inversion of scattered field data modeled up to an arbitrarily large (possibly infinite) number of terms in the Born series. A computer simulation study is included to illustrate the performance of the algorithms for the case of scattering objects with cylindrical symmetry.

Index Terms—Born series, diffraction tomography, image reconstruction, Volterra series.

I. INTRODUCTION

A. Historical Development of Diffraction Tomography

IN INVERSE scattering, an unknown scattering object is probed with known waves with the goal to deduce (reconstruct) a quantitative estimate of the object structure from measurements of the wavefields diffracted by it [7], [9], [42]. Applications from a number of different scientific disciplines, such as crystal structure determination [36], medical ultrasound tomography [25], acoustic and electromagnetic underground surveying [17], [75]–[77], optical and coherent X-ray microscopy [39], and elastic wave inverse scattering [20] can be addressed within the same unified mathematical theory of inverse scattering.

The structure determination objective of inverse scattering usually consists of an attempt to estimate the spatial distribution of the complex-valued index of refraction of the object by inverting the mathematical mapping relating the probing wave, the refraction index, and the measurable total wave. This objective is nontrivial to achieve due to the inherent nonuniqueness and nonlinearity of the mapping from index of refraction to scattered wave in any single scattering experiment [13]. The nonuniqueness issue can be partially addressed by employing a multiplicity of experiments, where the object is probed from several incident wave directions, and the full scattering data set is then available for the inversion. However, the issue of nonlinearity is significantly harder to address and, to date, research has

only produced mathematical results or computationally intensive iterative algorithms [2], [5], [6], [11], [12], [26], [28], [31], [32], [43], [70], [81] as opposed to practically implementable reconstruction algorithms.

Over the past 20 years, an alternative approach to the Inverse Scattering problem has been employed based on certain linearizing approximations [15], [18], [79], [80]. This approach has led to an expanded discipline within the regime of tomography, known as *diffraction tomography (DT)*. The first application of linearized inverse scattering seems to date back in 1912, when von Laue suggested that Friedrich and Knipping try diffracting X-rays by crystals in order to test the hypothesis that X-rays had wavelengths on the order of 10^{-10} m. The experiment was successful and led, within less than a year, to the first structure determination by X-ray methods (sodium chloride by Bragg) [3], [23]. Since then, X-ray probes are typically used to determine the structure of crystals using reconstruction algorithms based on the Born scattering model and measurement of far field intensity distributions [23], [36]. Indeed, the foundation of modern linearized DT lies in the generalized projection-slice theorem of (1.2), which forms the core of X-ray crystal structure determination and the basis of Wolf's pioneering work in 1969 [79].

In [79], Wolf showed how near field measurements can be employed to generate reconstructions within the Born model. Wolf's formulation was extended in 1974 by Iwata and Nagata [27] to determine the structure of a less restrictive class of scatterers satisfying the Rytov rather than the Born approximation. In 1979, Mueller *et al.* [41] employed the same concepts of the Born and Rytov approximations and presented Fourier interpolation-based algorithms for the inverse problem of ultrasound tomography, while in 1982 Devaney [15] derived an inversion algorithm, named "*the filtered backpropagation algorithm of DT*," for the inversion of full view, scattered field data under the Born or Rytov approximations. When scattering experiments are done at a wavelength λ , the filtered backpropagation algorithm returns an estimate of the unknown index of refraction distribution whose frequency content is the same as of the true distribution over a circular disk in Fourier space of radius $(2\pi/\lambda)\sqrt{2}$ and zero elsewhere [19].

The filtered backpropagation algorithm has been recognized as the one providing highest quality in the reconstructed images [45] and modifications to it have been presented by Devaney [17] in 1984, Deming and Devaney [10] in 1996, and Hansen and Johansen in 2000 to adjust it to the configurations employed in geophysical tomographic surveys. Tsihrintzis and Devaney addressed the reconstruction problem of linearized DT

from noisy scattered field data and showed that the optimum (Wiener) estimation filter attains again the form of a filtered backpropagation algorithm [66], [67]. Recently, a class of DT reconstruction algorithms with noise control was presented in [46]. Finally, iterative algorithms for inversion of an angularly limited set of noise-free linearized scattering data were presented by Ladas and Devaney in [33] and [34].

B. Mathematical Formulation of Diffraction Tomography

For two-dimensional (2-D) objects, the reconstruction problem of linearized DT consists of obtaining an estimate $\hat{f} \in L^2(R^2)$ of an unknown “object function” $f \in L^2(R^2)$ from its generalized projections (“propagations”) [19]

$$P_\theta f(t_0; s_0) = f(x) *_{\theta} \Gamma_\theta(x_0 - x); \quad \theta \in [0, 2\pi) \quad (1.1)$$

where $x_0 = t_0 u + s_0 v$, $t_0 \in R^1$ and s_0 : fixed, is a point on a “measurement line” that lies totally outside the support volume of the object. Here, θ is the angle between the t axis of a rotated Cartesian coordinate system (t, s) and the x_1 axis of a fixed Cartesian coordinate system (x_1, x_2) , and u, v denote unit vectors in the t, s directions respectively, as in Fig. 1. The transform kernel Γ_θ is such that the “generalized projection-slice theorem” holds [19]

$$\tilde{P}_\theta f(p; s_0) = \begin{cases} \frac{k}{m} e^{i(m-k)s_0} \tilde{f}[pu + (m-k)v], \\ \text{with } m = \sqrt{k^2 - p^2}, & \text{if } |p| \leq k \\ 0, & \text{otherwise} \end{cases} \quad (1.2)$$

where $k = (2\pi/\lambda)$ is the wavenumber of the probing wavefields and the tilde \sim denotes the Fourier transform

$$\tilde{P}_\theta f(p; s_0) = \int_{-\infty}^{\infty} dt_0 e^{-ipt_0} P_\theta f(t_0; s_0).$$

The generalized projection-slice theorem is illustrated in Fig. 2 and relates the one-dimensional (1-D) Fourier transform of a

Fig. 2. Generalized projection-slice theorem of diffraction tomography.

generalized projection to a semicircular slice through the 2-D Fourier transform of the object function f itself.¹

The above formulation of the inverse problem of DT is based on the assumption that the object being probed interacts weakly with the incident waves, so that either the Born or the Rytov approximations [15] hold. In that case, the object function f is related to the tomographic data $y(t_0, \theta)$ through the linear transform (1.1), provided that the data are defined as [15]

$$\begin{aligned} P_\theta f(t_0; s_0) &= y(t_0, \theta) \\ &= \begin{cases} \frac{e^{-iks_0}}{ik} \psi_\theta^{(s)}(x_0) & \text{within the Born approximation} \\ \frac{1}{ik} \delta\Phi_\theta(x_0) & \text{within the Rytov approximation.} \end{cases} \end{aligned} \quad (1.3)$$

In (1.3), $\psi_\theta^{(s)}(x_0)$ is the scattered wavefield measured at the point $x_0 = t_0 u + s_0 v$, $t_0 \in R^1$, s_0 : fixed, while $\delta\Phi_\theta(x_0)$ is the deviation of the unwrapped complex phase (i.e., the unwrapped complex log) of the total wavefield measured at x_0 from the complex phase $ik s_0$ of the incident wavefield at x_0 .

The inverse problem of DT, as formulated above, has been extensively studied in the literature and reconstruction algorithms have been devised of the Fourier interpolation type [41], or the filtered backpropagation type [15], [18], and, recently, of an iterative nature [33], [34]. Of particular importance to this paper is the filtered backpropagation algorithm [15], [18], which provides a reconstruction \hat{f} that corresponds to a lowpass filtered version of the unknown object function f . In particular, the filtered backpropagation algorithm estimates \hat{f} as [15]

$$\hat{f}(x) = \frac{1}{2} \frac{1}{(2\pi)^2} \int_0^{2\pi} d\theta \int_{-k}^k dp |p| e^{ipt} e^{i(m-k)(s-s_0)} \tilde{P}_\theta \hat{f}(p; s_0) \quad (1.4)$$

¹The remainder of the circular slice is associated with the reflected field, i.e., the scattered field along the measurement line $s = -s_0$.

where $x = tu + sv$. It is readily shown that the estimate \hat{f} has the same spatial frequency content as the unknown f over a disk \mathcal{D} in Fourier space of radius $k\sqrt{2}$ and zero frequency content outside that disk. Since its first appearance [15], the filtered back-propagation algorithm has been modified and extended to other data acquisition geometries [17] and tested on computer simulated [14], [45] and experimental data [60], [65].

C. State of the Art and Present Contribution

Linearized DT has reached today the stage of being implemented in prototype commercial tomographic scanners for ultrasonic [60], [65], underground [48], [75], and optical [39] imaging systems. Particularly successful have been geophysical DT algorithms when applied to a range of underground imaging problems such as oil field prospecting and reservoir monitoring [78], locating underground tunnels between North and South Korea [75], and searching for dinosaur bones in the New Mexico desert [74]. The success of the linearized DT algorithms depends critically, however, on the two assumptions of linearity and availability of multiple experiments and in many cases, the linearity assumption fails, while different constraints (economic, safety, operating, geometric, or physical) limit the number of scattering experiments that can be performed and/or provide low signal-to-noise ratio data. Even though algebraic reconstruction techniques reduce the effect of availability of only a small number of scattering experiments, the effects of nonlinearity are much harder to combat and remain an issue of current research. To overcome these limitations a more modest inverse scattering problem was addressed by Tsihrintzis and Devaney, originally within the framework of linearized [21], [63], [65], [68], [69] and later exact [64], [65], [69] scattering theory. The goal of this more modest inverse problem, motivated in part by earlier work on a related problem in X-ray computed tomography [52], was to estimate the location of a *known* scatterer having unknown central location from noisy scattered field data. It was found that for monochromatic plane-wave probing the optimum (in the maximum likelihood sense) location estimate could be obtained via a filtered backpropagation algorithm, in which partial images formed by filtering and backpropagating scattered field data for different probing directions were coherently summed. The algorithm yields an *image* of the log likelihood function of the object's location and can be used for target detection and classification as well as target location estimation. The detection/estimation/classification procedure is optimum (in the maximum likelihood sense) for any given number of scattering experiments and returns good estimates even from a single experiment as long as the wavelength of the probing radiation is comparable with the typical dimensions of the target [21].

One practically important imaging situation arises when the object consists of a number of distinct scatterers. As pointed out by Azimi and Kak [1] and Slaney, Kak, and Larsen [54], even though each scatterer individually may be weak enough for validity of the Born approximate model, multiple scattering interactions among several scatterers degrade the performance of linearized DT reconstruction algorithms. The situation can be partially ameliorated if the reconstruction algorithms are based on higher-order (nonlinear) scattering models and, indeed, formal

Scattered fields in the first computer simulation: (a) the first Born term, (b) the second Born term, (c) the third Born term, (d) the first Born approximation, (e) the second Born approximation, and (f) the third Born approximation. The real (imaginary) part of the fields is plotted in solid (dashed) line

series solutions to the inverse scattering problem have been presented in the literature [22], [37], [38], [49]–[51], [55]–[57], [71], [72]. In [22], [37], and [38] more specifically, perturbative expansions of the scattering object's Fourier transform were utilized to develop DT reconstruction algorithms of arbitrary order, which contained linear reconstruction algorithms as special cases and effectively attained the form of nonlinear data filtering followed by a linear operation. The algorithms in [22], [37], [38] attempt to estimate samples of the Fourier transform of the object function and use them to obtain an estimate of the object function itself. On the other hand, recent attempts (see [4] and [47] and references therein) to invert a second-order scattering model have resulted in algorithms of the form of iterative numerical solutions of systems of quadratic equations and revealed significantly higher fidelity than their linear counterparts. In this paper, we address the reconstruction problem of DT within the framework of higher-order (nonlinear) scattering approximations and derive analytical reconstruction algorithms for the, so-called, “*classical scan configuration of DT*” of Fig. 1, that can be implemented via use of a fast Fourier transform algorithm and, in fact, make extensive use

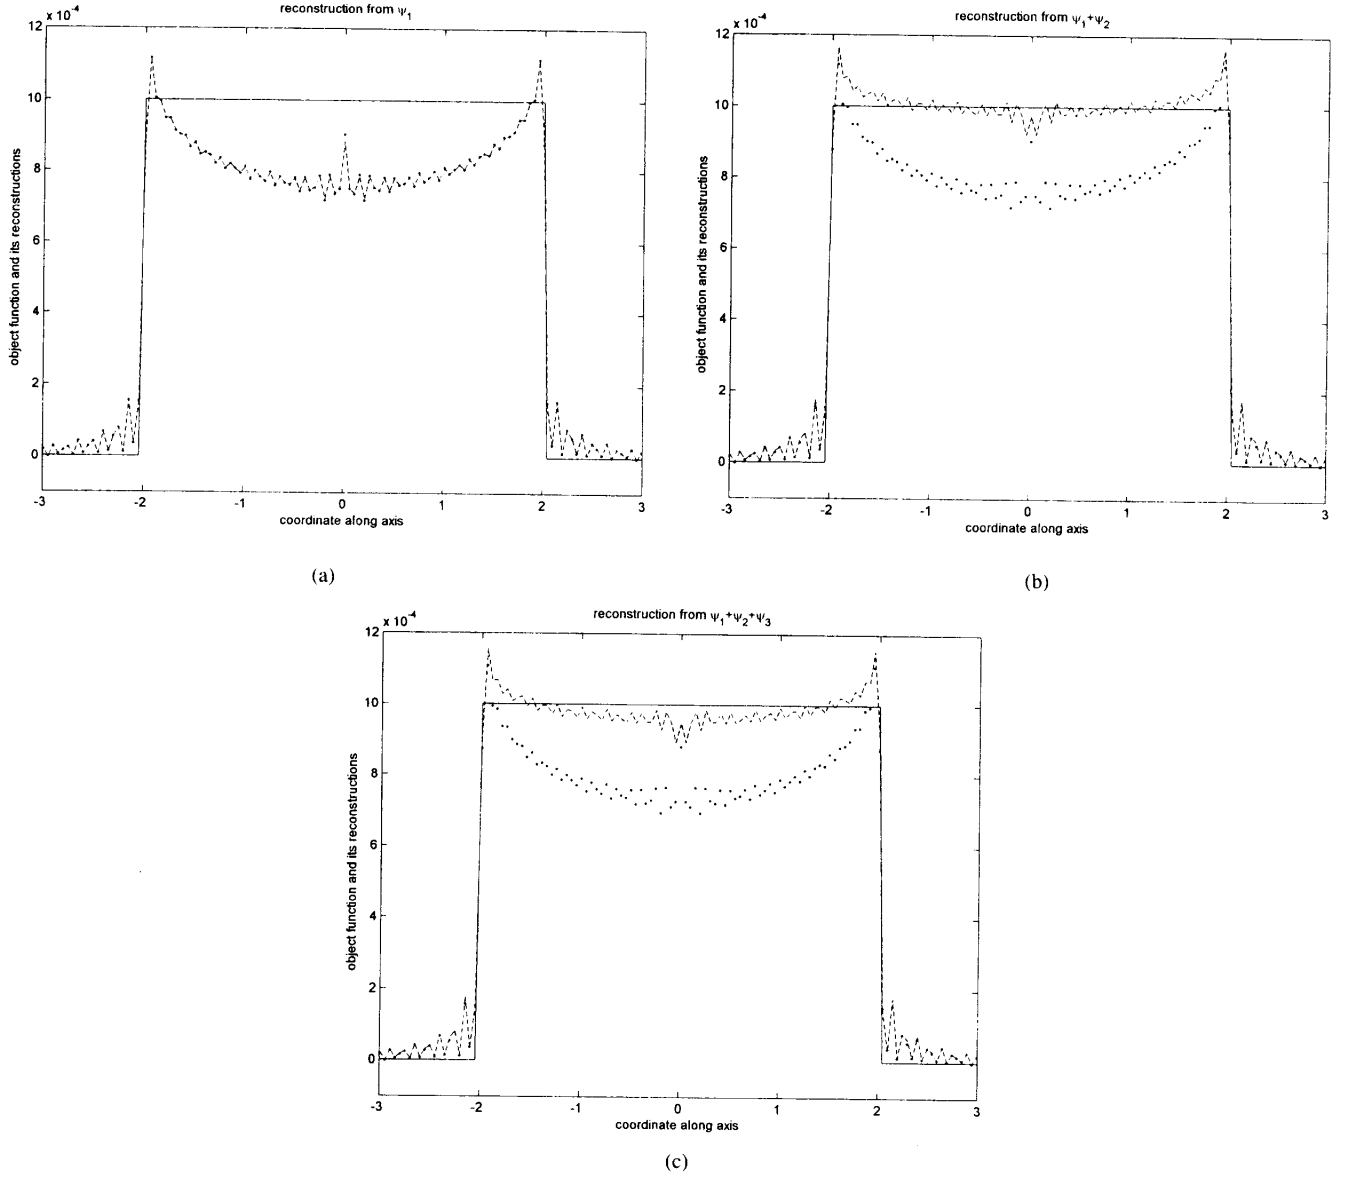

Fig. 4. Original object function (solid line) and reconstructions returned from the filtered backpropagation (dotted line) and the second-order algorithm (dashed line) in the first computer simulation: (a) reconstruction from the first-order Born approximation, (b) reconstruction from the second-order Born approximation, and (c) reconstruction from the third-order Born approximation

of the filtered backpropagation algorithm. The algorithms are illustrated in a computer simulation study.

More specifically, the paper is organized as follows: Section II defines nonlinear propagation transforms as the mathematical mapping from the object structure to the scattered wave data that arises from higher-order Born approximations. Section III is devoted to study of the inversion of nonlinear propagation transforms and a computer implementation, while Section IV summarizes the paper, draws conclusions, and points to future related research.

II. NONLINEAR PROPAGATION TRANSFORMS FOR DIFFRACTION TOMOGRAPHY

A. Configuration and Scattering Equations

Consider the data collection configuration illustrated in Fig. 1, where a known monochromatic plane wave

$\psi_0(x) = \exp(ik\langle v, x \rangle)$ of wavenumber k propagates in the direction of the unit vector v and is incident on a scattering object of support \mathcal{V} and the total wave is measured over a line located outside the object and perpendicular to the unit vector v . A point on the measurement line is denoted with the coordinate vector $x_0 = t_0 u + s_0 v$ where s_0 is the distance of the measurement line from the origin. The object is assumed to be embedded in a nonattenuating, homogeneous medium of wave velocity c_0 and wavenumber $k = (\omega/c_0)$ and characterized by its distribution of complex-valued index of refraction $n(x) = c_0/c(x)$, where $c(x)$ is the wave velocity distribution inside the scatterer.

The interaction of the incident wave with the object results in the formation of a wavefield $\psi(x)$ that satisfies the time-independent inhomogeneous Helmholtz equation

$$(\nabla^2 + k^2)\psi(x) = -2k^2 f(x)\psi(x) \quad (2.1)$$

where $f(x) = (1/2)[n^2(x) - 1]$ is the *object function*, the quantity whose determination is the ultimate goal of Inverse Scattering theory and DT. The solution of the Helmholtz equation (2.1) can be decomposed into the sum of the incident field and a scattered field in the form $\psi(x) = \psi_0(x) + \psi^{(s)}(x)$ where the scattered field component is related to the object function and total field via the integral equation

$$\psi^{(s)}(x) = -2k^2 \int_{\mathcal{V}} dx' f(x') \psi(x') G(x - x') \quad (2.2)$$

with $G(x - x') = -(i/4)H_0^{(1)}(k|x - x'|)$ the outgoing wave Green function to the Helmholtz equation [40].

Equation (2.2) provides a link between source and scattering problems in wave theory and shows that the scattered field *outside* the scattering region \mathcal{V} is uniquely determined from the total field *inside* \mathcal{V} . As a result, approximate scattering models, such as the Born models of the following section, seek to replace the “*induced source*” $f\psi$ in (2.2) with an approximate expression that leads to a tractable inverse problem. The first Born and Rytov approximations lead to linear models that are inverted via DT as outlined in the Introduction. The objective of this paper is to improve these linear models by including higher-order Born terms.

B. Born Series

Equation (2.2) implies a nonlinear mapping from the object function f to the scattered field $\psi^{(s)}$, which under certain weak scattering conditions can be expanded into a convergent Liouville–Neumann expansion, known as the Born series. The Born series is, thus, a perturbational expansion for the field scattered by an object f , obtained by introducing a smallness parameter ϵ and replacing the object function f in (2.1) and (2.2) by ϵf . The total field $\psi(x; \epsilon)$ inside the scattering region \mathcal{V} is assumed an analytic function of the parameter ϵ around the point $\epsilon = 0$, so that the Taylor series expansion around $\epsilon = 0$

$$\psi(x; \epsilon) = \psi_0(x) + \epsilon \psi_1(x) + \epsilon^2 \psi_2(x) + \dots \quad (2.3)$$

converges for sufficiently small ϵ . The terms $\epsilon \psi_1(x)$, $\epsilon^2 \psi_2(x)$, \dots are the first, second, \dots order corrections made to the incident field $\psi_0(x)$ to yield the total field $\psi(x; \epsilon)$. Clearly, this expansion is compatible with the fact that the scattered field $\psi^{(s)}(x; \epsilon) = \epsilon \psi_1(x) + \epsilon^2 \psi_2(x) + \dots$ is solely due to the presence of the scatterer with object function ϵf and in the absence of it (i.e., for $\epsilon = 0$) the total field $\psi(x; \epsilon = 0)$ reduces simply to the known incident field $\psi_0(x)$.

Inserting (2.3) into (2.2) and equating the coefficients of equal powers of ϵ on the two sides of the resulting expression, one obtains

$$\begin{aligned} \psi_1(x_0) &= -2k^2 \int_{\mathcal{V}} dx' G(x_0 - x') f(x') \psi_0(x') \\ \psi_2(x_0) &= -2k^2 \int_{\mathcal{V}} dx' G(x_0 - x') f(x') \psi_1(x') \\ &\vdots \\ \psi_n(x_0) &= -2k^2 \int_{\mathcal{V}} dx' G(x_0 - x') f(x') \psi_{n-1}(x') \\ &\vdots \end{aligned} \quad (2.4)$$

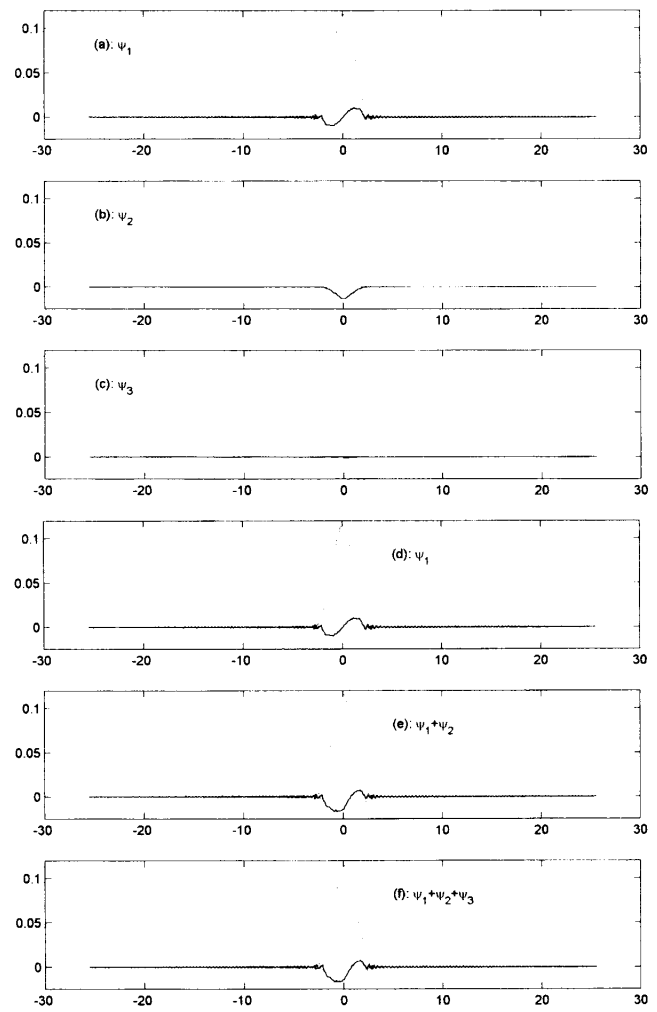

Fig. 5. Scattered fields in the second computer simulation: (a) the first Born term, (b) the second Born term, (c) the third Born term, (d) the first Born approximation, (e) the second Born approximation, and (f) the third Born approximation. The real (imaginary) part of the fields is plotted in solid (dashed) line

Clearly, the Born term of order n can be computed from the Born term of order $n - 1$, $n = 1, 2, 3, \dots$, by replacing the induced source $f\psi$ with the product $f\psi_{n-1}$. After computation of the Born terms up to some desired order N , the total field ψ resulting from the interaction of the incident wave ψ_0 with the scatterer f is computed as $\psi(x_0) = \psi_0(x_0) + \psi^{(s)}(x_0)$ with the scattered field approximated as

$$\psi^{(s)}(x_0) \approx \psi_1(x_0) + \psi_2(x_0) + \dots + \psi_N(x_0). \quad (2.5)$$

Of course, the assumption is made that the expansion (2.3) is valid for $\epsilon = 1$.²

The first-order Born approximation, simply referred to as the Born approximation [42], has been extensively employed in quantum mechanical scattering theory [24], [42]. From (2.4), the Born approximation estimates the scattered field $\psi^{(s)}$ by substituting the incident field ψ_0 for the total field ψ in the integrand in the right hand side of (2.2) and therefore requires that 1) $|\psi^{(s)}| \ll |\psi_0|$ inside the scatterer support \mathcal{V} and 2) the volume of scatterer support \mathcal{V} itself be small [30].

²For conditions under which the Born series converges, see [7], [9].

It is seen that the Born approximation is quite restrictive, since it requires both the size and the strength of the scattering object to be “small.” Additionally, it is a low frequency approximation, since it requires the frequency of the incident wave to be low. The Born approximation has been extensively used for predictions in direct [8], [62] and inverse [16] scattering theory. Its domain of validity, has been extensively explored in the literature [29], [30], [35], [44], [58], [59], [73] and compared with experimental results [39], [61].

C. Nonlinear Propagation Transforms of 2-D DT

Consider again the classical scan configuration of Fig. 1, but assume that the scattered field along the line $x_0 = t_0 u + s_0 v$, $t_0 \in \mathbb{R}^1$, with s_0 fixed, is well approximated by the first N terms of the Born series, as in (2.5). Let $G(x - x')$ denote the outgoing wave Green function to the Helmholtz operator and consider its Weyl expansion [40]

$$\begin{aligned} G[(t - t')u + (s - s')v] \\ &= -\frac{i}{4\pi} \int_{-\infty}^{\infty} dp e^{ip(t-t')} \frac{e^{im|s-s'|}}{m} \\ &\approx -\frac{i}{4\pi} \int_{-k}^k dp e^{ip(t-t')} \frac{e^{im|s-s'|}}{m} \\ &\equiv G_L[(t - t')u + (s - s')v] \end{aligned} \quad (2.6)$$

where

$$m = \begin{cases} \sqrt{k^2 - p^2}, & \text{if } |p| \leq k \\ i\sqrt{p^2 - k^2}, & \text{if } |p| > k. \end{cases}$$

The Weyl expansion in (2.6) decomposes the Green function $G(x - x')$ into a superposition of both homogeneous (corresponding to $|p| \leq k$) and evanescent (corresponding to $|p| > k$) plane waves. The evanescent plane waves decay exponentially with $|s - s'|$ and the approximation G_L on the far right hand side of (2.6) is a lowpass approximation to G that consists only of homogeneous plane wave components and is valid for $|s - s'| \gg \lambda$.

Next, define the Hilbert spaces \mathcal{F} , \mathcal{F}_L , and \mathcal{P} as follows: \mathcal{F} is $L^2(\mathcal{D}_a)$, where \mathcal{D}_a is a disk of radius a in \mathbb{R}^2 that includes the scattering region \mathcal{V} . \mathcal{F}_L is the subspace of \mathcal{F} consisting of the functions in \mathcal{F} lowpass filtered down to a disk of radius $k\sqrt{2}$ in Fourier space, i.e.,³

$$\mathcal{F}_L = \left\{ (f_L|_{\mathcal{D}_a}): \exists (f|_{\mathcal{D}_a}) \in \mathcal{F} \text{ such that } \begin{aligned} \tilde{f}_L(K) &= \begin{cases} \tilde{f}(K), & \text{for } |K| \leq k\sqrt{2} \\ 0, & \text{otherwise.} \end{cases} \end{aligned} \right\}.$$

Finally, \mathcal{P} is the space of functions defined on $\mathbb{R}^1 \times [0, 2\pi)$ whose frequency content with respect to the first variable is zero outside the $[-k, k]$ interval.

³Since the functions f in \mathcal{F} are compactly supported, their Fourier transform is an entire function. Therefore, for given f_L , the corresponding f is unique and can, in principle, be obtained by analytically continuing the Fourier transform of f_L . The lowpass filtering is essentially a regularization procedure that makes the inverse of the linear propagation transform continuous.

Define the nonlinear operators

$$\mathcal{G}_n: \mathcal{F}_L \rightarrow \mathcal{P} \quad (2.7)$$

where

$$(\mathcal{G}_n f_L)(t_0, \theta) = \frac{e^{-ik s_0}}{ik} \psi_n^L(t_0 u + s_0 v, \theta) \quad (2.8)$$

and $\psi_n^L(t_0 u + s_0 v, \theta)$ is the n th term of the Born series to the scattered field along the measurement line $x_0 = t_0 u + s_0 v$, lowpass filtered with respect to t_0 down to the frequency interval $[-k, k]$. From (2.4), it is seen that \mathcal{G}_n is a homogeneous Volterra operator of order n

$$\begin{aligned} (\mathcal{G}_n f_L)(t_0, \theta) &= \frac{e^{-ik s_0} (-2k^2)^n}{ik} \cdot \int_{\mathcal{V}} dx^{(1)} G_L(x_0 - x^{(1)}) \\ &\quad \cdot \int_{\mathcal{V}} dx^{(2)} G(x^{(1)} - x^{(2)}) \cdots \int_{\mathcal{V}} dx^{(n)} \\ &\quad \cdot G(x^{(n-1)} - x^{(n)}) e^{ik \langle v, x^{(n)} \rangle} f(x^{(1)}) \\ &\quad \cdot f(x^{(2)}) \cdots f(x^{(n)}). \end{aligned} \quad (2.9)$$

In (2.9), f is the function in \mathcal{F} obtained by analytic continuation of the Fourier transform of f_L . The choice of G_L (as opposed to G) in the first integration is practically valid as long as the measurement offset s_0 is on the order of at least several wavelengths for attenuation of evanescent wave components in the scattered fields outside of the object ($s_0 \gg \lambda$). However, evanescent wave components inside the object will, in general, give rise to homogeneous wave components of higher-order in multiple scattering interactions; therefore, the full G needs to be utilized in the remaining integrations.

To write the nonlinear propagation transforms in (2.9) in a computationally attractive form, use is made of the Weyl expansion of (2.6). We have

$$\begin{aligned} (\mathcal{G}_1 f_L)(t_0, \theta) &= \frac{e^{-ik s_0}}{ik} \frac{2ik^2}{4\pi} \iint_{\mathcal{V}} dt^{(1)} ds^{(1)} \int_{-k}^k dp \\ &\quad \cdot e^{ip(t_0 - t^{(1)})} \frac{e^{im(s_0 - s^{(1)})}}{m} f(t^{(1)}u + s^{(1)}v) e^{iks^{(1)}} \\ &= \frac{ke^{-ik s_0}}{2\pi} \int_{-k}^k dp e^{ipt_0} \frac{e^{im s_0}}{m} \iint_{\mathcal{V}} dt^{(1)} ds^{(1)} \\ &\quad \cdot e^{-ipt^{(1)}} e^{-i(m-k)s^{(1)}} f(t^{(1)}u + s^{(1)}v) \\ &= \frac{1}{2\pi} \int_{-k}^k dp e^{ipt_0} \frac{ke^{i(m-k)s_0}}{m} \tilde{f}[pu + (m-k)v] \end{aligned} \quad (2.10)$$

where \tilde{f} denotes the 2-D Fourier transform of f . Equation (2.10) is simply a statement of the generalized projection-slice theorem of (1.2) and verifies that the proposed (nonlinear) propagation transforms include the usual linear propagation transform as a special case. It is seen that the linear propagation transform (2.10) of an object function f is directly computable via use of a fast Fourier transform algorithm (FFT). The nonlinear propagation transforms $\mathcal{G}_n f$ (2.9) are not directly computable

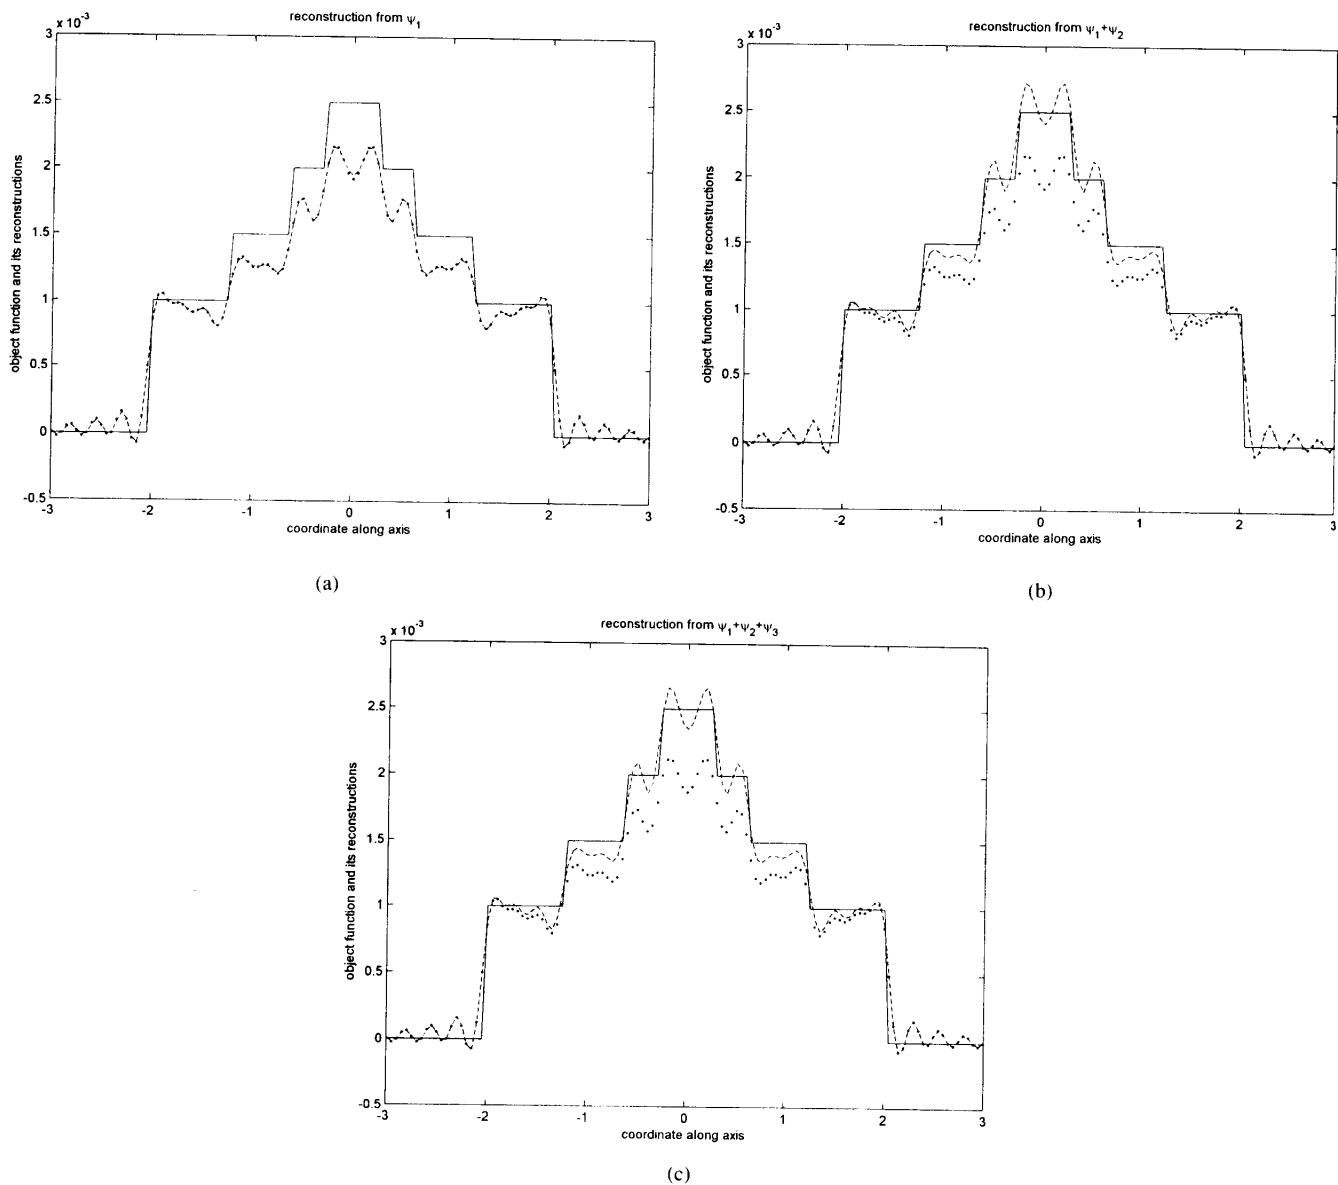

Fig. 6. Original object function (solid line) and reconstructions returned from the filtered backpropagation (dotted line) and the second-order algorithm (dashed line) in the second computer simulation: (a) reconstruction from the first-order Born approximation, (b) reconstruction from the second-order Born approximation, and (c) reconstruction from the third-order Born approximation

using a FFT, since they require computation of the Fourier transform of the object function f over a set of complex frequencies. However, if the lowpass approximations to the Weyl expansion in (2.6) is used, a valid approximation for sufficiently high wavenumber, the nonlinear propagation transforms can also be computed approximately by FFT-based algorithms.

Define now the linear operator

$$\mathcal{B}: \mathcal{P} \rightarrow \mathcal{F}_L \quad (2.11)$$

with

$$(\mathcal{B}d)(x = tu + sv) = \frac{1}{2} \frac{1}{(2\pi)^2} \int_0^{2\pi} d\theta \int_{-k}^k dp |p| \cdot e^{ipt} e^{i(m-k)(s-s_0)} \tilde{d}(p, \theta). \quad (2.12)$$

The operator $(\mathcal{B}|\mathcal{P})$ is the inverse of $(\mathcal{G}_1|\mathcal{F}_L)$, as stated in (1.4).

D. Cylindrically Symmetric Case

A particularly important imaging situation is that of scattering objects with cylindrical symmetry, that is scatterers whose properties vary only with the radial distance from the scatterer center and, thus, their object function is of the form

$$f(x) = f_r(r), \quad r = |x|. \quad (2.13)$$

This important situation arises in practical applications such as reconstruction of the structure of optical fibers or large molecules, but also provides a paradigm for both analytical and computer simulation study of DT reconstruction algorithms. Both the filtered backpropagation algorithm (1.4) and the nonlinear propagation transforms attain a simpler form that makes use of 1-D Fourier-Bessel transforms.

Indeed, let

$$\tilde{f}_r(|K|) = 2\pi \int_0^\infty dr r J_0(|K|r) f_r(r). \quad (2.14)$$

Then, the Fourier transform of the object function f becomes

$$\tilde{f}(K) = \tilde{f}_r(|K|) \quad (2.15)$$

and the generalized projection-slice theorem (1.2) reads⁴

$$\tilde{P}_\theta f(p; s_0) = \begin{cases} \frac{k}{m} e^{i(m-k)s_0} \tilde{f}_r[\sqrt{2k(k-m)}], & \text{if } |p| \leq k, \\ 0, & \text{otherwise} \end{cases} \quad (2.16)$$

where the generalized projections $P_\theta f$ are independent of the view angle θ . The filtered backpropagation algorithm is now put in the form

$$\hat{f}(x) = \frac{1}{2\pi} \int_0^k dp p e^{i(k-m)s_0} J_0[r\sqrt{2k(k-m)}] \cdot \tilde{P}_\theta f(p; s_0), \quad r = |x| \quad (2.17)$$

where the integration with respect to view angle θ has been eliminated.⁵ Finally, the nonlinear propagation transforms can be computed in a similar yet more complicated, manner.

III. INVERSION OF NONLINEAR PROPAGATION TRANSFORMS

A. Theory

Define the inhomogeneous Volterra operator of order N

$$\mathcal{G}^N = \mathcal{G}_1 + \mathcal{G}_2 + \cdots + \mathcal{G}_N: \mathcal{F}_L \rightarrow \mathcal{P} \quad (3.1)$$

where

$$(\mathcal{G}^N f_L)(t_0, \theta) = \frac{e^{-ik s_0}}{ik} (\psi_1^L + \psi_2^L + \cdots \psi_N^L)(t_0 u + s_0 v, \theta) \quad (3.2)$$

and $\psi_n^L(t_0 u + s_0 v, \theta)$, $n = 1, 2, \dots$, is the n th term of the Born series to the scattered field along the measurement line $x_0 = t_0 u + s_0 v$, lowpass filtered with respect to t_0 down to the frequency interval $[-k, k]$. The existence of a local inverse of the operator \mathcal{G}^N and its representation by a convergent series is guaranteed by the existence of the inverse $(\mathcal{B}|\mathcal{P})$ of the linear term $(\mathcal{G}_1|\mathcal{F}_L)$ [55].⁶ Specifically, there exists a region in the data space \mathcal{P} , on which the operator

$$\mathcal{B}_1 + \mathcal{B}_2 + \cdots + \mathcal{B}_n + \cdots \quad (3.3)$$

is the inverse of \mathcal{G}^N , where \mathcal{B}_n is a homogeneous Volterra operator of order n in the data.

⁴More generally

$$\tilde{f}_1(pu + s_0 v) = \begin{cases} \frac{ik^2}{m} e^{im s_0} \tilde{f}_r[\sqrt{2k(k-m)}], & \text{if } |p| \leq k, \\ \frac{ik^2}{m} e^{im s_0} \tilde{f}_r(|p|\sqrt{2}), & \text{if } |p| > k \end{cases}$$

which includes evanescent wavemodes in the scattered field data.

⁵In the case of noisy data, the measurements at each view angle are generally distinct and, thus, the angular integration cannot be eliminated. Equation (2.17) is no longer the statistically optimal strategy, but one needs to use the more general algorithms in [48] and [68].

⁶The stability (continuity) of the inverse operator series is guaranteed by the boundedness of the operators \mathcal{B} and \mathcal{G}_n , [7], [9].

Fig. 7. Scattered fields in the second computer simulation: (top plot) noise-free third Born approximation and (bottom plot) typical noisy measurement at a signal-to-noise ratio of 25 dB. The real (imaginary) part of the fields is plotted in solid (dashed) line

More specifically

$$\mathcal{B}_1 = \mathcal{B} \quad (3.4)$$

$$\mathcal{B}_2 = -\mathcal{B}\mathcal{G}_2\mathcal{B} \quad (3.5)$$

$$\mathcal{B}_3 = \mathcal{B}\mathcal{G}_2\mathcal{B}\mathcal{G}_2\mathcal{B} - \mathcal{B}\mathcal{G}_3\mathcal{B} \quad (3.6)$$

\vdots

It is observed that the terms $\mathcal{B}_1, \mathcal{B}_2, \mathcal{B}_3$, etc. are *universal* in the sense that they do not depend on the order N of the forward model \mathcal{G}^N . Thus, the operator series in (3.3) can be truncated to desired order n and return DT inversion algorithms of order n in the data. For example, the usual filtered backpropagation algorithm provides a universal DT inversion algorithm of first-order (linear) in the data. The general Volterra theory of nonlinear systems can be applied to provide bounds on the error resulting from truncation of the series (3.3) at an arbitrary term. However, these bounds are functionals of the object function and cannot be computed beforehand. A practical approach to determine the term at which to terminate the series (3.3) is to monitor the norm of each new term in (3.3) and stop when it has become sufficiently small.

A second observation is that if the data are sufficiently modeled by the first Born term, i.e., $\psi^{(s)} = \psi_1$ and $\psi_2 = \psi_3 = \cdots = 0$, then each higher-order term in series (3.3) returns an identically zero contribution to image reconstruction, as close examination of the expressions in (3.4)–(3.6) reveals. This fact is also verified in the simulations of this section. A final observation is that the resulting algorithms are effectively of the form of *nonlinear* data filtering followed by backpropagation. Indeed, the series (3.3) can be written as

$$\mathcal{B}(\mathcal{I} - \mathcal{G}_2\mathcal{B} + \mathcal{G}_2\mathcal{B}\mathcal{G}_2\mathcal{B} - \mathcal{G}_3\mathcal{B} - \cdots) \quad (3.7)$$

where $\mathcal{I}: \mathcal{P} \rightarrow \mathcal{P}$ is the identity operator. The operator in brackets in (3.7) maps $\mathcal{P} \rightarrow \mathcal{P}$ and, thus, this term is a higher-order nonlinear Volterra filter applied on the data. Therefore, the series (3.3) gives rise to an entire class of *nonlinear filtered backpropagation* algorithms for inversion of DT data.

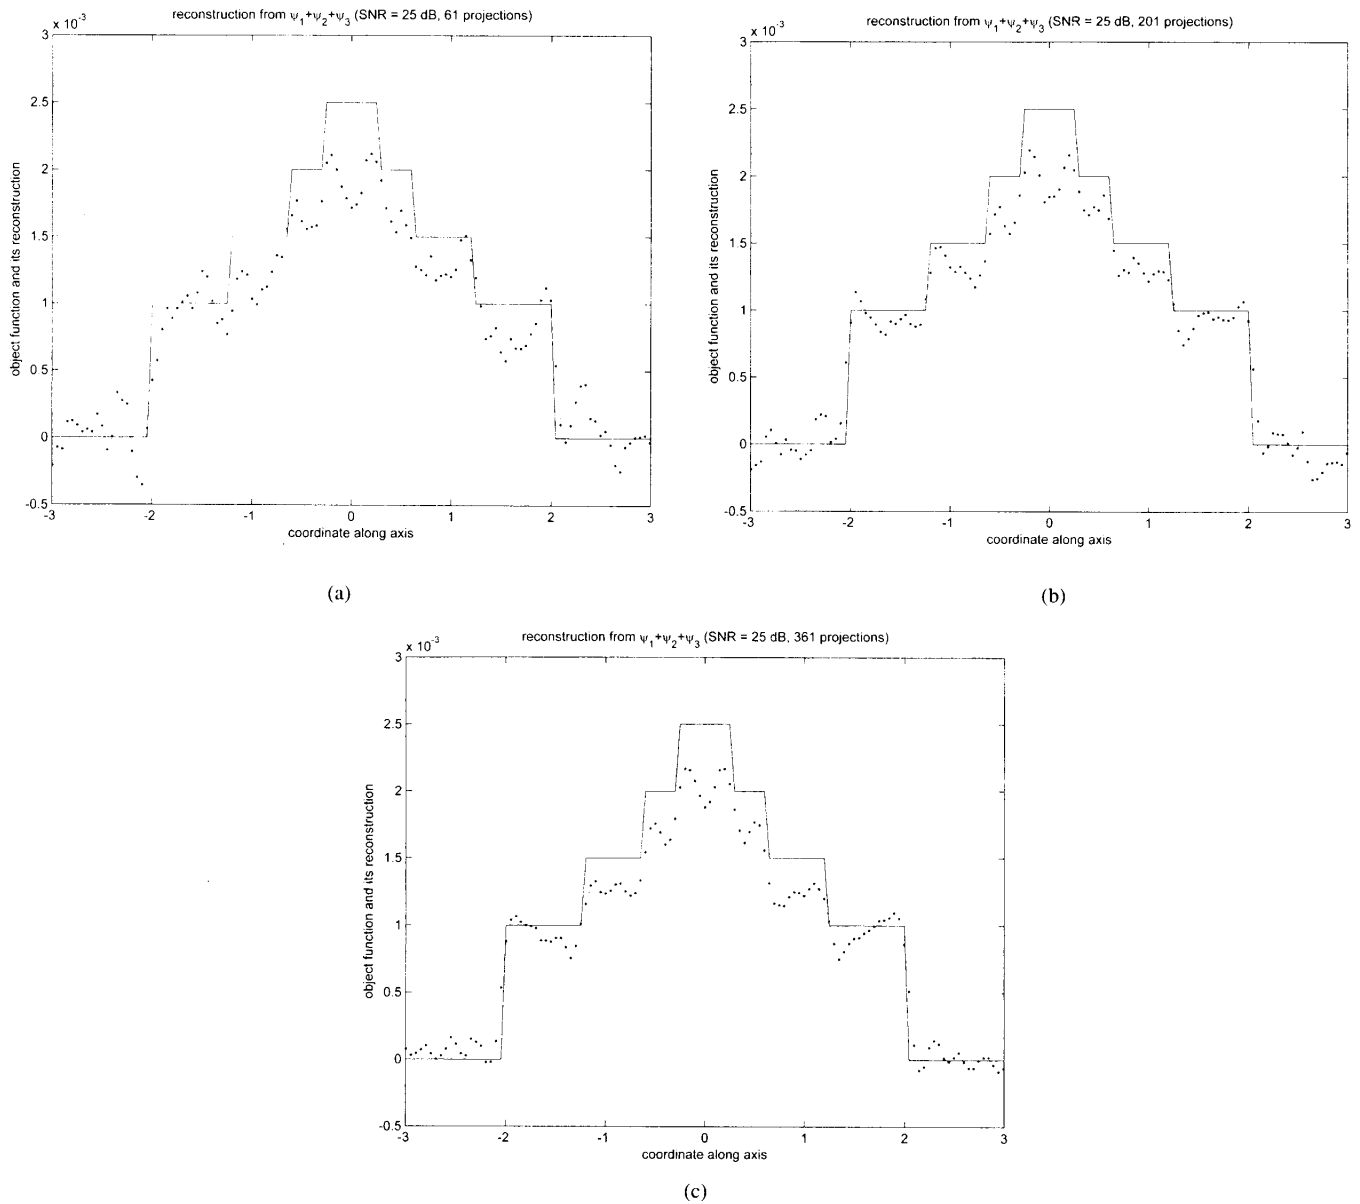

Fig. 8. Original object function (solid line) and reconstructions returned from the filtered backpropagation algorithm (dash-dotted line) as applied to 61 [Fig. 8(a)], 201 [Fig. 8(b)], and 361 [Fig. 8(c)] noisy projections measured at angles equally spaced over 360° .

B. Computer Simulation of Higher-Order DT

The proposed nonlinear diffraction tomographic reconstruction algorithms were implemented and studied in two different computer simulations. In both simulations, the scattering object exhibited cylindrical symmetry and, in the case of noiseless data, could be reconstructed from a single scattering experiment.

Computer Simulation 1: The scattering object consisted of a single disk of radius 2, within which the object function was constant and equal to 0.001, i.e.,

$$f(x) = \begin{cases} 0.001, & \text{if } |x| \leq 2 \\ 0, & \text{elsewhere.} \end{cases} \quad (3.8)$$

The wavenumber was set to $k = 12\pi$, corresponding to a wavelength $\lambda = (1/6)$, so that the object was 12 wavelengths in di-

ameter. Fig. 3 show plots of the real (solid line) and imaginary (dashed line) parts of the first [Fig. 3(a)], second [Fig. 3(b)], and third [Fig. 3(c)] Born terms and the corresponding first- [Fig. 3(d)], second- [Fig. 3(e)], and third-order Born approximations to the scattered field for a measurement distance of $s_0 = 0$. Fig. 4 show the object function reconstructions returned by the filtered backpropagation (dotted line) and the second-order (dashed line) and compare it to the original object function (solid line). Specifically, the data consisted of 1) the first Born approximation [Fig. 4(a)], 2) the second Born approximation [Fig. 4(b)], and 3) the third Born approximation [Fig. 4(c)] to the scattered field. Clearly, the second-order algorithm returns the same reconstruction as the filtered backpropagation algorithm when the data consists of only the first Born term, but outperforms the filtered backpropagation algorithm when the data consists of the second- or third-order Born approximation.

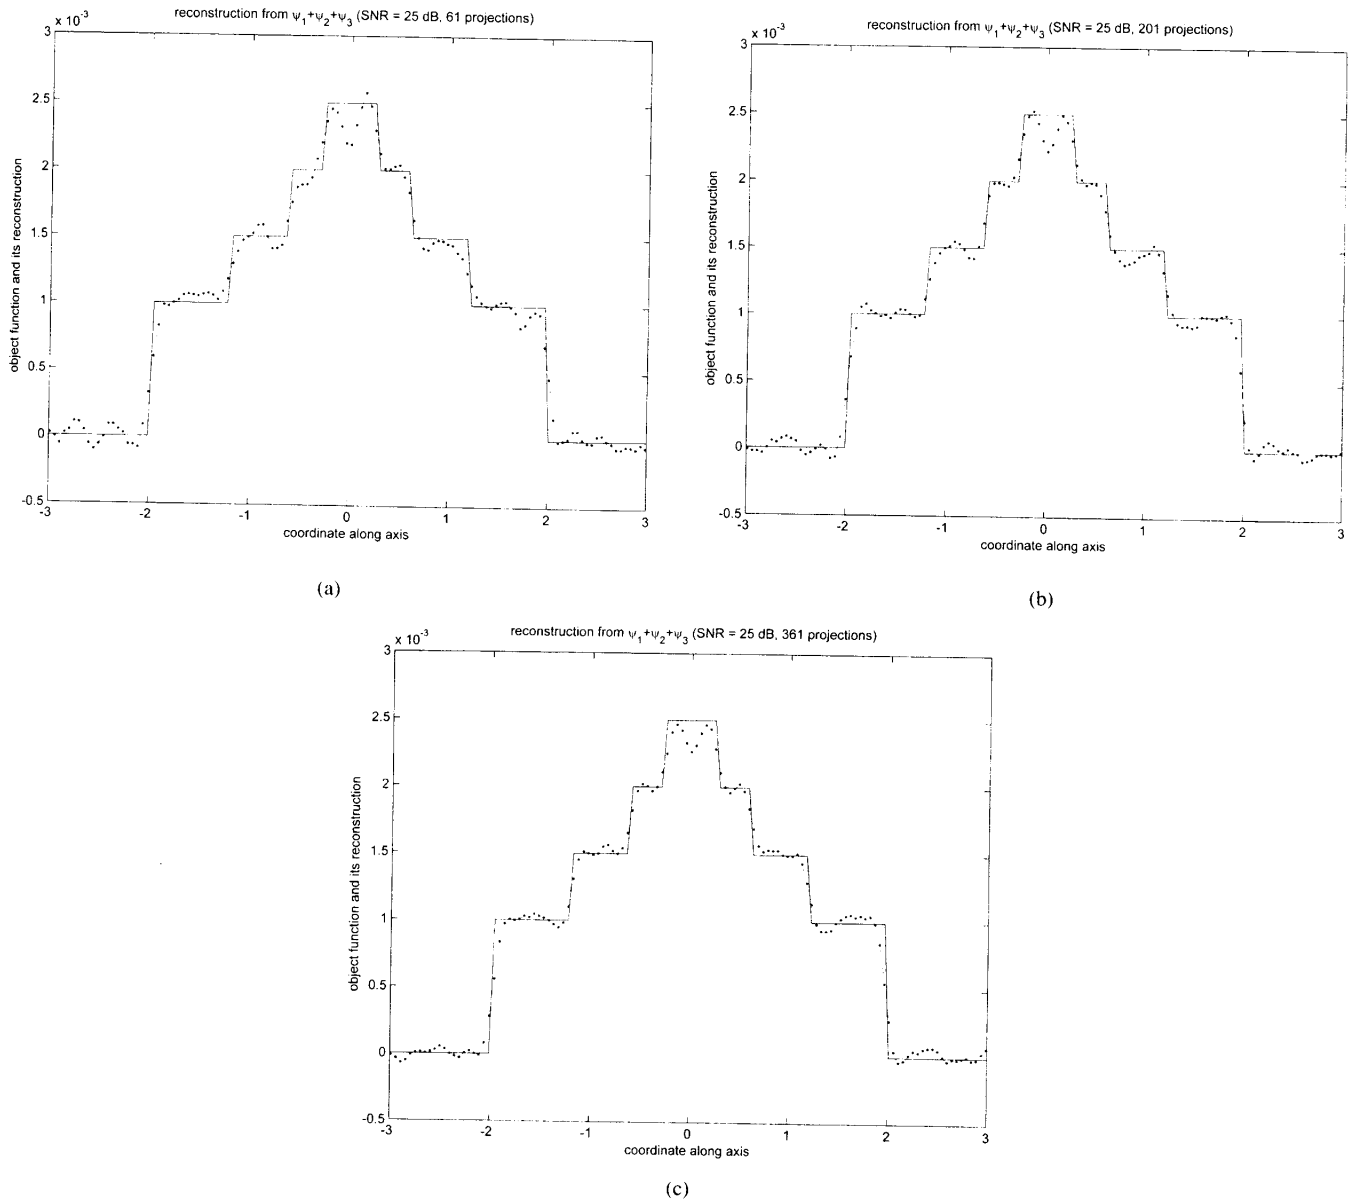

Fig. 9. Original object function (solid line) and reconstructions returned from the second-order inversion algorithm (dash-dotted line) as applied to 61 [Fig. 9(a)], 201 [Fig. 9(b)], and 361 [Fig. 9(c)] noisy projections measured at angles equally spaced over 360° .

Computer Simulation #2: The scattering object consisted of a circular core and three concentric circular coatings and constitutes a good model for small optical fibers. Specifically

$$f(x) = \begin{cases} 0.0025, & \text{if } |x| \leq 0.25 \\ 0.002, & \text{if } 0.25 \leq |x| \leq 0.6 \\ 0.0015, & \text{if } 0.6 \leq |x| \leq 1.2 \\ 0.001, & \text{if } 1.2 \leq |x| \leq 2 \\ 0, & \text{elsewhere.} \end{cases} \quad (3.9)$$

The wavenumber was equal to $k = 6\pi$, corresponding to a wavelength $\lambda = (1/3)$ and the measurement distance was set to $s_0 = 0$. Fig. 5 show plots of the first three Born terms and approximations to the scattered field, in correspondence with Fig. 3. Clearly, the contribution of the third Born term is negligible, when compared to the first two Born terms; thus, termination of the Born series at its second term seems to be valid. Fig. 6 show the object function reconstructions returned by the filtered

backpropagation and the second-order algorithms, in correspondence with Fig. 4. Clearly, the second-order algorithm returns the same reconstruction as the filtered backpropagation algorithm in the case of data consisting of only the first Born term. In the other cases, however, the filtered backpropagation algorithm misses the core of the object, while the second-order algorithm returns a more accurate reconstruction and reveals the core.

At this point, we need to stress that the oscillations observed in the object function reconstructions in areas where the original object function is uniform are due to the fact that the reconstruction algorithms are effectively sharp lowpass filters. Therefore, the observed oscillations are Gibbs phenomena that can be eliminated via use of a smoother lowpass filter. Such an approach has been followed successfully in [14]; however, the resulting reconstructions, even though smoother, are no longer optimum in the least-squares sense.

Next, we study the performance of the proposed algorithms when the input data are limited in both angular coverage and signal-to-noise ratio. In Fig. 7, we show the third-order Born approximation $\psi_1 + \psi_2 + \psi_3$ to the scattered field $\psi^{(s)}$ (top plot) and a typical noisy measurement of it (bottom plot). In the bottom plot, the noise was an additive white Gaussian process of variance σ^2 . The variance was chosen so as to set the signal-to-noise ratio, defined as $(\int_{-\infty}^{\infty} |\psi^{(s)}(t_0 u + s_0 v)|^2 dt_0 / \sigma^2)$, to 25 dB, probably an unrealistically low value given published experimental studies on DT.

Fig. 8 compare the original object function and its reconstruction returned by the filtered backpropagation algorithm⁷ as applied to 61 [Fig. 8(a)], 201 [Fig. 8(b)], and 361 [Fig. 8(c)] projections measured at angles equally spaced over 360 degrees. Clearly, the reconstructions are "close" to the reconstruction obtained from noise-free, full-view data in Fig. 6(c). In fact, the signal-to-noise ratio in the reconstructions has improved because of the lowpass filtering effected on the data. As the number of tomographic projections increases, the signal-to-noise ratio improves further as can be seen in Fig. 8(c). The robustness to noise and limited angular coverage of the filtered backpropagation algorithm is not unknown in the relevant literature (e.g., see [21, Figs. 12 and 13, p. 680] for a simulation study or the cited literature for experimental performance evaluations).

Fig. 9 compare the original object function and its reconstruction returned by the second-order inversion algorithm, in which only 61 [Fig. 9(a)], 201 [Fig. 9(b)], and 361 [Fig. 9(c)] projections are measured. Clearly, the reconstructions are "close" to the reconstruction obtained from noise-free, full-view data in Fig. 6(c) and outperform the filtered backpropagation algorithm in the corresponding simulations.

IV. SUMMARY, CONCLUSIONS, AND FUTURE RESEARCH

In this paper, the usual propagation transform of linearized diffraction tomography was generalized into higher-order (nonlinear) propagation transforms via use of the Born series as the data-generating model in scattering experiments. Tomographic reconstruction algorithms were developed for inversion of scattered field data and image formation. A computer simulation study was included to illustrate the performance of the algorithms in the case of imaging objects with cylindrical symmetry. From this study, it was found that a second-order algorithm returned essentially the same reconstruction as the usual filtered backpropagation algorithm when applied to first-order Born data, but clearly outperformed the filtered backpropagation algorithm when applied to data consisting of the second- or third-order Born approximation. Similar results were found when we processed measured projection data that were limited both in angular coverage and by noise.

It should be noted that the proposed nonlinear reconstruction algorithms are easily extended to a stochastic framework

in which the object function is considered as a realization from a wide sense stationary second-order process, the measured data are corrupted by noise, and an inversion algorithm is sought that is optimum in a mean squared error sense. In our previous work [68], [69], we addressed this problem within the framework of linearizing approximations and showed that the optimum linear inversion algorithm (Wiener filter) is a filtered backpropagation algorithm with a properly modified filter. It seems, therefore, that further investigation in that direction is due. Future relevant research may also follow the avenues of inversion of higher-order Rytov data (see [71]) or higher-order Diffraction Tomography with alternative data measurement configurations (e.g., ground-penetrating radar tomography). These and other research avenues are currently being pursued and the findings will be reported elsewhere.

⁷The filtered backpropagation algorithm of (1.4) is no longer optimum as the number of tomographic projections available is finite. The optimum algorithm is of the form of a filtered backpropagation algorithm, where, however, the filter is no longer the "rho" filter appropriate for inversion of full-view data. The appropriate filter is not known in closed form, but can be computed via optimization. The reader is referred to [19] for further details.

George A. Tsihrintzis (S'88-M'93) was born in Athens, Greece. He received the Diploma in electrical engineering (with honors) from the National Technical University of Athens in 1987 and the M.S. and Ph.D. degrees in electrical engineering from Northeastern University, Boston, MA, in 1988 and 1992, respectively.

He is currently an Associate Professor with the Department of Informatics, University of Piraeus, Greece, and a Visiting Professor in the Department of Electrical and Computer Engineering, Northeastern University. Previously, he was a Research Associate with the Signal and Image Processing Institute, University of Southern California, Los Angeles, and Assistant Professor of electrical engineering at the University of Virginia, Charlottesville. His expertise combines signal and image processing and electromagnetic wave theory and his research interests include pattern recognition, detection and estimation theory, statistical signal processing, and inverse problems in scattering with applications in imaging, radar, and communications. He has contributed to more than 100 publications in these areas and is the author of the article on radar applications in the *Wiley Encyclopedia of Electrical and Electronics Engineering* (New York: Wiley, 1999).

Anthony J. Devaney (M'87) received the B.S.E.E. degree in electrical engineering from Northeastern University, Boston, MA, in 1964, the M.S. degree in engineering and applied science from Yale University, New Haven, CT, in 1965, and the Ph.D. degree from the Institute of Optics, University of Rochester, Rochester, NY, in 1971.

He is currently Professor of electrical and computer engineering at Northeastern University, Boston, President of A. J. Devaney Associates, Boston, and Vice President for Technology of Witten Technologies, Washington, DC. Previously, he held positions with Eikonix Corporation, Bedford, MA, and Schlumberger-Doll Research, Ridgefield, CT. He was formerly the Topical Editor for propagation and scattering for the *Journal of the Optical Society of America*. Currently he is a member of the editorial boards of *Wave Motion*, *Electronic Imaging*, and *Inverse Problems* and is an Associate Editor of *Ultrasonic Imaging*. He has published more than 120 papers in refereed journals, holds six patents, and has presented scientific papers at a number of conferences and universities. He has also contributed articles to a number of books and is the author of the entry on acoustical holography in the *Encyclopedia of Applied Physics*, published by the American Institute of Physics.

Dr. Devaney is a Fellow of the Optical Society of America and a Member of the Acoustical Society of America.

A Volterra Series Approach to Nonlinear Traveltime Tomography

George A. Tsihrintzis and Anthony J. Devaney

Abstract—Nonlinear tomographic reconstruction algorithms are developed for inversion of traveltime measurements in scattering experiments in which data models are derived from an arbitrarily large (possibly infinite) number of terms in the perturbation solution to the ray or eikonal equations. The algorithms attain the form of a Volterra series of nonlinear operators, with the usual linear reconstruction algorithm of Traveltime Tomography as the leading term. A computer simulation study is included to illustrate the performance of the algorithms for the case of scattering objects with cylindrical symmetry.

Index Terms—Eikonal equation, inverse scattering, ray tracing, traveltime tomography, Volterra series.

I. INTRODUCTION

SIGNIFICANT research activity has taken place over the past 25 years on the problem of quantitative determination of the structure of an unknown object by computerized processing of measurements of the waves diffracted by the object in a set of scattering experiments [47], [13], [15], [43] [9], [48], [40]. The structure to be reconstructed is usually the spatial distribution of the (complex-valued) index of refraction inside the object. This activity falls, therefore, within the regime of inverse scattering [30], [9], [8], [11] and is applicable in a number of seemingly different scientific disciplines, such as crystal structure determination [26], medical ultrasound tomography [14], [45], [46], [43], [44], acoustic and electromagnetic underground surveying [28], optical and coherent x-ray microscopy [16], and elastic wave inverse scattering [21], [24]. It also falls within the regime of computerized tomography [1], in that it utilizes computerized processing of data collected from several probing directions to form an image of the distribution of the object's refraction index, and, in fact, x-ray computerized tomography is the special case of the general discipline of inverse scattering obtained as the wavelength of the probing radiation approaches zero.

The essence of tomographic imaging with diffracting waves is an attempt to invert the (nonlinear) mathematical mapping that relates the probing wave, the object's refraction index, and the measurable total wave. However, such a task is nontrivial to achieve and, to date, research has only produced theoretical

results and computer-intensive iterative numerical inversion algorithms. An alternative approach that has often met with success was based on approximations to the exact wave model that arose either from perturbation expansions or from application of the geometric (ray) theory of diffraction. The former led to the scientific regime known as (linearized) diffraction tomography [47], [13], [15], [48], [40], [41], while the latter led to the regime of traveltime tomography [36], [2], [29], [31], [3], [4]. Given the domain of validity of the underlying approximations (Born or Rytov), diffraction tomography is applicable when the wavelength of the probing radiation is comparable with the typical dimension of the object. On the other hand, the geometric theory of diffraction is valid in the limit of vanishing wavelength, and traveltime tomography is applicable when the wavelength of the probing radiation is several orders of magnitude smaller than the typical dimension of the object. Consequently, while diffraction tomography provides appropriate reconstruction algorithms when probing with low frequency waves, traveltime tomography is valid in the limit of high frequency probing.

A common assumption in the early developments of traveltime tomography was that the wave propagated along straight line rays through the object [42], [43]. Although this assumption is approximately valid in the limit of very weakly scattering objects (e.g., soft biological tissue), it breaks down in many practical cases. Therefore, ray tracing through the object becomes required. The ray traces can be determined by application of Fermat's principle and minimization of the wave path [1], [5], [9], but in imaging applications, the refraction index distribution inside the object is unknown. Therefore, exact inversion of traveltime measurements is a nonlinear problem. Iterative algorithms have been proposed that, in each iteration, invert the traveltime measurements on the basis of the current ray traces and use the refraction index distribution thus obtained to compute the ray traces for the next iteration [36], [6], [27], [7], [1], [3], [4]. The straight line ray propagation model is an inaccurate model, especially for strong scatterers, but the corresponding algorithms are similar to the algorithms for x-ray tomography [21], [24] and are fast to implement. On the other hand, the iterative algorithms based on successive ray tracing and reconstruction are valid over a much broader set of scatterers, at the cost, however, of significant computational load.

In the present paper, we derive nonlinear reconstruction algorithms for inversion of traveltime measurements that rely on perturbations of the straight line ray wave propagation model [22], [2], [29], [31]. The algorithms present a compromise in both validity and computational load, between the existing linear and iterative nonlinear algorithms and could, in fact, serve as either the final estimates or providers of good preliminary estimates

Clearly, the term T_1 is a linear functional of the refraction index perturbation δn . On the other hand, the term T_2 is a homogeneous quadratic functional of δn , as can be seen from (2.17), and in general, T_j , $j = 1, 2, 3, \dots$ is a homogeneous functional of order j in δn .

D. Perturbation Series Solution to the Eikonal Equation

Now we return to the eikonal equation (2.1) and derive a perturbation series solution to it. Equation (2.1) is a first-order partial differential equation. Therefore, its general solution depends on one integration constant, the value of which is specified by the proper boundary conditions. Since the object is assumed to lie completely beyond the line $x = \tau u - s_0 v$, $\tau \in R^1$, s_0 , fixed, the proper boundary condition is

$$W(x = \tau u - s_0 v) = \langle v, x \rangle = -s_0 \quad (2.24)$$

simply stating that the incident wave has not yet interacted with the object and therefore, the eikonal W on the line $x = \tau u - s_0 v$ equals the eikonal W_0 in the object-free case. This boundary condition is compatible with the ray boundary conditions in (2.4) and (2.5). Indeed, from (2.2) and (2.24), we see that $n(dl/ds)|_{s=-s_0} = (\partial W/\partial l/\partial W/\partial s)|_{s=-s_0} = 0$, as in (2.5).

In the absence of the object ($f \equiv 0$), the eikonal is a function $W = W_0$, with $W_0(x) = \langle v, x \rangle$ at any point x . In the presence of the object f , we will express the eikonal as $W = W_0 + W_f$, i.e., as the sum of the object-free term W_0 and a correction term W_f that is solely due to the presence of the object and, therefore, contains all the information about the object function f . This decomposition is similar to the decomposition of the total (measurable) wave into the sum of the background and the scattered wave in diffraction tomography, the latter of which is solely due to the presence of the object and contains all information about it.

Under conditions, the solution W to the eikonal equation (2.1) admits a series representation of the form of an iterated perturbational expansion. To begin, f is replaced by ϵf in (2.1) and its solution $W(x; \epsilon)$ is obtained by substituting in (2.1) the formal series

$$W(x; \epsilon) = W_0(x) + \epsilon W_1(x) + \epsilon^2 W_2(x) + \dots \quad (2.25)$$

where W_0 is the eikonal in the absence of the object (i.e., for $\epsilon = 0$). The resulting equations that specify the individual terms in the series (2.25) are obtained by equating terms of the same power in ϵ in both sides of (2.1). The result is

$$\langle \nabla W_0, \nabla W_0 \rangle = 1 \quad (2.26)$$

$$\langle \nabla W_0, \nabla W_1 \rangle = f \quad (2.27)$$

$$\langle \nabla W_0, \nabla W_n \rangle = -\frac{1}{2} \sum_{k=1}^{n-1} \langle \nabla W_k, \nabla W_{n-k} \rangle; \quad n \geq 2. \quad (2.28)$$

Equations (2.26), (2.27), and (2.28) are each first-order partial differential equations. Therefore, their general solution will depend on one integration constant which will be specified from the proper boundary conditions. The solution to (2.26) is the complex phase of the incident field, normalized by $1/ik$ (i.e., $W_0(x) = \langle v, x \rangle = s$), which satisfies the boundary condition

(2.24). Therefore, the boundary condition to be satisfied by W_j , $j \geq 1$, requires that

$$W_j(\tau u - s_0 v) = 0; \quad \tau \in R^1, \quad j \geq 1. \quad (2.29)$$

The solution to (2.27) and (2.28) is given next.

Clearly, (2.27) is converted to

$$\langle v, \nabla W_1 \rangle = f \quad (2.30)$$

or, equivalently

$$\frac{\partial W_1}{\partial s} = f. \quad (2.31)$$

Thus

$$W_1(x = \tau u + s v) = \int_{-s_0}^s f(\tau u + s' v) ds' + c_1 \quad (2.32)$$

where from the boundary condition (2.29) $c_1 = 0$. Similarly,

$$W_j(x = \tau u + s v) = -\frac{1}{2} \int_{-s_0}^s \left[\sum_{k=1}^{j-1} \langle \nabla W_k, \nabla W_{j-k} \rangle \right] (\tau u + s' v) ds'; \quad j \geq 2. \quad (2.33)$$

E. Volterra Series Model for Traveltime Data from the Eikonal Equation

It can be shown [5] that $c_0 T(x_0 = \tau u + s_0 v) = \Re\{W(\tau u + s_0 v) - W(\tau u - s_0 v)\}$, where W is the eikonal of (2.1) and \Re denotes the real part. Therefore, similarly to (2.20), we have

$$T(x_0) = T_0(x_0) + \epsilon T_1(x_0) + \epsilon^2 T_2(x_0) + \dots \quad (2.34)$$

where

$$T_0(x_0) = \frac{2s_0}{c_0} \quad (2.35)$$

$$T_1(x_0) = \frac{1}{c_0} W_1(x_0) \quad (2.36)$$

$$T_2(x_0) = \frac{1}{c_0} W_2(x_0), \quad (2.37)$$

$$\vdots$$

F. Relation between Volterra Series Models for Traveltime Data

Equation (2.34) provides a Volterra series expansion to the traveltime time T measured at x_0 , similar to the power series of (2.20). Comparing the procedure that resulted in (2.20) and (2.34), we observe that while T_j in (2.20) is a homogeneous Volterra functional of order j in the refraction index perturbation δn , T_j in (2.34) is a homogeneous Volterra functional of order j in the object function f . However, for $f = \frac{1}{2}(n^2 - 1)$, with $n = 1 + \delta n$, we find $f = \delta n + ((\delta n)^2/2)$. Therefore, $\epsilon f = \epsilon \delta n + \mathcal{O}(\epsilon^2)$, which when combined with (2.22), (2.32), and (2.36), leads to the conclusion that the linear ray perturbation and the linear eikonal perturbation models result in identical traveltime predictions.

III. NONLINEAR TOMOGRAPHIC INVERSION OF TRAVELTIME DATA

A. The General Case

Define the Hilbert spaces \mathcal{F} and \mathcal{P} as follows. \mathcal{F} is $L^2(\mathcal{D}_a)$, where \mathcal{D}_a is a disk of radius a in R^2 , which includes the object

support \mathcal{V} , and \mathcal{P} is the space of functions defined on $R^1 \times [0, 2\pi)$, which are square-integrable with respect to the first variable. Define the nonlinear operators

$$T_j: \mathcal{F} \rightarrow \mathcal{P} \quad (3.1)$$

where

$$(T_j f)(\tau, \theta) = T_j(s_0; \theta, \tau) \quad (3.2)$$

and $T_j(s_0; \theta, \tau)$ is the j th term of the series (2.20) or (2.34) to the traveltime perturbation along the measurement line $s = s_0$ parameterized by the probing wave angle θ and the parameter τ . Clearly, T_j is a homogeneous Volterra operator of order j . More specifically, the operator $T_1: \mathcal{F} \rightarrow \mathcal{P}$ is linear and implementable via use of a fast Fourier transform-based algorithm. Indeed

$$(T_1 f)(\tau, \theta) = \frac{1}{c_0} \int_{-\infty}^{\infty} f(\tau u + s'v) ds'. \quad (3.3)$$

Therefore, the one-dimensional (1-D) Fourier transform $(\widetilde{T_1 f})(p, \theta) \equiv \int_{-\infty}^{\infty} e^{-ip\tau} T_1(s_0; \theta, \tau) d\tau$ is given as

$$\begin{aligned} (\widetilde{T_1 f})(p, \theta) &= \frac{1}{c_0} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} e^{-ip\tau} f(\tau u + s'v) d\tau ds' \\ &= \tilde{f}(pu) \end{aligned} \quad (3.4)$$

where $\tilde{f}(K) = \int e^{-i(K,x)} f(x) dx$ is the 2-D Fourier transform of f . Equation (3.4) is a statement of the well-known *projection-slice theorem* of x-ray computerized tomography and relates the 1-D Fourier transform of a tomographic projection to a linear slice through the 2-D Fourier transform of the object function [21], [24].

Define now the linear operator

$$\mathcal{B}: \mathcal{P} \rightarrow \mathcal{F} \quad (3.5)$$

with

$$\begin{aligned} (\mathcal{B}d)(x = tu + sv) &= \frac{c_0}{(2\pi)^2} \int_0^\pi d\theta \int_{-\infty}^{\infty} e^{ipt} |p| \tilde{d}(p, \theta) dp, \\ &\quad -s_0 \leq s \leq s_0 \end{aligned} \quad (3.6)$$

where the tilde denotes a Fourier transform, i.e., $\tilde{d}(p, \theta) = \int_{-\infty}^{\infty} e^{-ipt} d(t, \theta) dt$. The operator $(\mathcal{B}|\mathcal{P})$ defines the *filtered backprojection algorithm* of x-ray computerized tomography and is thus the inverse of $(T_1|\mathcal{F})$ [21], [24]. Indeed, if $d(\tau, \theta) = \int_{-\infty}^{\infty} f(\tau u + s'v) ds'$, then the projection-slice theorem implies that $\tilde{d}(p, \theta) = \tilde{f}(pu)$, and algebraic manipulation of (3.6) shows that $(\mathcal{B}d)(x) = f(x)$ [21], [24].

Define the inhomogeneous Volterra operator of order N

$$\mathcal{T}^N = T_1 + T_2 + \cdots + T_N; \mathcal{F} \rightarrow \mathcal{P} \quad (3.7)$$

where

$$(\mathcal{T}^N f)(\tau, \theta) = (T_1 + T_2 + \cdots + T_N)f(s_0; \theta, \tau) \quad (3.8)$$

and $T_j(s_0; \theta, \tau)$, $j = 1, 2, \dots$, is the j th term of the series (2.20) or (2.34) to the traveltime along the measurement line $s = s_0$ parameterized by the probing angle θ and the parameter τ . The existence of a local inverse of the operator \mathcal{T}^N and its representation by a convergent series is guaranteed by the existence of the inverse $(\mathcal{B}|\mathcal{P})$ of the linear term $(T_1|\mathcal{F})$ [20], [35]. Specifically, there exists a region in the data space \mathcal{P} on which the operator series

$$B_1 + B_2 + \cdots + B_j + \cdots \quad (3.9)$$

is the inverse of \mathcal{T}^N , where B_j is a homogeneous Volterra operator of order j in the data. Conditions for convergence of inverse Volterra series of the form of (3.9) are stated in the relevant literature (e.g., [20], [25]). However, the application of the general conditions to the specific Volterra series examined here is not only nontrivial, but also nonpractical. Indeed, the conditions require knowledge of the object function, the unknown that the traveltime measurements seek to determine. A better and more practical approach would be to compute successive terms of the proposed series until convergence (or divergence) is observed. The general Volterra series theory guarantees that when the inverse series converges, its limit is the true inverse.

More specifically, the first few terms in the series (3.9) are

$$B_1 = \mathcal{B} \quad (3.10)$$

$$B_2 = -\mathcal{B}T_2\mathcal{B} \quad (3.11)$$

$$B_3 = \mathcal{B}T_2\mathcal{B}T_2\mathcal{B} - \mathcal{B}T_3\mathcal{B} \quad (3.12)$$

\vdots

It is observed that the terms B_1, B_2, B_3 , etc. are *universal*, in the sense that they do not depend on the order N of the forward model \mathcal{T}^N . Thus, the operator series in (3.9) can be truncated to desired order j and return inversion algorithms of order j in the data. For example, the usual filtered backprojection algorithm provides a universal inversion algorithm that is first-order (linear) in the data. A second observation is that if the data are sufficiently modeled by the first-order term (i.e., $T = T_1$ and $T_2 = T_3 = \cdots = 0$), then each higher-order term in series (3.9) returns an identically zero contribution to image reconstruction, as close examination of the expressions in (3.10)–(3.12) reveals. This fact is also verified in the simulations of the next section. A final observation is that the resulting algorithms are effectively of the form of *nonlinear* data filtering followed by backprojection. Indeed, the series (3.9) can be written as

$$\mathcal{B}(\mathcal{I} - T_2\mathcal{B} + T_2\mathcal{B}T_2\mathcal{B} - T_3\mathcal{B} + \cdots) \quad (3.13)$$

where $\mathcal{I}: \mathcal{P} \rightarrow \mathcal{P}$ is the identity operator. Effectively, the term in brackets in (3.13) is a higher-order nonlinear Volterra filter applied on the data and thus, the series (3.9) gives rise to an entire class of nonlinear filtered backprojection algorithms for inversion of traveltime data.

B. Cylindrically Symmetric Case

A particularly important imaging situation is that of objects with cylindrical symmetry or scatterers whose refraction index (object function) varies only with the radial distance from their center and thus is of the form

$$f(x) = f_r(r), \quad r = |x|. \quad (3.14)$$

This important situation arises in practical applications such as reconstruction of the structure of optical fibers or large molecules but also provides a paradigm for both analytical and computer simulation study of reconstruction algorithms. Both the filtered backprojection inversion algorithm and the nonlinear forward models attain a simpler form.

Indeed, let

$$\tilde{f}_r(|K|) = 2\pi \int_0^\infty r J_0(|K|r) f_r(r) dr. \quad (3.15)$$

Then, the Fourier transform of the object function f becomes

$$\hat{f}(K) = \hat{f}_r(|K|) \quad (3.16)$$

and is inverted as

$$f_r(r) = \frac{1}{2\pi} \int_0^\infty |K| J_0(|K|r) \hat{f}_r(|K|) d|K|. \quad (3.17)$$

The projection-slice theorem reads

$$(\widehat{T_1 f})(p) = \frac{1}{c_0} \hat{f}_r(|p|) \quad (3.18)$$

where the projections $T_1 f$ are independent of the view angle θ . The filtered backprojection algorithm is now put in the form

$$\hat{f}(x = tu) = \frac{c_0}{2\pi} \int_0^\infty J_0(p|t|) p \hat{d}(p) dp \quad (3.19)$$

where the integration with respect to view angle θ has been eliminated.

Similarly, (2.33) gives

$$(\mathcal{T}_2 f)(\tau, \theta) = -\frac{1}{2c_0} \int_{-s_0}^{s_0} \left[\left(\frac{\partial W_1}{\partial t} \right)^2 + \left(\frac{\partial W_1}{\partial s} \right)^2 \right] (\tau u + sv) ds \quad (3.20)$$

where

$$\frac{\partial W_1}{\partial s}(x) = f_r(|x|) \quad (3.21)$$

$$\frac{\partial W_1}{\partial t}(x = \tau u + sv) = \tau \int_{-s_0}^s \frac{f'_r(\sqrt{\tau^2 + s'^2})}{\sqrt{\tau^2 + s'^2}} ds'. \quad (3.22)$$

IV. COMPUTER SIMULATION

The proposed nonlinear tomographic reconstruction algorithms were implemented and studied in a limited computer simulation. The scatterer was cylindrically symmetric with a Gaussian object function

$$f(x) = f_r(|x|) \equiv A \exp\left(-\frac{|x|^2}{2\sigma^2}\right) \quad (4.1)$$

where we chose $\sigma = 0.5$ and considered the two cases $A = 0.002$ and $A = 0.02$. The case $A = 0.002$ represents a (perhaps unrealistically) weak scatterer for which traveltimes measurements are sufficiently modeled by only the first traveltimes term. On the other hand, the case $A = 0.02$ represents more common scatterers, such as those encountered in ultrasonic imaging of soft tissue [38], [37], [39]. Effectively, the object is contained within the disk $|x| \leq 1.5$, i.e., has a diameter of approximately 3. The measurement distance was set to $s_0 = 25.5$.

For this object, the eikonal terms W_n and the corresponding traveltimes terms T_n can be computed in closed form. Indeed, we find that (3.18) and (3.20) give the first two traveltimes terms as

$$T_1(\tau) = \sqrt{\frac{\pi}{2}} \frac{\sigma}{c_0} \exp\left(-\frac{\tau^2}{2\sigma^2}\right) \cdot \left[\operatorname{erf}\left(\frac{s_0}{\sigma\sqrt{2}}\right) - \operatorname{erf}\left(-\frac{s_0}{\sigma\sqrt{2}}\right) \right] \quad (4.2)$$

$$T_2(\tau) = -\frac{1}{2c_0} \int_{-s_0}^{s_0} \left[\left(\frac{\partial W_1}{\partial t} \right)^2 + \left(\frac{\partial W_1}{\partial s} \right)^2 \right] (\tau u + sv) ds \quad (4.3)$$

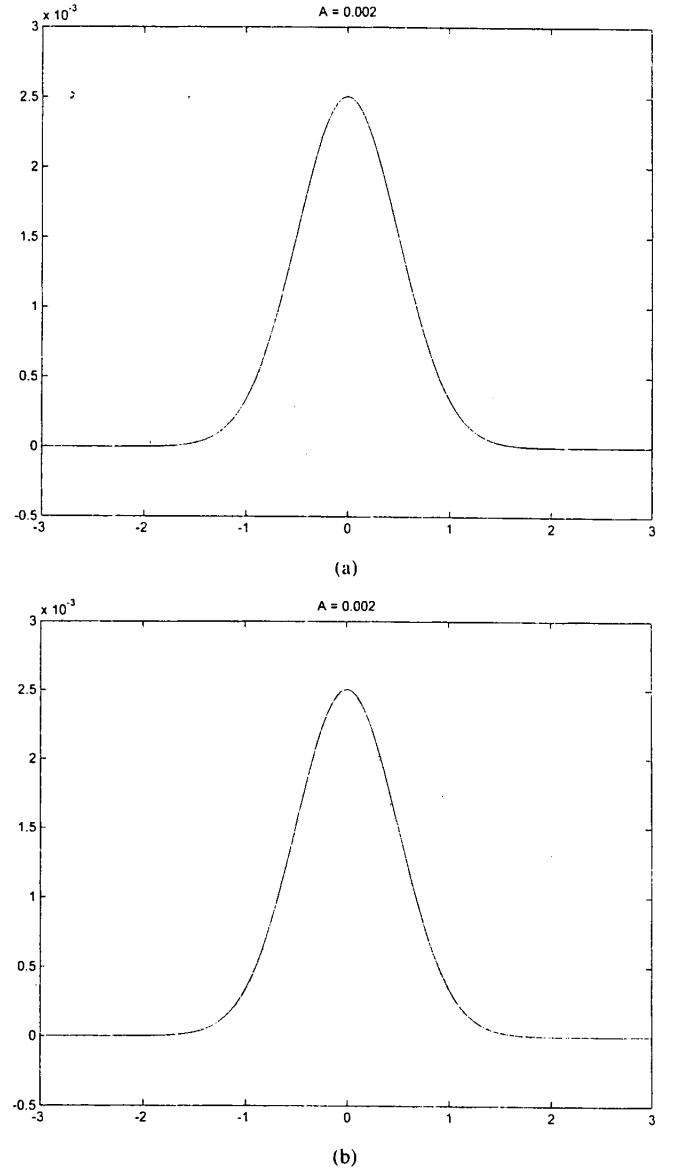

Fig. 2. (a) First (second) traveltimes term for the weak scatterer ($A = 0.002$) is plotted in solid (dashed) line. (b) The first-(second) order traveltimes approximation for the weak scatterer ($A = 0.002$) is plotted in solid (dashed) line.

where from (3.21) and (3.22), we have

$$\begin{aligned} \frac{\partial W_1}{\partial s}(x) &= A \exp\left(-\frac{|x|^2}{2\sigma^2}\right) \\ \frac{\partial W_1}{\partial t}(x = \tau u + sv) &= -\sqrt{\frac{\pi}{2}} \tau \exp\left(-\frac{\tau^2}{2\sigma^2}\right) \\ &\quad \cdot \left[\operatorname{erf}\left(\frac{s}{\sigma\sqrt{2}}\right) - \operatorname{erf}\left(-\frac{s}{\sigma\sqrt{2}}\right) \right]. \end{aligned} \quad (4.4)$$

In Fig. 2(a), we show plots of the traveltimes terms T_1 (solid line) and T_2 (dashed line), as computed from (4.2) and (4.3) for $c_0 = 1$ and for the weak scatterer with $A = 0.002$. Fig. 2(b) shows plots of the first-order (solid line) and second-order (dashed line) traveltimes approximations $T = T_1$ and $T = T_1 + T_2$, respectively. We observe that the second

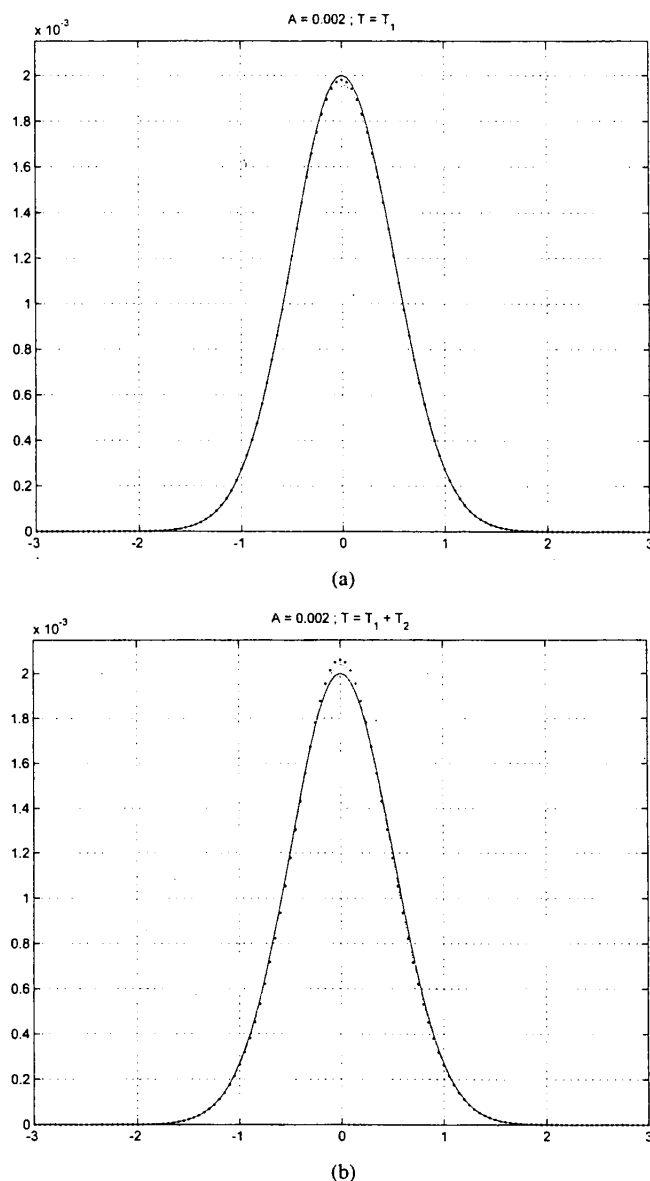

Fig. 3. (a) Original object function (solid line) and reconstructions from the first-order traveltime data returned by the filtered backprojection (dotted line) and the second-order algorithm (dashed line) in the computer simulation of the weak scatterer ($A = 0.002$). (b) Original object function (solid line) and reconstructions from the second-order traveltime data returned by the filtered backprojection (dotted line) and the second-order algorithm (dashed line) in the computer simulation of the weak scatterer ($A = 0.002$).

traveltime term is more than 40 times smaller in magnitude than the first traveltime term ($(\max |T_2| / \max |T_1|) \approx 0.0233$). Thus, the traveltime T is well (but not quite perfectly) approximated by the first term T_1 . Fig. 3 shows the object function reconstructions returned by the filtered backprojection and the second-order algorithm based on the traveltime series from first-[Fig. 3(a)] and second-order [Fig. 3(b)] traveltime approximations. Due to the weakness of the scatterer, the filtered backprojection algorithm returns an accurate reconstruction that is almost identical to the original object function even for data $T = T_1 + T_2$. The second-order reconstruction algorithm returns essentially the same reconstruction as the filtered backprojection algorithm for data $T = T_1$ and slightly improved for data $T = T_1 + T_2$.

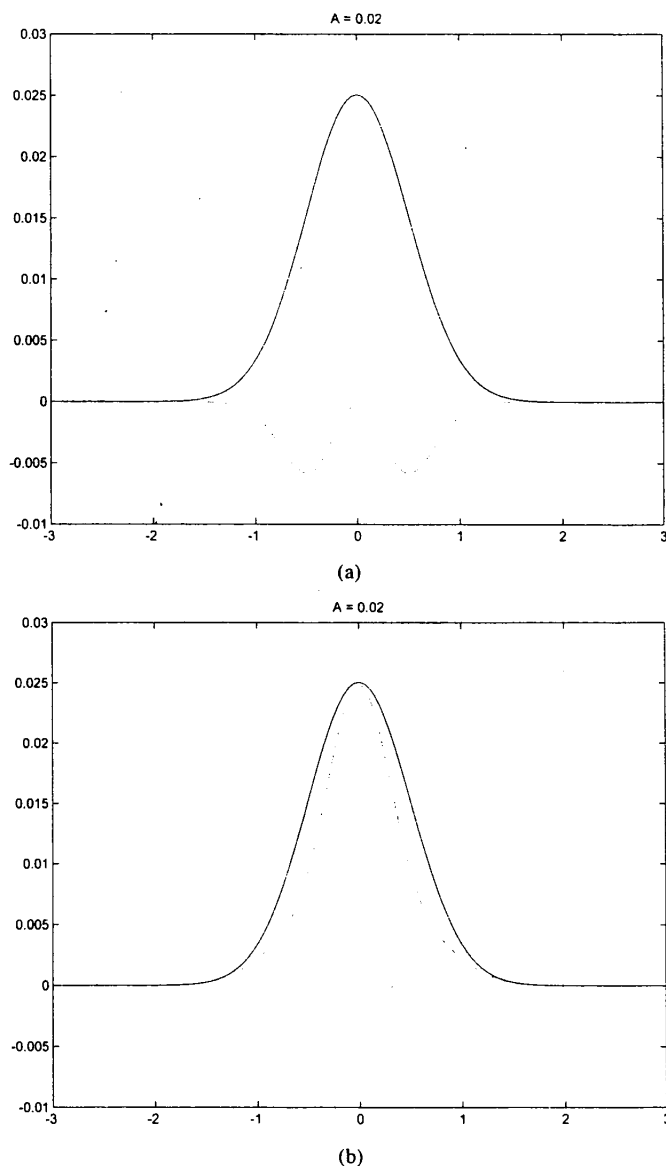

Fig. 4. (a) First (second) traveltime term for the stronger scatterer ($A = 0.02$) is plotted in solid (dashed) line. (b): The first-(second) order traveltime approximation for the stronger scatterer ($A = 0.02$) is plotted in solid (dashed) line.

In Fig. 4(a), we show plots of the traveltime terms T_1 (solid line) and T_2 (dashed line), as computed from (4.2) and (4.3) for $c_0 = 1$ and for the scatterer with $A = 0.02$. Fig. 4(b) shows plots of the first-order (solid line) and second-order (dashed line) traveltime approximations $T = T_1$ and $T = T_1 + T_2$, respectively. We observe that the second traveltime term is more than four times smaller in magnitude than the first traveltime term ($(\max |T_2| / \max |T_1|) \approx 0.2330$). Additionally, the third traveltime term T_3 (not shown) is about 16 times smaller in magnitude than the first traveltime term T_1 . Thus, the traveltime T is now well (but not perfectly) approximated by the sum of the first two terms T_1 and T_2 . Fig. 5 shows the object function reconstructions returned by the filtered backprojection and the second-order algorithm based on the traveltime series, from first- [Fig. 5(a)] and second-order [Fig. 5(b)] traveltime approximations. Clearly, the second-order algorithm returns the same reconstruction as the filtered backprojection algorithm in the

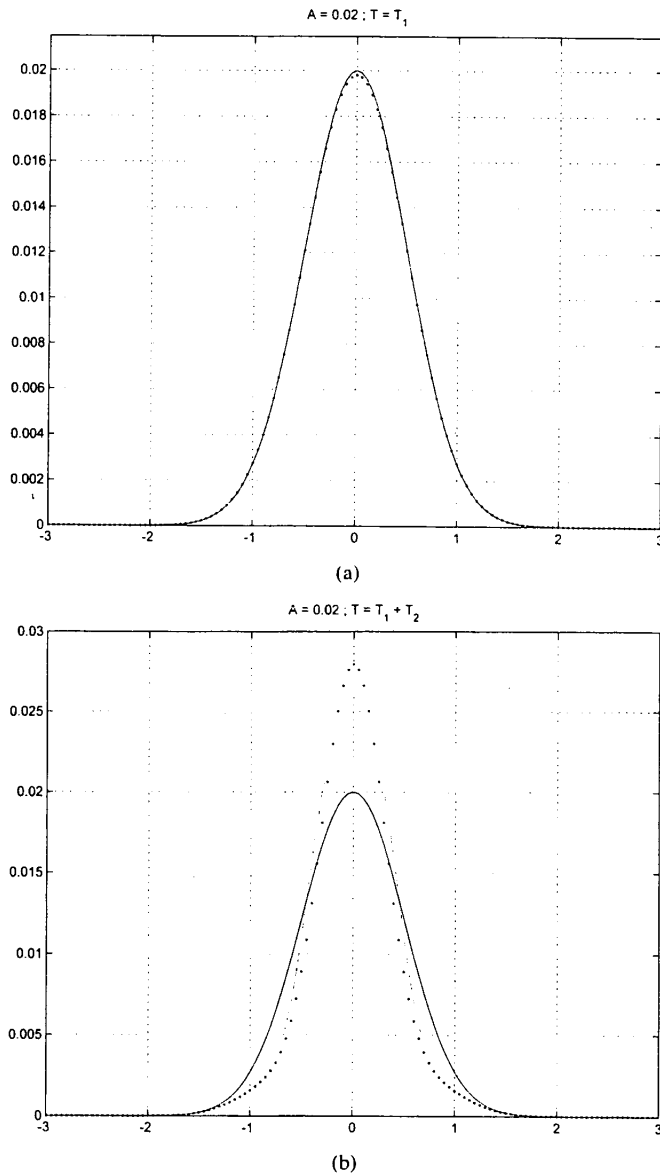

Fig. 5. (a) Original object function (solid line) and reconstructions from the first-order traveltime data returned by the filtered backprojection (dotted line) and the second-order algorithm (dashed line) in the computer simulation of the stronger scatterer ($A = 0.02$). (b) Original object function (solid line) and reconstructions from the second-order traveltime data returned by the filtered backprojection (dotted line) and the second-order algorithm (dashed line) in the computer simulation of the stronger scatterer ($A = 0.02$).

case of data consisting of only the first traveltime term. However, the filtered backprojection algorithm underperforms the second-order algorithm by a significant margin when the second traveltime term is not negligible. We also observe in Fig. 5(b) that the inverted profiles still differ from the true profile even when a second-order inversion algorithm is used. This implies that the third and perhaps higher terms in the inverse series (3.9) are significant.

Further testing of the proposed nonlinear inversion algorithms is currently under way. These tests involve processing traveltime measurements collected using a pulsed laser and scatterers whose object functions are well-known. These tests will be completed soon and the results will be announced at that point.

V. SUMMARY, CONCLUSIONS, AND FUTURE RESEARCH

In this paper, linearized traveltime tomography was extended into a higher-order (nonlinear) regime via use of an arbitrarily large number of terms from the ray or eikonal series as the data-generating model in scattering experiments. Nonlinear tomographic reconstruction algorithms were developed for inversion of wavefield data and image formation, which attained the form of a series of Volterra operators in which the leading (linear) term was the usual filtered backprojection algorithm of linearized traveltime tomography. A limited computer simulation study was included to illustrate the performance of the algorithms in the case of scattering objects with cylindrical symmetry. From this study, it was found that a second-order algorithm returned the same reconstruction as the usual filtered backprojection algorithm when applied to first-order traveltime data, but clearly outperformed the filtered backprojection algorithm when applied to data consisting of the second-order traveltime approximation.

This paper establishes a unified paradigm for development of linear and nonlinear reconstruction algorithms for traveltime tomography and thus further investigation in its direction is due. Future relevant research may follow the avenues of higher-order traveltime tomography with alternative data measurement configurations (e.g., spherical incident waves) and higher-order traveltime tomography of stochastic objects. These and other research avenues are currently being explored, and the findings will be reported elsewhere.

APPENDIX ELEMENTS OF THE VOLTERRA THEORY OF NONLINEAR SYSTEMS

A homogeneous Volterra operator (VO) of order $k \geq 1$ is a nonlinear system represented by a functional relation of the form

$$y(\cdot) = \int \cdots \int d\tau_1 \cdots d\tau_k h_k(\cdot; \tau_1, \cdots, \tau_k) x(\tau_1) \cdots x(\tau_k) \quad (\text{A.1})$$

between its input $x(\cdot)$ and the corresponding output $y(\cdot)$. The $(k+1)$ -dimensional function $h_k(\cdot; \tau_1, \cdots, \tau_k)$ is the *kernel* of the homogeneous k th-order VO, and for uniqueness, it is assumed symmetric (i.e., its value does not change under a permutation of its arguments). Clearly, a homogeneous VO of order $k = 1$ is a linear system and its kernel $h_1(\cdot; \tau_1)$ is also its impulse response. A homogeneous VO of order k as in (A.1) is a homogeneous polynomial system of order k in the sense that the system response to input $cx(\cdot)$ is $c^k y(\cdot)$ for arbitrary constant c .

A general (inhomogeneous) VO of order N is a nonlinear system consisting of the summation of homogeneous VO's of the form of (A.1) of order less than or equal to N , i.e., a nonlinear system represented by a functional relation of the form

$$y(\cdot) = h_0 + \sum_{k=1}^N \int \cdots \int d\tau_1 \cdots d\tau_k h_k(\cdot; \tau_1, \cdots, \tau_k) x(\tau_1) \cdots x(\tau_k) \quad (\text{A.2})$$

where h_0 is a constant. Clearly, an inhomogeneous VO of order N is a polynomial system of order N in the sense that its response to input $cx(\cdot)$ is a polynomial in c of order N for arbitrary constant c . (A.2) can be generalized further by letting the order N of the inhomogeneous VO become infinite, assuming convergence of the resulting functional series

$$y(\cdot) = h_0 + \sum_{k=1}^{\infty} \int \cdots \int d\tau_1 \cdots d\tau_k h_k(\cdot; \tau_1, \cdots, \tau_k) x(\tau_1) \cdots x(\tau_k). \quad (\text{A.3})$$

In practice, both the number of terms in (A.3), as well as the support of the Volterra kernels must be truncated. Issues of approximation of nonlinear systems with infinite and truncated Volterra systems, as well as issues of existence and uniqueness of inverses of Volterra systems, have been extensively addressed in the literature (e.g., [10], [20], [25], [18], [35], [33], [32], [17], [34]), to which the interested reader is pointed.

George Tsihrintzis (S'88–M'93) was born in Athens, Greece. He received the electrical engineer degree from the National Technical University of Athens (Hons.), Athens, Greece, in 1987, and the M.S. and Ph.D. degrees in electrical engineering from Northeastern University, Boston, MA, in 1988 and 1992, respectively.

He is currently an Associate Professor with the Department of Informatics, The University of Piraeus, Piraeus, Greece, and a Visiting Professor with the Department of Electrical and Computer Engineering, Northeastern University, Boston, MA. Previously, he was a Research Associate with the Signal and Image Processing Institute, University of Southern California, Los Angeles, and an Assistant Professor of Electrical Engineering, University of Virginia, Charlottesville. His expertise combines signal and image processing and electromagnetic wave theory, and his research interests include pattern recognition, detection and estimation theory, statistical signal processing, and inverse problems in scattering with applications in imaging, radar, and communications. He has contributed over 100 publications in these areas and is the author of the article on *Radar Applications* in the *Wiley Encyclopedia of Electrical and Electronics Engineering* (1999).

Anthony J. Devaney (M'87) received the B.S.E.E. in electrical engineering from Northeastern University, Boston, MA, in 1964, the M.S. degree in engineering and applied science from Yale University, New Haven, CT, in 1965, and the Ph.D. degree from the Institute of Optics, University of Rochester, Rochester, NY, in 1971.

He is currently Professor of Electrical and Computer Engineering with Northeastern University, and is also President of A. J. Devaney Associates, Boston, MA and Vice President of Technology of Witten Technologies, Washington, DC. Previously, he held positions with Eikonix Corporation, Bedford, MA, and Schlumberger–Doll Research, Ridgefield, CT. He has published more than 120 papers in refereed journals, holds six patents, and has presented scientific papers at a number of conferences and universities.

Dr. Devaney is a Fellow of the Optical Society of America and a member of the Acoustical Society of America. He was formerly the topical Editor for propagation and scattering for the *Journal of the Optical Society of America*. Currently, he is a member of the editorial boards of the journals *Wave Motion*, *Electronic Imaging*, and *Inverse Problems*, and is an Associate Editor of *Ultrasonic Imaging*.

Time Domain Processing of Frequency Domain GPR Signatures for Buried Land Mine Detection¹

Abstract

This paper investigates the feasibility of detecting plastic antipersonnel land mines buried in lossy, dispersive, rough soils using a stepped-frequency ultra wideband (WB) ground-penetrating radar (GPR). Realistic land mine scenarios were modeled using a two-dimensional (2D) finite difference frequency domain (FDFD) technique. Assuming normal incidence plane wave excitation, the scattered fields were generated over a large frequency bandwidth (.5 to 5 GHz) for a variety of mine-like shapes, different soil types, and multiple receiver locations. The simulation results showed that for a ground penetration sensor located just above the soil surface, the strong reflection signals received from the rough ground surface obscured the buried target's frequency response signal.

The simulated GPR WB frequency response data at each receiver location was transformed to the time domain using the fast fourier transform. Time domain processing permits high resolution measurement of target features that are invariant to the ground roughness and also that are dependent on the soil characteristics as well as the burial depth and size of the mine. Specifically, two or more characteristic timing peaks are observed in the simulation results suggesting that the ultra-wideband spectral radar response may yield particular advantages not exploited by currently employed detection systems. It is also shown that by using time-gating to remove the strong ground reflection signals, the target signals are selectively enhanced (as expected), but more surprisingly, the target frequency response signature is almost completely recovered.

Keywords: mine detection, ground-penetrating radar, ultra-wideband radar, resonance, dielectric target imaging

1. Introduction

The detection and removal of buried land mines is a serious problem that affects both civilians and soldiers throughout the world. Metal detectors are the current sensors of choice for detecting mines, but they are relatively ineffective in locating plastic land mines that contain little to no metal. In this case, an improved sensor capability and/or advanced signal processing technology is necessary to effectively detect all types of mines.

This paper investigates the feasibility of using an ultra wideband stepped-frequency ground penetrating radar sensor to detect nonmetallic antipersonnel land mines buried in lossy dispersive soil. GPR is one of the oldest sensor technologies for subsurface sensing. The geophysical community has used it successfully for decades as a cost effective and noninvasive measure to probe the ground in determining the underlying strata. GPR has proven to be a useful sensor when (1) the soil is not exceedingly lossy, (2) the target or layer of interest has a high-dielectric constant contrast with the surrounding or adjacent ground, (3) the target is not excessively deep, and (4) the search area is not extremely large. The limiting factor in using GPR for mine detection within the surface a few feet is not so much attenuation, but clutter. In radar terminology, the GPR problem is clutter-limited not noise limited. The sources of clutter can include vegetation and other non-metallic objects such as rocks, tree branches, etc. The rejection of clutter is an essential part of a successful GPR system. In addition, for GPR applications the target of interest is characterized not only by the inherent properties of the buried object and soil but also by the strong effects of the air-ground interface. This is due to the fact that the rough soil surface may also scatter much of the transmitted sensing signal and be a significant source of detection clutter.

In order for a GPR to be successful sensor in mine detection, it must be able to identify the buried target, i.e. determine the mine's shape, size, and material characteristics. This is a necessary requirement in order to separate the reflected mine signals from the clutter signals (rocks, branches, debris, etc.). For most subsurface sensing systems, the GPR relies on the magnitude of the target backscatter as its only classification measure. Detection difficulties arise when you have a low dielectric constant contrast target (small permittivity difference between the mine and soil) that would produce a weak target response, for example, a TNT mine buried in sand. In addition due to the small size of mine, the mine's response would be even weaker at the lower frequencies. Yet it is extremely difficult to separate a buried mine from the ground surface clutter even at low frequencies. At higher frequencies the propagation loss and clutter from both the ground roughness and the soil inhomogeneity will become severe and therefore also increase the detection difficulty. Another frequency dependent response factor to consider is the conductivity of the soil. If the soil has high loss then accordingly the strength of the reflected target signal is attenuated as the frequency increases. Therefore a WB GPR experiences several frequency dependent effects.

The signal processing transformation of ultra-wideband GPR-based frequency domain reflection signals to the time domain will enable highly resolved target features to appear that are invariant to the ground roughness. The power spectral density of the reflected signal yields a time domain signature dependent on the soil characteristics as well as the burial depth and size of the mine. Specifically, two or more characteristic time peaks are uniquely observed suggesting that the ultra-wideband spectral

radar response may yield particular discrimination advantages not exploited by currently employed detection systems.

It is shown that by using time-gating to remove the strong ground reflection signals, the target signals are selectively enhanced (as would be expected), but more surprisingly, the target frequency response signature is almost completely recovered. This study determines the feasibility of detecting mine-like targets based on time domain processed GPR frequency signatures.

2. Frequency Domain Scattering

For this investigation, a 2D FDFD electromagnetic modeling simulation code was used to generate the near zone scattered electric fields resulting from a normally incident TM uniform plane wave on a random rough dielectric half-space containing a buried dielectric mine-like target. The simulated scattered electric field results generated by the FDFD code were validated with the scattered field results computed from another numerical electromagnetic simulation technique, a semi-analytic mode matching (SAMM) algorithm¹⁻². Excellent scattering agreement was achieved between the two codes for dielectric targets buried beneath randomly rough soils³⁻⁴. FDFD is an ideal technique for computing the near-field scattered fields since it permits an accurate representation at each frequency for the random rough surface and various target shapes. The only shortcoming was the extensive computational requirement in both memory and runtime.

Several realistic land mine simulation scenarios were modeled. A variety of modeling parameters were considered such as the mine shape, the surface roughness, and the soil type. The datasets were generated over a densely sampled wide frequency bandwidth (.5 to 5 GHz, 100 MHz increments). Each FDFD data set for the entire frequency bandwidth took approximately 12 hours to run on a Silicon Graphics Octane workstation (R12000; 300 MHz). Since most anti-personnel mines can be described by a simple geometry, three buried targets were considered in this investigation --- a circular-shaped TNT mine (10 cm diameter), a rectangular-shaped TNT mine (10 cm by 4 cm), and an elliptical-shaped TNT mine (major axis: 10 cm and minor axis: 6 cm). All the targets were modeled having the electrical characteristics of TNT ($\epsilon_m = 2.9(1+i0.001)\epsilon_o$), which was held constant over the frequency bandwidth.

Two different ground soil types were considered in this analysis. One is representative of the material characteristics of a low loss, dry sand ($\epsilon_g = 2.55(1+i0.01)\epsilon_o$) that remained constant over the frequency band. Note the permittivity of the sand is very similar to the permittivity of the TNT mine. The second soil model was a dispersive Bosnian soil⁵⁻⁷ ($\epsilon_g = 8.82(1+i0.13)\epsilon_o$ at 3 GHz), which was measured at the test site Alicia. The Bosnian soil had a higher permittivity than the mine and also a higher loss than the dry sand case. Therefore in these two cases, the TNT target buried in sand is considered a low dielectric constant contrast target and in the Bosnian soil the mine is a high dielectric constant contrast target. The simple targets were buried in these soils at a fixed depth of 10 cm from the air-ground surface. The air-ground interface was modeled both as smooth interface and a randomly rough interface. The rough soils had an average roughness equal to 1 cm and a correlation length equal to 4 cm.

Figure 1 schematically shows two FDFD input scattering model geometries representative of an infinite dielectric cylinder buried in the ground beneath a smooth and rough air-ground interface. In both cases a TNT target (dielectric constant = 2.9, loss tangent = 0.001) is embedded in a half space of dry sand (dielectric constant = 2.55, loss tangent = 0.01) or dispersive Bosnian soil (dielectric constant = 8.9, loss tangent = 0.13 at 3 GHz). All the rough surface scattering results to follow will exhibit the same roughness interface as displayed in the figure.

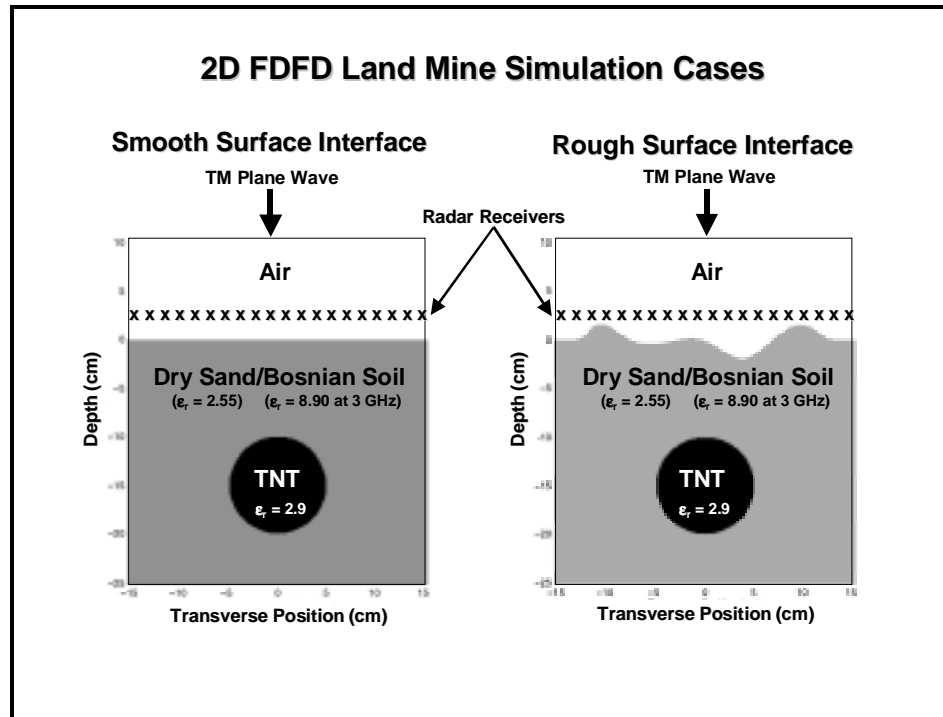

Figure 1: Representative 2D FDFD input geometry for an infinite dielectric cylindrical target buried 10 cm deep in the ground beneath both a smooth and rough air-ground interface.

The scattered TM electric field results (magnitude) in Figure 2 were generated by the 2D FDFD code using Figure 1's input model geometries and assuming normal incidence plane wave excitation. Displayed in the figure are the frequency-based spatial (as a function of depth and transverse position) scattered electric fields. Specifically, Figure 2 displays the scattered fields for the circular TNT target buried in both the sand and the Bosnian soil at individual frequencies (.5, 1, 2, 3, and 4 GHz) and beneath both the smooth and rough air-ground surface. All of the scattered field results had subtracted from them the scattering due to the smooth air ground interface alone, i.e. the ground reflection. Note that the scales in the figure vary to show the dominant scatterers in each plot in the figure.

The major differences in the scattering results for the circular mine buried under a smooth interface in the two different soils are as follows: (1) the TNT mine buried in the Bosnian soil exhibited a higher scattering response than the dry sand since it was a higher contrast target, (2) and at high frequencies the same target (buried in Bosnian soil) behaved like a cavity and thus the scattering was localized inside the target. When a rough surface interface was included for both ground types, the rough

surface scattering dominated the target scattering response as the frequency increased. Also notice in the Bosnian soil rough surface cases attenuation occurred at the higher frequencies due to the loss in the model.

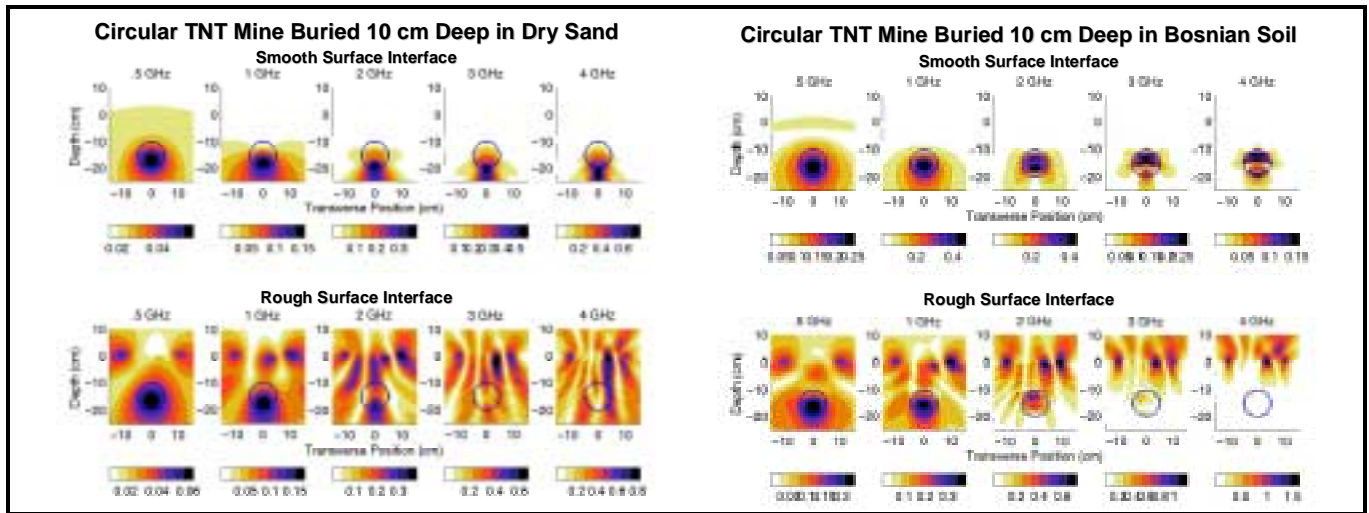

Figure 2: Spatial (Depth versus Position) E-Field scattering (magnitude) at individual frequencies (.5, 1, 2, 3, and 4 GHz) for a cylindrical mine (as denoted by the circles) buried 10 cm deep beneath a smooth and rough air-ground interface in two different soils (dry sand and Bosnian soil).

While the spatial scattering results (as displayed in Figure 2) helps one to understand the frequency dependent electromagnetic propagation and scattering effects associated with the different soil properties combined with the electrical characteristics of the target and the air-ground interface effects, the most important response to examine would be at the radar receiver/receivers locations. For this case, the analysis further assumes the radar receivers, as seen in Figure 1, to be placed across in the transverse position above the mine, and 2.5 cm above the ground surface. As would be expected, the most ideal radar receiver location is to be as close to the ground surface as possible for strong signal reception.

Figure 3 displays scattered fields (dBsm) for the three targets (circular, elliptical, and rectangular) as a function of frequency and transverse position of the receivers. The three objects were modeled as being buried 10 cm deep in the two soils (dry sand and Bosnian) beneath both the smooth and the rough air-ground interface. Also modeled was the case for the rough surface alone and no target is present. For the dry sand and a smooth air-ground interface cases, the received scattered fields for the three targets exhibited a constant resonating pattern across the frequency bandwidth. But in the case of the Bosnian soil, the received signal attenuated or faded as the frequency increased due to the presence of loss in the soil. The scattered field pattern of the rectangular object seem to be more distinctive than the circular and elliptical objects. As expected due to the large frequency bandwidth, the objects buried under a rough surface regardless of the soil type were indistinguishable from the rough surface case when no target was present. Also for both soil types the characteristic resonating pattern as seen in the smooth surface case was hidden by the rough ground surface reflections.

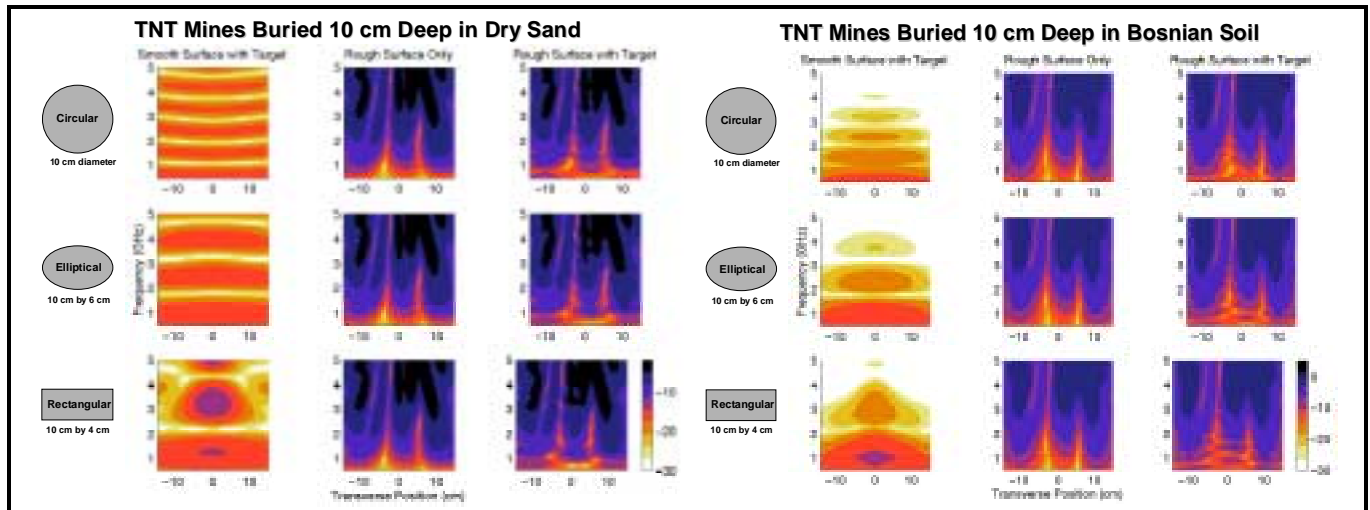

Figure 3: E-Field scattering (dBsm) versus frequency (GHz) and transverse position (cm) when radar receivers are placed 2.5 cm above a smooth and rough air-ground interface with a target buried 10 cm deep in soils (dry sand and Bosnian soil), and a rough air-ground interface with no buried targets present.

3. Time Domain Scattering Derived from GPR Frequency Signatures

This investigation examines the spectral response derived from the GPR frequency signatures as a viable discrimination technique in identifying a buried land mine from the clutter. A variety of spectral estimation techniques could be utilized to transform the GPR wideband frequency response to the time domain. These techniques have their associated benefits and limitations as widely known in the signal processing community. For example, before a waveform (one sweep over a given frequency range or bandwidth) is fourier transformed a weighting function is typically applied. This weighting function is used to mitigate the sidelobes that are produced by using a truncated fourier transform. A non-weighted transform will have a sidelobe level 13 dB below the peak response, but will have maximum resolution at 6 dB below the peak. In most cases, a Hamming weight is used to reduce the sidelobes to better than 40 dB below the peak. Unfortunately, the Hamming weight produces a loss of resolution by a factor of about 1.8. Therefore applying the Hamming weight is a trade-off since it helps to reduce the sidelobe levels but with the associated cost of decreasing the resolution.

After the wideband frequency data is fourier transformed to the time domain, highly resolved target features appear which directly correspond to the target's shape, size, and material content, the target's burial depth in the soil, and the soil's electrical properties. In particular, two or more characteristic timing peaks occur in the processed time domain signatures. For the case of a circular-shaped mine, as displayed in Figure 4, the peaks directly correspond to the scattering response from the top and bottom of the target. Due to the fact that the target is penetrable, these timing peaks (T_0 and T_1) correspond to the two-way travel times. T_0 corresponds to the round trip time for a transmitted wave to hit the top of mine and return back to the receiver. And accordingly, T_1 is the round trip time for the transmitted wave to hit the bottom of the mine and then return back to the receiver. Note due to the diffraction effects, the timing paths do not ideally correspond to a straight line as displayed in the figure. Other peaks can occur due to the geometry of the object, which might also include scattering effects from

sharp corners. If the dielectric constant of the land mine and the soil are known a priori then these timing peaks can be used to uniquely determine the target size and depth. Time domain processing shows features that are invariant to the ground roughness.

Figure 4: Schematic drawing of two way travel times, T_0 and T_1 , for a buried cylinder when radar receivers are transversely placed 2.5 cm above a smooth air-ground interface.

The simulated frequency response results for the buried mine-like targets in Figure 3 were transformed to the time domain using a traditional signal processing technique, the fast fourier transform (FFT). The WB frequency response for each receiver location was fourier transformed to the time domain producing a synthetic aperture-like response. Specifically, each column (or WB frequency response results for each receiver position, labeled transverse position) in the data sets displayed in Figure 3 was individually fourier transformed to the time domain. The time domain results as a function of transverse position (at fixed height 2.5 cm above the surface) or equivalently angle are displayed in Figure 5. As seen in the figure, the timing peaks as a function of position, as denoted by T_0 and T_1 , are clearly resolved for the three different targets shapes buried in both soils (dry sand and Bosnian soil) and beneath a smooth air-ground interface with the ground reflections removed. Since the dielectric constant of the Bosnian soil was higher than that of the sand the velocity of wave through the soil is slower and therefore the timing peaks are delayed in time. The difference between the timing peaks ($T_0 - T_1$), which directly corresponds to the size of the object, is always constant regardless of the soil type. Thus the quantity $T_0 - T_1$ is independent of the soil.

The timing peaks in Figure 5 are also distinguishable for the cases when the targets are buried beneath a rough surface for both soil types. The time domain results for the rough surface interface alone (no targets present) are also displayed as a visual comparison. When the buried target is modeled beneath a rough surface, the timing peaks associated with the target are sometimes obscured in the sidelobes of the signal at different transverse positions. But a different signal processing technique combined with coherent integration in position could also help this artifact. Due to the fourier transform of the data to the time domain, there is now a difference between the case when the target is present beneath a rough surface interface and the case when it is not present, notably, the timing peaks beneath the rough surface are observable.

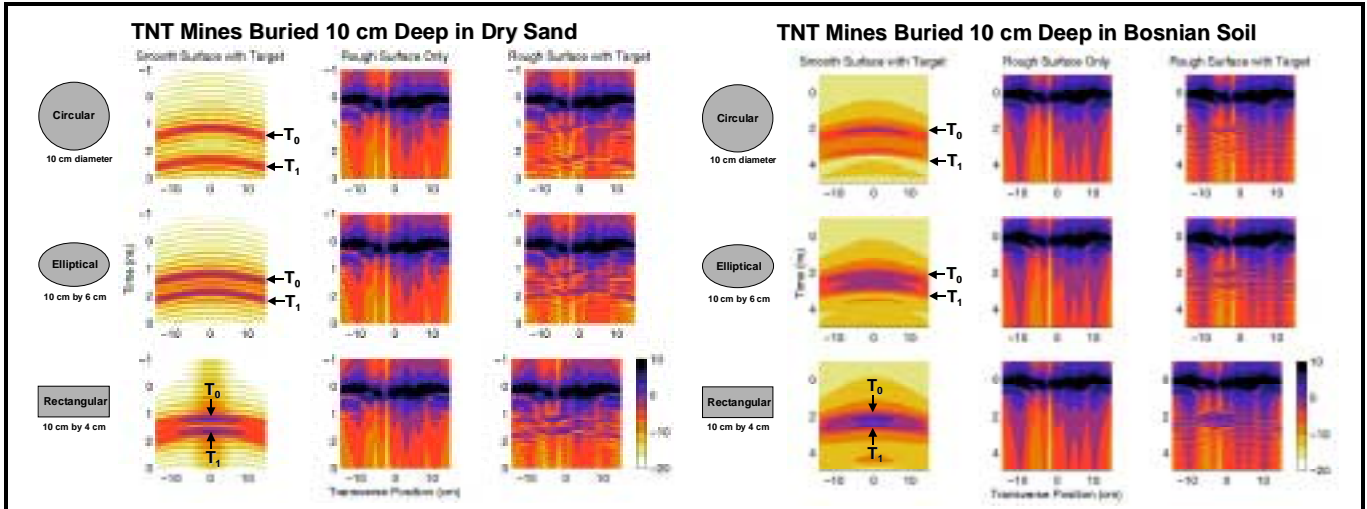

Figure 5: Processed time domain E-Field scattering (dBsm) versus time (ns) and transverse position (cm) for the three targets buried in soils beneath both a smooth air-ground interface and a rough air-ground interface, and a rough interface only (no target present)

The processed time domain scattered field results in Figure 5 were nominally time gated using a gaussian tapered high pass filter to remove some of the ground surface clutter effects as seen in Figure 6.

Figure 6: Removal of strong ground reflections: time domain E-Field scattering (dBsm) with gaussian tapered high pass filtering for the three targets buried in sand and Bosnian soil beneath both a smooth air-ground interface and a rough air-ground interface, and a rough interface only (no target present)

The time-gated scattered fields from Figure 6 were then inverse fourier transformed to return back to the frequency domain. It is shown in Figure 7 that by using time-gating to remove the strong ground reflection signals, the target signals are selectively enhanced (as would be expected), but more surprisingly, the target frequency response signature is almost completely recovered (as seen in the right most column for each ground type in the figure).

Figure 7: Processed frequency domain E-field scattering (dBsm). The processed time-gated data in Figure 6 was inverse fourier transformed for the three targets buried in sand and Bosnian soil beneath both a smooth air-ground interface and a rough air-ground interface, and a rough interface only (no target present).

4. Conclusions

The FDFD electromagnetic modeling technique proved to be a valuable computational tool in understanding the wideband propagation and scattering effects of buried dielectric mine-like objects in lossy dispersive rough soils. The reflected target frequency response is severely dependent on the nature of the soil both permittivity and loss, the target dielectric constant contrast with the soil, and the roughness of the soil. It is vital to understand these combined effects before a useful discrimination technique can be identified and developed. The wideband stepped-frequency GPR-based simulation results showed that the clutter from the rough ground reflections masked the target's frequency response signatures.

The signal processing of the ultra WB GPR simulated data to the time domain helped to resolve unique target features that are invariant to the ground roughness. In particular two or more timing peaks are observed which can specifically determine the size and depth of a target if the electrical characteristics of the soil and target are known a priori. These time-domain based features could uniquely characterize the target from the clutter. The target frequency response signature was almost completely recovered after nominally time-gating the ground reflection signals and then inverse fourier transforming the signatures to the frequency domain.

To be able to solve the challenging inverse problem of identifying small buried plastic land mines, one must be able to separate the ground surface reflections from the target signal response. If using a frequency resonance-based discrimination algorithm, the ground clutter clearly necessitates removal as seen in the simulation results presented herein.

Future target detection and identification algorithms will be explored in the delayed time domain environment after signal processing the frequency response signatures. This will include the detection of a land mine-like target from multiple objects (rocks, branches, debris, etc.) buried in lossy rough soils.

FDTD Computation of Wave Propagation in Dispersive Soil with a Perfectly Matched ABC Lattice Termination

Carey M. Rappaport and Scott C. Winton
Center for Electromagnetics Research
Northeastern University
Boston, MA 02115

In order to better predict the propagation and scattering of radar signals in inhomogeneous soil, it is important to use efficient computational techniques, such as the Finite Difference Time Domain method, suitably adjusted for lossy, dispersive media. In particular, the recently reported Perfectly Matched Layer absorbing boundary condition (Berenger *J. Comp. Phys.*, 10/1994) must be modified to most effectively prevent reflections from the computational lattice boundary.

The FDTD method is ideally suited for ultra-wideband ground penetrating radar simulation in applications of identifying land mines, buried waste, and excavation obstacles. FDTD efficiently models the irregular surface boundary and provides the needed flexibility in predicting radar scattering from both metal and plastic targets, buried in soil with rock inclusions and topped with vegetation. Such realistic scenarios are impractical for moment method calculations.

Dispersive FDTD algorithms exist which include the effects of frequency-dependent conductivity and dielectric constant (Weedon & Rappaport *IEEE Trans. Ant. Prop.*, to appear 1997; Gandhi, *IEEE Trans. Micro. Thry. Tech.*, 4/93). These methods are based on converting the frequency domain dispersive constitutive relation into differential or difference equations in the time domain. Because of the computational expense of storing previous time steps, it is essential to keep the order of any electromagnetic parameter approximation as low as possible.

Another important difference in using FDTD (or FDFD or finite element analysis) with a lossy, dispersive medium is the ABC used to terminate the computational grid. While the PML is an excellent ABC when applied at the periphery of a free space scattering domain, unless its parameters are modified, it will not be as effective when terminating a region modeling soil. The soil-tuned PML must be inherently matched to the soil at the ABC boundary. In the frequency domain, this is accomplished by matching the impedances of the two regions:

$$\eta_{soil} = \sqrt{\frac{\mu}{\epsilon_0(\epsilon_r - j\sigma/\omega\epsilon_0)}} = \eta_{PML} = \sqrt{\frac{\mu_{PML}}{\epsilon_{PML}}}$$

To maintain the frequency independence of this match the permeability and permittivity of the PML must have the form:

$$\mu_{PML} = \mu(1 - j\frac{\sigma_{PML}}{\omega\epsilon_0})$$

and

$$\sigma_{PML} = \epsilon_0(\epsilon_r - j\frac{\sigma}{\omega\epsilon_0})(1 - j\frac{\sigma_{PML}}{\omega\epsilon_0})$$

Converting this last expression into the time domain is problematic because of the double frequency dependence—which leads to a second time derivative in Ampere's Law. However, computed FDTD results for several soil cases show excellent suppression of unwanted edge boundary reflections.

Higher Order (Nonlinear) Diffraction Tomography: Inversion of the Rytov Series

George A. Tsihrintzis, *Member, IEEE*, and Anthony J. Devaney, *Member, IEEE*

Abstract—Nonlinear tomographic reconstruction algorithms are developed for inversion of data measured in scattering experiments in which the complex phase of the wavefields is modeled by an arbitrarily large (possibly infinite) number of terms in the Rytov series. The algorithms attain the form of a Volterra series of nonlinear operators, with the usual filtered backpropagation algorithm of Diffraction Tomography as the leading linear term. A computer simulation study is included to illustrate the performance of the algorithms for the case of scattering objects with cylindrical symmetry.

Index Terms—Born series, diffraction tomography, inverse scattering, Rytov series, Volterra series.

I. INTRODUCTION

A. Early Development of Diffraction Tomography

DIFFRACTION Tomography (DT) emerged over the past twenty years as a linearized approach to the problem of quantitative determination of the structure of an unknown object from measurement of the waves diffracted by the object in a suite of scattering experiments [102], [17], [22], [103]. The structure to be reconstructed by DT is usually the spatial distribution of the complex-valued index of refraction inside the object. Therefore, DT lies within the field of Inverse Scattering [56], [6], [9] and is applicable in a number of seemingly different scientific disciplines, such as crystal structure determination [48], medical ultrasound tomography [33], acoustic and electromagnetic underground surveying [19], [98], [99], [97], [52], [100], optical and coherent X-ray microscopy [51], and elastic wave inverse scattering [25]. DT differs from other Inverse Scattering theories [104], [35], [2], [5], [4], [37], [92], [57], [41], [42], [12], [13] in that it utilizes linearizing approximations, namely, the Born or the Rytov approximation, to the nonlinear mathematical mapping that relates the probing wave, the object refraction index, and the measurable total wave.

The foundation of modern linearized DT lies in the generalized projection-slice theorem of (A.10), which was recognized by Wolf [102] in 1969. Wolf [102] employed the Born approximation together with truncation of the evanescent wave modes

in the Weyl expansion and the need was recognized for a tomographic procedure employing different directions of illumination for a reasonable reconstruction of an object's complex-valued index of refraction. Wolf's formulation was extended in 1974 by Iwata and Nagata [36] to determine the structure of a less restrictive class of scatterers satisfying the Rytov rather than the Born approximation. In 1979, Mueller *et al.* [55] employed the same concepts of the Born and Rytov approximations and presented Fourier interpolation-based algorithms for the inverse problem of ultrasound tomography, while in 1982, Devaney [17] derived an elegant inversion algorithm, named "*the filtered backpropagation algorithm of DT*," for the inversion of full view, scattered field data under the Born or Rytov approximations. When scattering experiments are done at a wavelength λ , the filtered backpropagation algorithm returns an estimate of the unknown index of refraction distribution whose frequency content is the same as of the true distribution over a circular disk in Fourier space of radius $\frac{2\pi}{\lambda}\sqrt{2}$ and zero elsewhere [23].

The filtered backpropagation algorithm has been recognized as the one providing highest quality in the reconstructed images [59] and modifications to it have been presented by Devaney [19] in 1984 and Deming and Devaney [11] in 1996 to adjust it to the configurations employed in geophysical tomographic surveys. Tsihrintzis and Devaney addressed the reconstruction problem of linearized DT from noisy scattered field data and showed that the optimum (Wiener) estimation filter attains again the form of a filtered backpropagation algorithm [85], [86]. Finally, iterative algorithms for inversion of an angularly limited set of noise-free linearized scattering data were presented by Ladas and Devaney in [44], [45].

B. Recent Developments in Diffraction Tomography

Linearized DT has reached today the stage of being implemented in prototype commercial tomographic scanners for ultrasonic [79], [84], underground [62], [97], [100], and optical [51] imaging systems. Particularly successful have been geophysical DT algorithms when applied to a range of underground imaging problems such as oil field prospecting and reservoir monitoring [101], locating underground tunnels between North and South Korea [97], [100], and searching for dinosaur bones in the New Mexico desert [96], [100]. The success of the linearized DT algorithms depends critically, however, on two assumptions: 1) linearity and 2) availability of multiple experiments [14]. In many cases, the linearity assumption fails, while different constraints (economic, safety, operating, geometric, or physical) limit the number of scattering experiments that can be performed and/or provide low signal-to-noise ratio data. Even though algebraic reconstruction techniques reduce the effect of

availability of only a small number of scattering experiments, the effects of nonlinearity are much harder to combat and remain an issue of current research. To overcome these limitations a more modest inverse scattering problem was addressed by Tsihrintzis and Devaney, originally within the framework of linearized [27], [82], [84], [87] and later exact [83], [84], [90], [91] scattering theory.¹ The goal of this more modest inverse problem, motivated in part by earlier work on a related problem in X-ray computed tomography [66], was to estimate the location of a single *known* scatterer having unknown central location from noisy scattered field data. It was found, that for monochromatic planewave probing, the optimum (in the maximum-likelihood sense) location estimate could be obtained via a filtered backpropagation algorithm, in which partial images formed by filtering and backpropagating scattered field data for different probing directions were coherently summed. The algorithm yields an *image* of the log-likelihood function of the object's location and can be used for target detection and classification as well as target location estimation. The detection/estimation/classification procedure is optimum (in the maximum-likelihood sense) for a single target and any given number of scattering experiments and returns good estimates even from a single experiment as long as the wavelength of the probing radiation is comparable with the typical dimensions of the target [27]. Its independent implementation in practice has revealed robustness to both high noise levels and the presence of unmodeled objects.

C. Present Contribution

One practically important imaging situation arises when the object consists of a number of distinct scatterers. As pointed out by Azimi and Kak [1] and Slaney, Kak, and Larsen [73], even though each scatterer individually may be weak enough for validity of the Born or Rytov approximate model, multiple scattering interactions among several scatterers degrade the performance of linearized DT reconstruction algorithms. The situation can be partially ameliorated if the reconstruction algorithms are based on higher order (nonlinear) scattering models and, indeed, formal series solutions to the inverse scattering problem have been presented in the literature [63]–[65], [28], [49], [50], [93], [94], [74]–[76]. In [28], [49], [50] more specifically, perturbative expansions of the scattering object's Fourier transform were utilized to develop DT reconstruction algorithms of arbitrary order, which contained linear reconstruction algorithms as special cases and effectively attained the form of nonlinear data filtering followed by a linear operation. The algorithms in [28], [49], and [50] attempt to estimate samples of the Fourier transform of the object function and use them to obtain an estimate of the object function itself. Recent attempts ([61], [3] and references therein) to invert a second-order scattering model have resulted in algorithms of the form of iterative numerical solutions of systems of quadratic equations and revealed significantly higher fidelity than their linear counterparts. In this paper, we address the reconstruction problem of DT within the

Fig. 1. The classical scan configuration of Diffraction Tomography

Fig. 2. The generalized projection-slice theorem of Diffraction Tomography

framework of higher order (nonlinear) scattering approximations. We derive reconstruction algorithms for the so-called, "classical scan configuration of DT" of Fig. 1 (and the associated Fig. 2), that can be implemented via use of a fast Fourier transform (FFT) algorithm, and illustrate them in a computer simulation study. Thus the paper presents a successive approximation procedure that recursively extracts increased information about a scatterer, where "increased information" is interpreted in the sense of reduction of the bias of the solution. In this sense, the present paper is also related to our previous work on information extraction from imperfectly modeled scattered wavefield data [27], [83], [82], [85], [84], [86], [90], [91] because it attempts to construct a wave-theoretic model for the error term that originally appeared as random noise in that work and suppress its biasing effect on the inversion algorithm output via the use of rigorous methodologies provided by the theory of Volterra system inversion.

More specifically, the paper is organized as follows. Section II defines nonlinear data-generating models for scattering experiments through nonlinear mathematical mappings from the object structure to the complex phase of the observed total wavefields that arise from an arbitrarily large number of terms in the

¹The algorithm was originally developed for homogeneous background media, but was recently extended to arbitrary one-dimensional (e.g., planar layered) media [91]. In the same manner, it can be extended to arbitrary two-dimensional media (e.g., a waveguide of arbitrary cross section).

Rytov series. Section III is devoted to study of the inversion of the nonlinear data-generating models, a discussion of the implementation procedure of the proposed algorithms, and a limited computer simulation, while Section IV summarizes the paper, draws conclusions, and points to future related research. Three appendices are attached to the paper. Appendix A summarizes the Born series representation of the mapping from object structure to scattered wavefield data. Appendix B makes use of the Weyl expansion to derive the generalized projection-slice theorem and define the propagation transform of linearized DT. Appendix C summarizes the key elements of the Volterra theory of nonlinear systems.

II. NONLINEAR DATA-GENERATING MODELS FOR DIFFRACTION TOMOGRAPHY

A. Configuration and Scattering Equations

Consider the data collection configuration illustrated in Fig. 1, where a known monochromatic plane wave $\psi_0(x) = e^{ik\langle v, x \rangle}$ of wavenumber k propagates in the direction of the unit vector v and is incident on a scattering object of support \mathcal{V} . The total wave is measured over a line located entirely outside the object and perpendicular to the unit vector v . A point on the measurement line is denoted with the coordinate vector $x_0 = t_0 u + s_0 v$, $t_0 \in \mathbb{R}^1$, where s_0 (fixed) is the distance of the measurement line from the origin. The object is assumed to be embedded in a *known* nonattenuating, homogeneous background medium of wave velocity c_0 and wavenumber $k = \frac{\omega}{c_0}$ and characterized by its distribution of complex-valued index of refraction $n(x) = c_0/c(x)$, where $c(x)$ is the wave velocity distribution inside the scatterer.

The interaction of the incident wave with the object results in the formation of a wavefield $\psi(x)$ that satisfies the time-independent inhomogeneous Helmholtz equation

$$(\nabla^2 + k^2)\psi(x) = -2k^2 f(x)\psi(x) \quad (2.1)$$

where $f(x) = \frac{1}{2}[n^2(x) - 1]$ is the *object function*, the quantity whose determination is the ultimate goal of inverse scattering theory and DT. The solution of the Helmholtz equation (2.1) can be decomposed into the sum of the incident field and a scattered field in the form $\psi(x) = \psi_0(x) + \psi^{(s)}(x)$, where the scattered field component is related to the object function and total field via the integral equation

$$\psi^{(s)}(x) = -2k^2 \int_{\mathcal{V}} dx' f(x') \psi(x') G(x - x') \quad (2.2)$$

with $G(x - x') = -\frac{i}{4} H_0^{(1)}(k|x - x'|)$ the outgoing wave Green function to the Helmholtz equation [53].

Equation (2.2) provides a link between source (radiation) and scattering problems in wave theory and shows that the scattered field *outside* the scattering region \mathcal{V} is uniquely determined from the total field *inside* \mathcal{V} . Subsequently, approximate scattering models, such as the Born or Rytov models, seek to replace the “induced source” $f\psi$ in (2.2) with an approximate expression that leads to a tractable inverse problem. The first Born and Rytov approximations lead to linear models that are inverted via the algorithms of linearized DT outlined in Section I. The objec-

tive of this paper is to improve these linear models by including higher order terms in the Rytov series and to establish a unified paradigm of both linear and nonlinear inversion algorithms for DT.

B. The Rytov Series

The Rytov series was originally developed within the context of wave scattering in random and turbulent media [81], [7], [72] and, as an approximation to exact scattering, its domain of validity is broader than the domain of validity of the Born series. It arises from a perturbational expansion of the complex phase (i.e., the complex logarithm) of the field rather than the field itself. To begin, f is replaced by ϵf in (2.1) and its solution $\psi(x; \epsilon)$ is set to

$$\psi(x; \epsilon) = e^{ikW(x; \epsilon)} \quad (2.3)$$

where $W(x; \epsilon)$ is the “wavenumber-normalized complex phase” of the total field $\psi(x; \epsilon)$. Substitution of (2.3) in (2.1) shows that the phase W satisfies the nonlinear Riccati equation

$$\nabla W \cdot \nabla W + \frac{1}{ik} \nabla^2 W - 1 = 2\epsilon f. \quad (2.4)$$

So far, no approximation has been made. Equation (2.4) is exact and mathematically equivalent to (2.1).

The Rytov series solution to (2.4) is obtained by substituting in (2.4) the formal series

$$W(x; \epsilon) = W_0(x) + \epsilon W_1(x) + \epsilon^2 W_2(x) + \dots \quad (2.5)$$

with $\psi_0 = e^{ikW_0}$. The resulting equations that specify the individual terms in the series (2.5) are

$$\nabla W_0 \cdot \nabla W_0 + \frac{1}{ik} \nabla^2 W_0 = 1 \quad (2.6)$$

$$2\nabla W_0 \cdot \nabla W_1 + \frac{1}{ik} \nabla^2 W_1 = 2f \quad (2.7)$$

$$2(\nabla W_0 \cdot \nabla W_2 + \nabla W_1 \cdot \nabla W_1) + \frac{1}{ik} \nabla^2 W_2 = 0$$

$$\vdots$$

$$2(\nabla W_0 \cdot \nabla W_n + \nabla W_1 \cdot \nabla W_{n-1} + \dots) + \frac{1}{ik} \nabla^2 W_n = 0 \quad (2.8)$$

From (2.8), it is clear that, unlike the Born series in which the n th-order Born term is computed directly from the Born term of order $n - 1$ only, computation of the n th-order Rytov term W_n makes use of all the Rytov terms $W_{n-1}, W_{n-2}, \dots, W_0$. The solution to (2.6)–(2.8) is given next. The solution to (2.6) is the complex phase of the incident field, i.e., $W_0(x) = \langle v, x \rangle$. To solve (2.7), the Rytov transformation [81], [7], [72] is applied

$$W_1 = e^{-ikW_0} F. \quad (2.9)$$

The quantity F is seen to satisfy the equation

$$(\nabla^2 + k^2)F = -\frac{2kf}{i} e^{ikW_0} \quad (2.10)$$

which is solved using Green function techniques to obtain²

$$F(x) = -\frac{2k}{i} \int_{\mathcal{V}} dx' G(x-x') f(x') e^{ikW_0(x')}. \quad (2.11)$$

Substitution in (2.9) of the expression in (2.11) leads to

$$W_1(x) = -\frac{2ke^{-ikW_0(x)}}{i} \int_{\mathcal{V}} dx' G(x-x') f(x') e^{ikW_0(x')}. \quad (2.12)$$

To obtain the term W_n in series (2.5), we rewrite (2.8) as

$$2\nabla W_0 \cdot \nabla W_n + \frac{1}{ik} \nabla^2 W_n = -\sum_{j=1}^{n-1} \nabla W_j \cdot \nabla W_{n-j} \quad (2.13)$$

and apply the Rytov transformation to it. The result is the expression in the right-hand side of (2.12) with $2f$ replaced by $-\sum_{j=1}^{n-1} \nabla W_j \cdot \nabla W_{n-j}$, i.e.,

$$W_n(x) = \frac{ke^{-ikW_0(x)}}{i} \int_{\mathcal{V}} dx' G(x-x') \cdot \left[\sum_{j=1}^{n-1} \nabla W_j \cdot \nabla W_{n-j} \right] (x') e^{ikW_0(x')}. \quad (2.14)$$

The Born and the Rytov terms are related [72], [67]. A Rytov term of order n can be expressed in terms of the Born terms of order $0, 1, \dots, n$. Indeed, substitution of the Born and the Rytov series in (2.3) gives

$$\sum_{n=0}^{\infty} \epsilon^n \psi_n = \exp \left(ik \sum_{n=0}^{\infty} \epsilon^n W_n \right) \quad (2.15)$$

which, after expanding around $\epsilon = 0$ and equating terms of equal power in ϵ , gives

$$W_0 = \frac{1}{ik} \log \psi_0 \quad (2.16)$$

$$W_1 = \frac{1}{ik} \frac{\psi_1}{\psi_0} \quad (2.17)$$

$$W_2 = \frac{1}{ik} \left[\frac{\psi_2}{\psi_0} - \frac{1}{2} \left(\frac{\psi_1}{\psi_0} \right)^2 \right] \quad (2.18)$$

$$W_3 = \frac{1}{ik} \left[\frac{\psi_3}{\psi_0} - \frac{\psi_2}{\psi_0} \frac{\psi_1}{\psi_0} + \frac{\psi_1^3}{3!} \right] \quad (2.19)$$

\vdots

Similar expressions can be written to express a Born term of order n in terms of the Rytov terms of order $0, 1, \dots, n$. Equations (2.16)-(2.19) reveal a pointwise (memoryless), with respect to the x variable, transformation from Born to Rytov terms. Given the fact that Born term computation can be approximately done by algorithms that are based on the fast Fourier transform, (2.16)-(2.19) indicate that an efficient

procedure for computing a Rytov term of order n would be to compute first the Born terms of order $0, 1, \dots, n$ and from these to find the n th-order Rytov term via a pointwise (memoryless), with respect to the x variable, transformation.

The first-order Rytov approximation, simply referred to as the Rytov approximation, consists of approximating the field phase W with the sum of only the zeroth- and first-order Rytov terms as $W(x) \approx W_0(x) + W_1(x)$, where the term W_1 is to be computed from (2.12) using the fact that $W_0(x) = \langle v, x \rangle$. In terms of the total field at point x

$$\begin{aligned} \psi(x) &\approx e^{ikW_0(x)} e^{ikW_1(x)} \\ &= \exp\{ik\langle v, x \rangle\} \exp \left\{ -2ke^{-ik\langle v, x \rangle} \int_{\mathcal{V}} dx' G(x-x') \cdot f(x') e^{ik\langle v, x' \rangle} \right\}. \end{aligned} \quad (2.20)$$

Clearly, the Rytov approximation estimates the total field as the product of the incident field $\psi_0 = e^{ikW_0}$ and a multiplicative factor e^{ikW_1} that depends on the object function f . This is in contrast with the Born approximation which estimates the total field by correcting the incident field by an additive term that depends on the object function f . As a result, the Rytov approximation implies a *nonlinear* mapping from the object function to the total and scattered fields. It is, however, a linearizing approximation for the direct scattering problem in the sense that the mapping from the object function to the *complex phase* of the total field has been linearized.

The Rytov approximation is less restrictive than the Born approximation. Indeed, the Rytov approximation is valid under the mild condition [40]

$$|\nabla W_1|^2 \ll f_m k^2, \quad \text{where } f_m = \max_x |f(x)| \quad (2.21)$$

in which no restriction on the size of the scattering region \mathcal{V} has been imposed. The main disadvantages, however, of the Rytov approximation are that 1) it works with the phase of the fields rather than the fields themselves, which creates phase unwrapping problems in inverse scattering applications [38], and 2) that it is a near-field approximation, since as observation points x_0 are considered further away from the scattering region \mathcal{V} , it deteriorates fast and in the far field it becomes identical to the Born approximation [10], [24]. This latter fact has led [24] to a modified form of the Rytov approximation, which combines aspects of both the Born and the Rytov models, named the "hybrid model."

Both the Born and the Rytov approximations have been extensively used for predictions in direct [81], [7], [72] and inverse [15], [18] scattering theory. Their domains of validity, as well as their relative advantages and disadvantages, have been extensively explored in the literature [40], [39], [58], [95], [77], [78], [47] and also compared with experimental results [80], [51]. A concise treatment of these and other approximate models for inverse scattering applications can be found in [80] and the references therein. In this paper, use is made of the Rytov series, on the basis of the fact that experimentation has shown for it better modeling properties than the Born series for the type of scattering problems encountered in DT [80], [51].

²Clearly, F is simply equal to the wavenumber-normalized Born approximation $\frac{\psi_1}{ik}$ to the scattered field, as seen from the top of (A.2) and the fact that $\psi_0 = e^{ikW_0}$. This leads to the simple expression $\psi_1 = ik\psi_0 W_1$ relating the first terms in the Born and the Rytov series. These two approximations have quite different domains of validity, however.

C. Nonlinear Data-Generating Models for Two-Dimensional DT

Consider again the classical scan configuration of Fig. 1, but assume that the complex phase of the total field along the line $x_0 = t_0 u + s_0 v$, $t_0 \in R^1$, s_0 : fixed, is well approximated by the first N terms of the Rytov series, where the possibility of $N \rightarrow \infty$ is not excluded

$$W(x_0) \approx W_0(x_0) + W_1(x_0) + \cdots + W_N(x_0). \quad (2.22)$$

Define the Hilbert spaces \mathcal{F} , \mathcal{F}_L , and \mathcal{P} as follows: \mathcal{F} is $L^2(\mathcal{D}_a)$, where \mathcal{D}_a is a disk of radius a in R^2 that includes the scattering region \mathcal{V} . \mathcal{F}_L is the subspace of \mathcal{F} consisting of the functions in \mathcal{F} lowpass filtered down to a disk of radius $k\sqrt{2}$ in Fourier space, i.e.,³

$\mathcal{F}_L = (f_L | \mathcal{D}_a): \exists (f | \mathcal{D}_a) \in \mathcal{F}$ such that

$$\tilde{f}_L(K) = \begin{cases} \tilde{f}(K), & \text{for } |K| \leq k\sqrt{2} \\ 0, & \text{otherwise.} \end{cases}$$

Finally, \mathcal{P} is the space of functions defined on $R^1 \times [0, 2\pi]$ whose frequency content with respect to the first variable is zero outside the $[-k, k]$ interval.

Define the nonlinear operators

$$\mathcal{W}_n : \mathcal{F}_L \rightarrow \mathcal{P} \quad (2.23)$$

where

$$(\mathcal{W}_n f_L)(t_0, \theta) = W_n^L(t_0 u + s_0 v, \theta) \quad (2.24)$$

and $W_n^L(t_0 u + s_0 v, \theta)$ is the n th term of the Rytov series to the wavenumber-normalized complex phase of the total field along the measurement line $x_0 = t_0 u + s_0 v$, lowpass-filtered with respect to t_0 down to the frequency interval $[-k, k]$. From (2.16) to (2.19) and Appendix A, it is seen that \mathcal{W}_n is a homogeneous Volterra operator (see Appendix C) of order n .

Define now the linear operator

$$\mathcal{B} : \mathcal{P} \rightarrow \mathcal{F}_L \quad (2.25)$$

with

$$(\mathcal{B}d)(x = tu + sv) = \frac{1}{2} \frac{1}{(2\pi)^2} \int_0^{2\pi} d\theta \int_{-k}^k dp |p| e^{ipt} e^{i(m-k)(s-s_0)} \tilde{d}(p, \theta). \quad (2.26)$$

The operator $(\mathcal{B}|\mathcal{P})$ is the inverse of $(\mathcal{W}_1|\mathcal{F}_L)$, as stated in (A.13).

³Since the functions f in \mathcal{F} are compactly supported, their Fourier transform is an entire function. Therefore, for given f_L , the corresponding f is unique and can, in principle, be obtained by analytically continuing the Fourier transform of f_L . The lowpass filtering is essentially a regularization procedure that makes the inverse of the propagation transform of linearized DT continuous.

D. The Cylindrically Symmetric Case

A particularly important imaging situation is that of scattering objects with cylindrical symmetry, that is, scatterers whose properties vary only with the radial distance from the scatterer center and, thus their object function is of the form

$$f(x) = f_r(r), \quad r = |x|. \quad (2.27)$$

This important situation arises in practical applications such as reconstruction of the structure of optical fibers or large molecules or buried pipes, but also provides a paradigm for both analytical and computer simulation study of DT reconstruction algorithms. Both the filtered backpropagation algorithm (A.13) and the nonlinear models (2.24) attain a simpler form that makes use of one-dimensional Fourier–Bessel transforms.

Indeed, let

$$\tilde{f}_r(|K|) = 2\pi \int_0^\infty dr r J_0(|K|r) f_r(r). \quad (2.28)$$

Then, the Fourier transform of the object function f becomes

$$\tilde{f}(K) = \tilde{f}_r(|K|) \quad (2.29)$$

and the generalized projection-slice theorem (A.10) (see Fig. 2) reads⁴

$$\begin{aligned} \widetilde{P_\theta f}(p; s_0) &= \begin{cases} \frac{k}{m} e^{i(m-k)s_0} \tilde{f}_r \left[\sqrt{2k(k-m)} \right], & \text{if } |p| \leq k \\ 0, & \text{otherwise,} \end{cases} \end{aligned} \quad (2.30)$$

where the generalized projections $P_\theta f$ are independent of the view angle θ . The filtered backpropagation algorithm is now put in the form

$$\hat{f}(x) = \frac{1}{2\pi} \int_0^k dp p e^{i(k-m)s_0} J_0 \left[r \sqrt{2k(k-m)} \right] \widetilde{P_\theta f}(p; s_0), \quad r = |x| \quad (2.31)$$

where the integration with respect to view angle θ has been eliminated. Finally, the nonlinear models (2.24) can be computed in a similar manner. For example, the first Born term is given by

$$\tilde{\psi}_1(pu + s_0 v) = \begin{cases} \frac{ik^2}{m} e^{im s_0} \tilde{f}_r \left[\sqrt{2k(k-m)} \right], & \text{if } |p| \leq k \\ \frac{ik^2}{m} e^{im s_0} \tilde{f}_r(|p|\sqrt{2}), & \text{if } |p| > k \end{cases} \quad (2.32)$$

and allows the computation of the first term W in the Rytov series. Similarly derivable, yet more complicated, expressions

⁴More generally,

$$\tilde{W}_1(pu + s_0 v) = \begin{cases} \frac{k}{m} e^{i(m-k)s_0} \tilde{f}_r \left[\sqrt{2k(k-m)} \right], & \text{if } |p| \leq k \\ \frac{k}{m} e^{i(m-k)s_0} \tilde{f}_r(|p|\sqrt{2}), & \text{if } |p| > k \end{cases}$$

which includes evanescent wavemodes in the wavefield data.

for terms in the Rytov series of order higher than the first can also be derived.

III. INVERSION OF NONLINEAR DATA-GENERATING MODELS FOR DT

A. Theory

Define the inhomogeneous Volterra operator of order N (where the possibility of $N \rightarrow \infty$ is not excluded)

$$\mathcal{W}^N = \mathcal{W}_1 + \mathcal{W}_2 + \cdots + \mathcal{W}_N: \mathcal{F}_L \rightarrow \mathcal{P} \quad (3.1)$$

where

$$(\mathcal{W}^N f_L)(t_0, \theta) = \frac{e^{-iks_0}}{ik} (W_1^L + W_2^L + \cdots + W_N^L)(t_0 u + s_0 v, \theta) \quad (3.2)$$

and $W_n^L(t_0 u + s_0 v, \theta)$, $n = 1, 2, \dots$, is the n th term of the Rytov series to the scattered field along the measurement line $x_0 = t_0 u + s_0 v$, lowpass-filtered with respect to t_0 down to the frequency interval $[-k, k]$. The existence of a local inverse of the operator \mathcal{W}^N and its representation by a convergent series is guaranteed by the existence of the inverse $(\mathcal{B}|\mathcal{P})$ of the linear term $(\mathcal{W}_1|\mathcal{F}_L)$ [71], [46].⁵ Specifically, there exists a region in the data space \mathcal{P} , on which the operator

$$\mathcal{B}_1 + \mathcal{B}_2 + \cdots + \mathcal{B}_n + \cdots \quad (3.3)$$

is the inverse of \mathcal{W}^N , where \mathcal{B}_n is a homogeneous Volterra operator of order n in the data.

More specifically,

$$\mathcal{B}_1 = \mathcal{B} \quad (3.4)$$

$$\mathcal{B}_2 = -\mathcal{B}\mathcal{W}_2\mathcal{B} \quad (3.5)$$

$$\mathcal{B}_3 = \mathcal{B}\mathcal{W}_2\mathcal{B}\mathcal{W}_2\mathcal{B} - \mathcal{B}\mathcal{W}_3\mathcal{B} \quad (3.6)$$

\vdots

It is observed that the terms $\mathcal{B}_1, \mathcal{B}_2, \mathcal{B}_3$, etc., are *universal* in the sense that they do not depend on the order N of the forward model \mathcal{W}^N . Thus the operator series in (3.3) can be truncated to desired order n and return DT inversion algorithms of order n in the data. For example, the usual filtered backpropagation algorithm provides a universal DT inversion algorithm of first order (linear) in the data. A second observation is that if the data are sufficiently modeled by the first Rytov term, i.e., $\delta W = W_1$ and $W_2 = W_3 = \cdots = 0$, then each higher order term in series (3.3) returns an identically zero contribution to image reconstruction, as close examination of the expressions in (3.4)-(3.6) reveals. This fact is also verified in the simulations of this section. A final observation is that the resulting algorithms are effectively of the form of *nonlinear* data filtering followed by backpropagation. Indeed, the series (3.3) can be written as

$$\mathcal{B}(\mathcal{I} - \mathcal{W}_2\mathcal{B} + \mathcal{W}_2\mathcal{B}\mathcal{W}_2\mathcal{B} - \mathcal{W}_3\mathcal{B} - \cdots) \quad (3.7)$$

⁵In [46], a detailed statement of a general theorem on inversion of Volterra systems is given, which includes a statement of an estimate of the range of existence and convergence of the inverse series.

where $\mathcal{I}: \mathcal{P} \rightarrow \mathcal{P}$ is the identity operator. Effectively, the term in brackets in (3.7) is a higher order nonlinear Volterra filter applied on the data and, thus the series (3.3) gives rise to an entire class of *nonlinear filtered backpropagation* algorithms for inversion of DT data.

B. Implementation of the Inversion Algorithms

The implementation of the proposed nonlinear diffraction tomographic reconstruction algorithms consists of several steps and requires the implementation of corresponding algorithmic modules. More specifically, distinct modules to be used are as follows.

- 1) An estimator of the complex phase (complex log) of the measured total wavefield and a phase unwrapper. The estimation of the complex phase of the total wavefield from the measurements may require the use of a proper phase unwrapping algorithm when noise is present in the data. The problem is not serious in the fully three-dimensional imaging case and, in fact, becomes increasingly less serious in higher dimensions. The best practical approach probably consists of two precautionary measures: i) to exploit the fact that the wave signal is bandlimited with zero Fourier content outside the frequency interval $[-k, k]$ and lowpass-filter the measurements accordingly to reduce the noise level and ii) to increase the sampling rate beyond the corresponding Nyquist rate. In previous (independent) experimentation with the theories of linearized DT, it was possible to image two-dimensional (2-D) objects, where the phase wrapping problem is worse, from scattered wavefield measurements in a prototype ultrasonic scanner, a prototype optical microscope, and several underground imaging devices (acoustic and ground penetrating radar), as discussed in Section I and references therein. If a better phase unwrapping approach is needed in some applications, the one we propose is based on modeling the phase with a low degree approximating polynomial, which is possible from the very requirement of phase continuity, and estimating the polynomial coefficients from the measurements.
- 2) An implementer of the two- or three-dimensional filtered backpropagation or equivalent linear inversion algorithm, which can be based on use of fast Fourier transform algorithms and, today, is considered a routine procedure. Even though the filtered backpropagation algorithm is particularly robust to high noise levels (see, for example, [27, the reconstruction in Fig. 13]), it is possible that regularization of the linear algorithm may be required in certain instances (e.g., wave probing only from a very limited number of directions). To counteract the effects of noise, a number of related publications exist which include [85], [11], [60]. In [60], more specifically, an infinite class of regularized inversion algorithms are proposed and studied, which propagate noise differently.
- 3) Born term calculators, that is, algorithms to compute Born terms of a given two- or three-dimensional input function using an FFT-based approach as discussed in [88], [89]. No regularization of these algorithms is required because

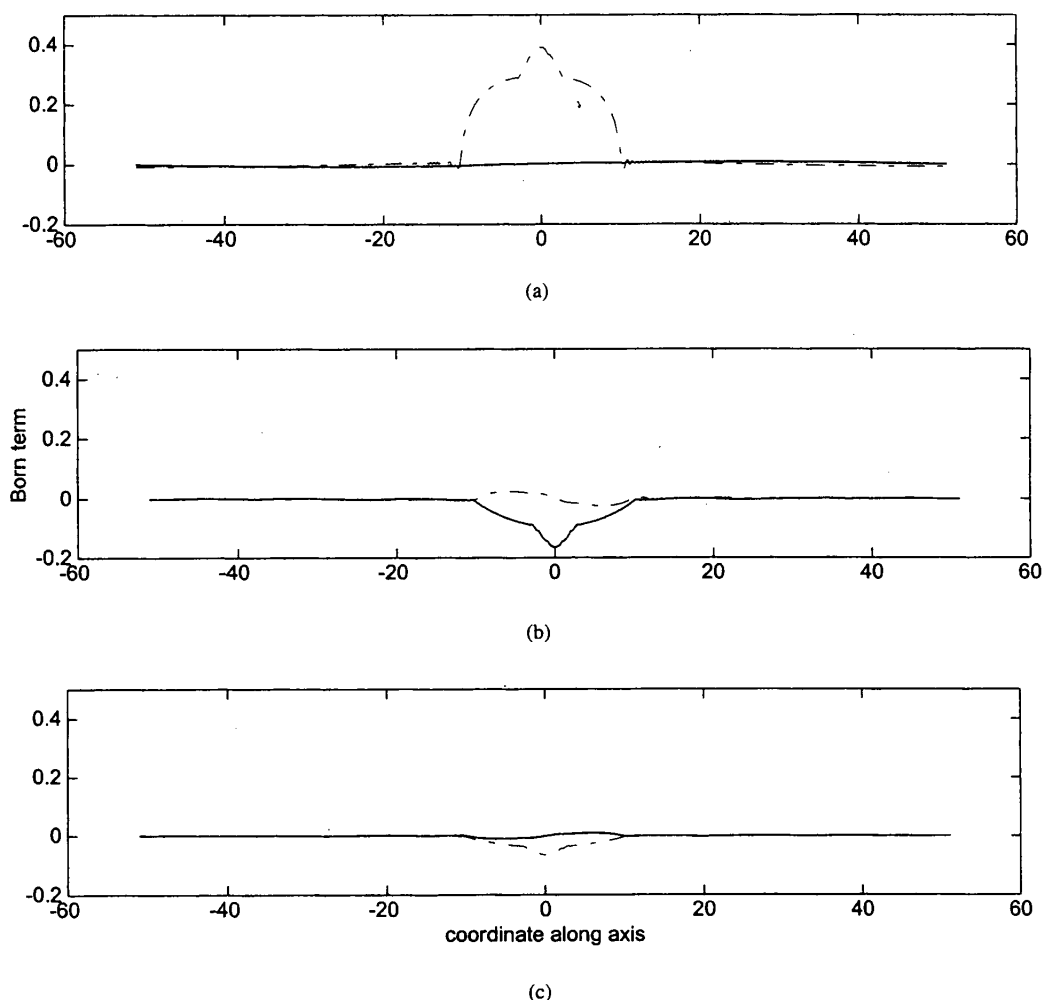

Fig. 3. Scattered fields in the computer simulation. (a) The first Born term ψ_1 . (b) The second Born term ψ_2 . (c) The third Born term ψ_3 . The real (imaginary) part of the fields is plotted in solid (dashed) line.

the corresponding operators are bounded and therefore continuous.

- 4) Implementers of pointwise Born to Rytov transformations, as in (2.16)–(2.19).
- 5) Combiners (adders) of the output of the above modules.

Once the above modules become available, the nonlinear diffraction tomographic reconstruction algorithms can be efficiently implemented in a scheme that successively adds higher order corrections to reduce the bias in the solution returned by a lower order inversion algorithm with repeated utilization of filtered backpropagation, Born term computation, Born to Rytov transformation, and addition as in (3.4)–(3.6).

C. Computer Simulation

The proposed nonlinear diffraction tomographic reconstruction algorithms were implemented and studied in a limited computer simulation, following the steps outlined in the previous section. For simplicity, the scattering object consisted of a circular core and three concentric circular coatings and constitutes a realistic model for cylindrical objects such as optical fibers,

large molecules, or buried pipes. Specifically, the object function was set to

$$f(x) = \begin{cases} 0.0025, & \text{if } |x| \leq 0.75 \\ 0.002, & \text{if } 0.75 \leq |x| \leq 1.8 \\ 0.0015, & \text{if } 1.8 \leq |x| \leq 2.6 \\ 0.001, & \text{if } 2.6 \leq |x| \leq 10 \\ 0, & \text{else.} \end{cases} \quad (3.8)$$

The wavenumber was equal to $k = 6\pi$, corresponding to a wavelength $\lambda = \frac{1}{3}$ and the measurement distance was set to $s_0 = 0$. This is a fairly big object, sixty wavelengths in diameter, for which the Born series converges slowly. The sampling rate was set to 0.04, which corresponds to approximately eight samples per wavelength and thus equals about four times the Nyquist rate. Thus the sample density is high enough to provide good numerical approximations to the continuous space signals and algorithms considered in here. Unfortunately, the exact scattered wave solution for the given scatterer is not known in analytic form. However, if the Born or Rytov series converge, their limit will be the exact solution. Fig. 3 shows plots of the

Fig. 4. Complex phase of total fields in the computer simulation. (a) The first Rytov term W_1 . (b) The second Rytov term W_2 . (c) The third Rytov term W_3 . The real (imaginary) part of the complex phase is plotted in solid (dashed) line.

first three Born terms, while plots of the first three Rytov terms are shown in Fig. 4. Clearly, a geometric similarity exists between Born and Rytov terms which is due to the transformations (2.16)–(2.19) and the relative simplicity of the object. We note, however, that the Rytov terms need to be nonlinearly distorted (via exponentiation) to yield the total wave and this may, in turn, distort the simple geometric correspondence.

The third Born term is approximately only six times smaller in magnitude than the first Born term ($\frac{\max |\psi_1|}{\max |\psi_3|} \approx 6$). By comparison, the third Rytov term is approximately thirty times smaller in magnitude than the first Rytov term ($\frac{\max |W_1|}{\max |W_3|} \approx 30$). Thus the Rytov series provides more accurate modeling of the complex phase of the total field than the Born series provides for the scattered field, a fact that is consistent with earlier investigations into the domains of validity of the Born and Rytov approximations [40], [39], [58], [95], [77], [78], [80], [47], [51].

Fig. 5 shows the object function reconstructions returned by the filtered backpropagation and a second-order algorithm based on the Born series [89], from first- (Fig. 5(a)), second- (Fig. 5(b)), and third-order (Fig. 5(c)) Born approximations. Clearly, the inversion procedure based on the Born series diverges.⁶ Fig. 6 shows the object function reconstructions returned by the filtered backpropagation and the second-order algorithm based on the Rytov series, from first- (Fig. 6(a)), second- (Fig. 6(b)), and third-order (Fig. 6(c)) Rytov approximations. Clearly, the second-order algorithm returns the same reconstruction as the filtered backpropagation algorithm in the case of data consisting of only the first Rytov term, as theoretically expected. In the other cases, however, the filtered backpropagation algorithm un-

derperforms the second-order algorithm by a significant margin, especially in the area close to the core of the object.

IV. SUMMARY, CONCLUSIONS, AND FUTURE RESEARCH

In this paper, linearized Diffraction Tomography was extended into a higher order (nonlinear) regime via the use of an arbitrarily large (possibly infinite) number of terms from the Rytov series as the data-generating model in scattering experiments. Nonlinear tomographic reconstruction algorithms were developed for inversion of wavefield data and image formation, which attained the form of a series of Volterra operators in which the leading (linear) term was the usual filtered backpropagation (or equivalent) algorithm of linearized DT. A limited computer simulation study was included to illustrate the performance of the algorithms in the case of imaging objects with cylindrical symmetry. From this study, it was found that a second-order algorithm returned essentially the same reconstruction as the usual filtered backpropagation algorithm when applied to first-order Rytov data, but clearly outperformed the filtered backpropagation algorithm when applied to data consisting of the second- or third-order Rytov approximation.

The paper establishes a unified paradigm for development of linear and nonlinear reconstruction algorithms for DT and thus further investigation in its direction is due. Future relevant research may follow the avenues of higher order DT with alternative data measurement configurations and higher order Diffraction Tomography of stochastic objects (including Bayesian inversion algorithms) and their time-domain counterparts. It seems that none of these research avenues are intractable in principle, but may require modification of the procedures presented in the present paper. Other related research directions to be followed in the future include study of the discretization of the proposed continuous space models and

⁶We observe, however, that the filtered backpropagation algorithm returns identical reconstructions when applied to either first-order Born (Fig. 5(a)) or first-order Rytov (Fig. 6(a)) data.

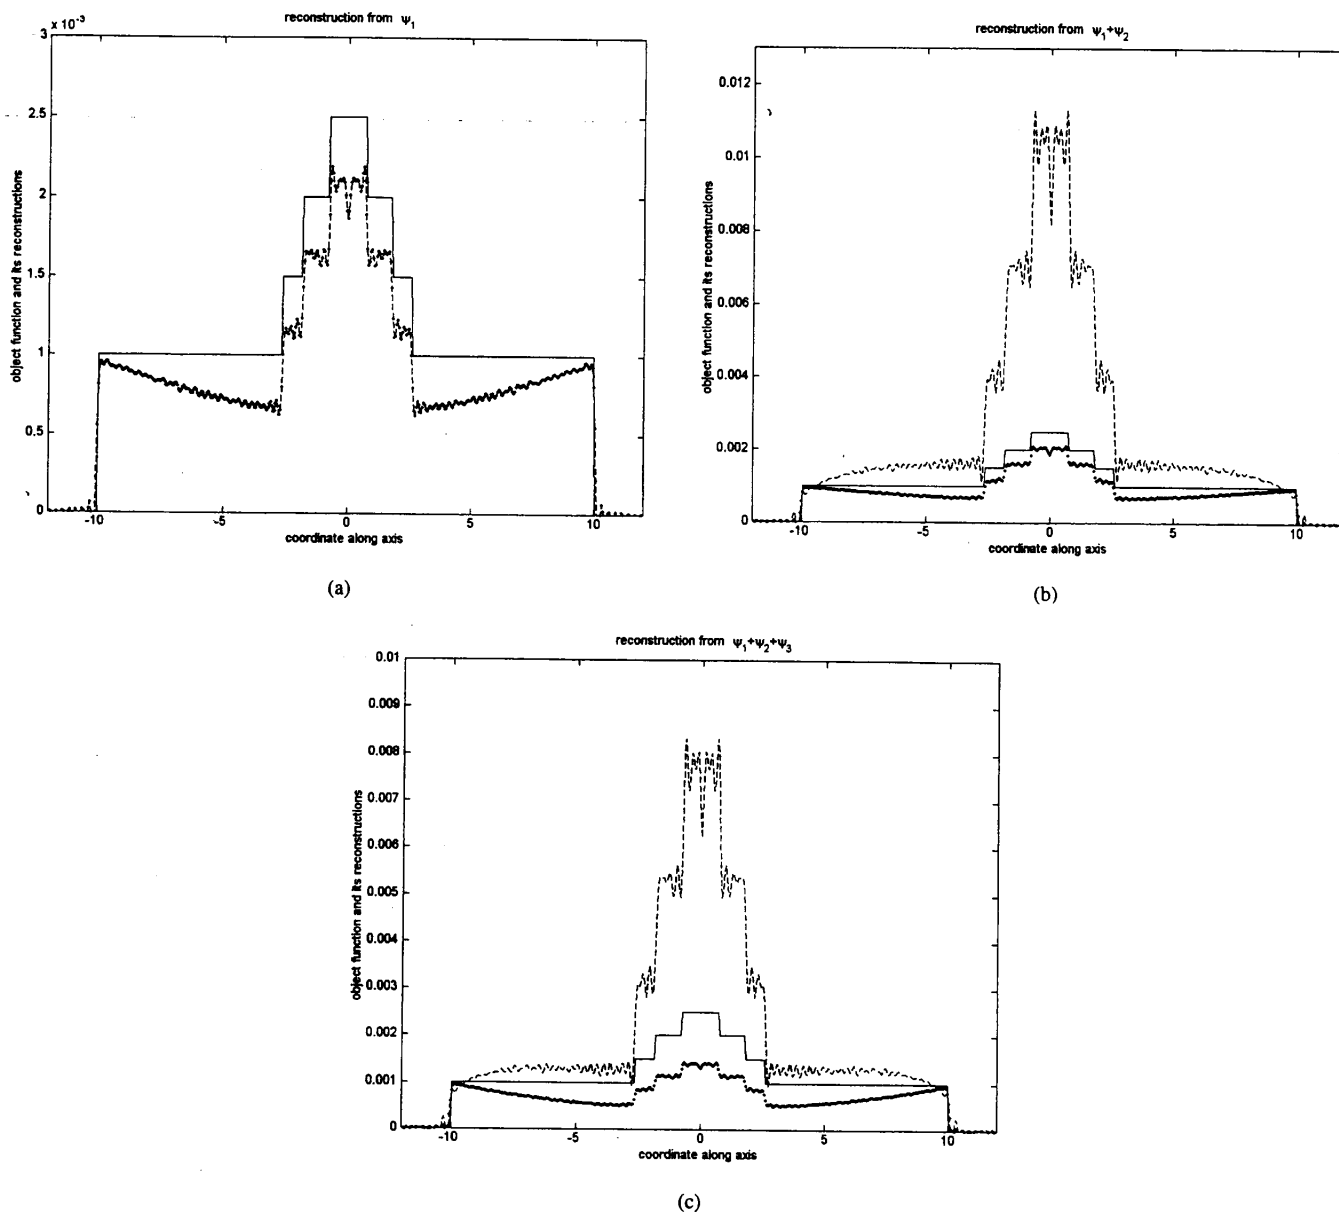

Fig. 5. Original object function (solid line) and reconstructions returned from the filtered backpropagation (dotted line) and the second-order algorithm based on the Born series (dashed line) in the computer simulation. algorithms and study of the discretization error and the efficient implementation of the discrete space algorithms. Finally, the application of these algorithms on fully three-dimensional real data is a high priority and, in fact, preliminary results of this process for data collected in a testbed that we are developing have been announced at recent conferences [26], [31]. These and other research avenues are currently being explored and the findings will be reported elsewhere.

APPENDIX A THE BORN SERIES

Equation (2.2) implies a nonlinear mapping from the object function f to the scattered field $\psi^{(s)}$, which under certain weak scattering conditions can be expanded into a convergent Liouville–Neumann expansion, known as the Born series. The Born

series is thus a perturbational expansion for the field scattered by an object f , obtained by introducing a smallness parameter ϵ and replacing the object function f in (2.1) and (2.2) by ϵf . The total field $\psi(x; \epsilon)$ inside the scattering region V is assumed an analytic function of the parameter ϵ around the point $\epsilon = 0$, so that the Taylor series expansion around $\epsilon = 0$

$$\psi(x; \epsilon) = \psi_0(x) + \epsilon\psi_1(x) + \epsilon^2\psi_2(x) + \dots \quad (\text{A.1})$$

converges for sufficiently small ϵ . The terms $\epsilon\psi_1(x)$, $\epsilon^2\psi_2(x)$, \dots are the first-, second-, \dots order corrections made to the incident field $\psi_0(x)$ to yield the total field $\psi(x; \epsilon)$. Clearly, this expansion is compatible with the fact that the scattered field

$$\psi^{(s)}(x; \epsilon) = \epsilon\psi_1(x) + \epsilon^2\psi_2(x) + \dots$$

is solely due to the presence of the scatterer with object function ϵf and in the absence of it (i.e., for $\epsilon = 0$) the total field $\psi(x; \epsilon = 0)$ reduces simply to the known incident field $\psi_0(x)$.

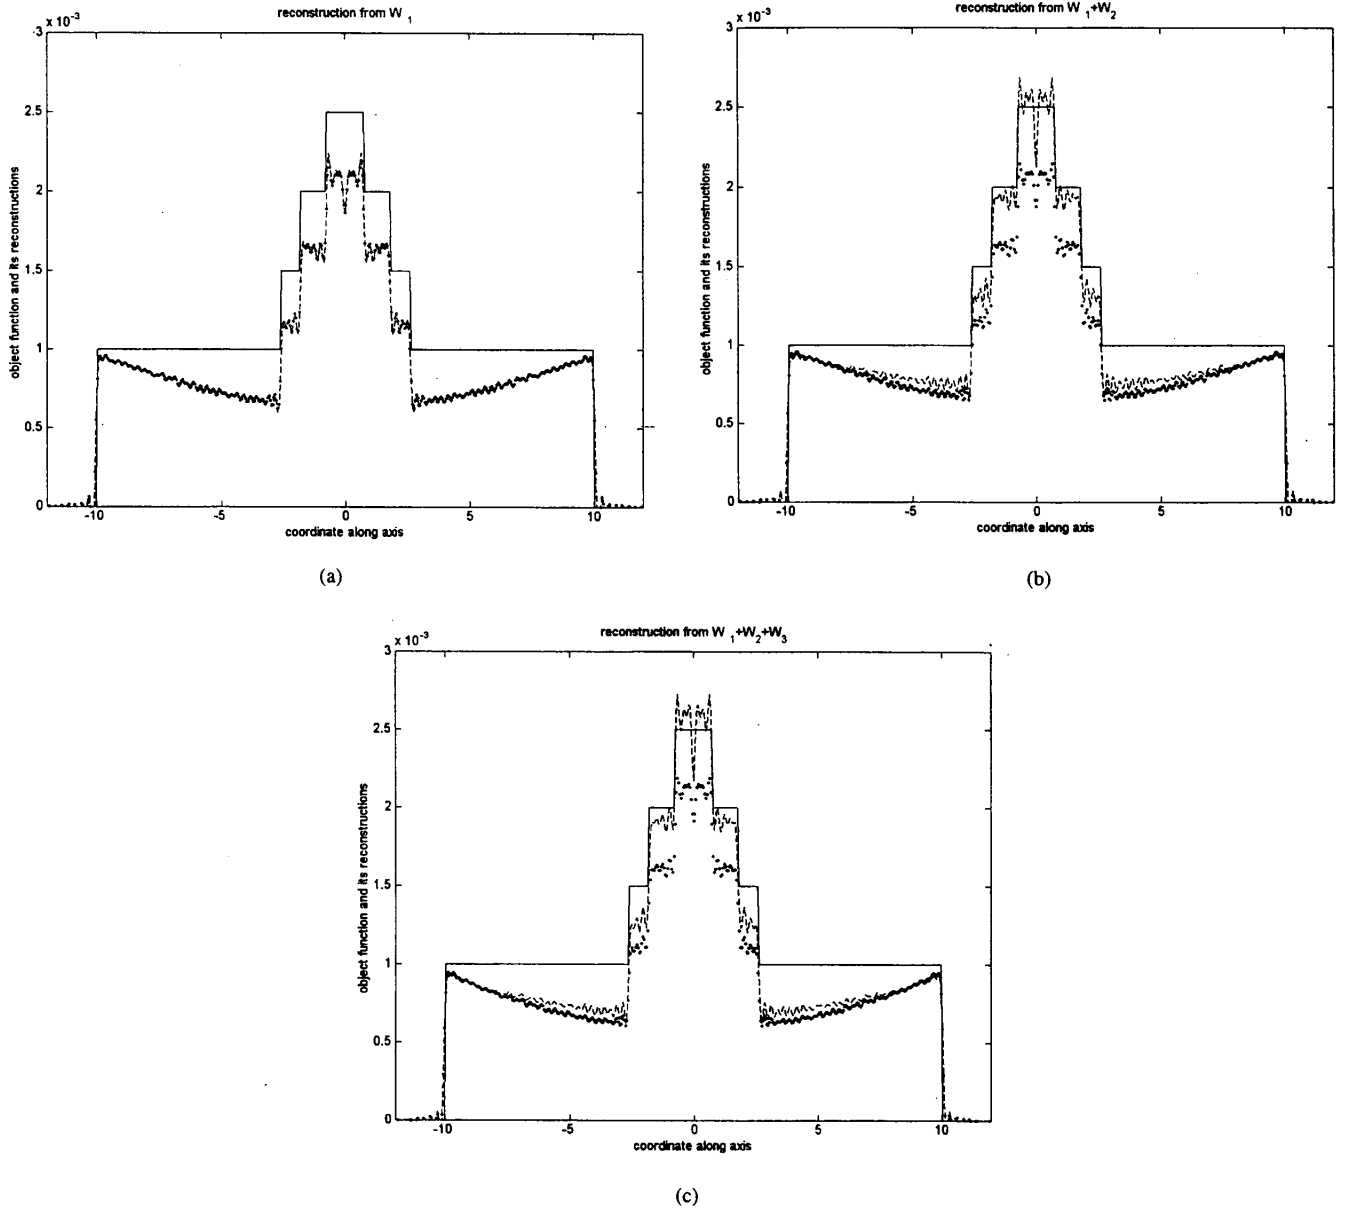

Fig. 6. Original object function (solid line) and reconstructions returned from the filtered backpropagation (dotted line) and the second-order algorithm based on the Rytov series (dashed line) in the computer simulation. (a) Reconstruction from the first-order Rytov approximation. (b) Reconstruction from the second-order Rytov approximation. (c) Reconstruction from the third-order Rytov approximation.

Inserting (A.1) into (2.2) and equating the coefficients of equal powers of ϵ on the two sides of the resulting expression, one obtains

$$\begin{aligned}
 \psi_1(x_0) &= -2k^2 \int_{\mathcal{V}} dx' G(x_0 - x') f(x') \psi_0(x') \\
 \psi_2(x_0) &= -2k^2 \int_{\mathcal{V}} dx' G(x_0 - x') f(x') \psi_1(x') \\
 &\vdots \\
 \psi_n(x_0) &= -2k^2 \int_{\mathcal{V}} dx' G(x_0 - x') f(x') \psi_{n-1}(x') \\
 &\vdots
 \end{aligned} \tag{A.2}$$

Clearly, the Born term of order n can be computed from the Born term of order $n-1$, $n = 1, 2, 3, \dots$, by replacing the induced source $f\psi$ with the product $f\psi_{n-1}$. After computation of the Born terms up to some desired order N , the total field ψ

resulting from the interaction of the incident wave ψ_0 with the scatterer f is computed as $\psi(x_0) = \psi_0(x_0) + \psi^{(s)}(x_0)$ with the scattered field approximated as

$$\psi^{(s)}(x_0) \approx \psi_1(x_0) + \psi_2(x_0) + \dots + \psi_N(x_0). \tag{A.3}$$

Of course, the assumption is made that the expansion (A.1) is valid for $\epsilon = 1$.

The first-order Born approximation, simply referred to as the Born approximation [56], has been extensively employed in quantum-mechanical scattering theory [56], [32]. From (A.2), the Born approximation estimates the scattered field $\psi^{(s)}$ by substituting the incident field ψ_0 for the total field ψ in the integrand in the right-hand side of (2.2) and, therefore, requires that i) $|\psi^{(s)}| \ll |\psi_0|$ inside the scatterer support \mathcal{V} and ii) the volume of scatterer support \mathcal{V} itself be small [40].

It is seen that the Born approximation is quite restrictive, since it requires both the size and the strength of the scattering

object to be “small.” Additionally, it is a low-frequency approximation, in that it requires the frequency of the incident wave to be low. The Born approximation has been extensively used for predictions in direct [81], [7], [72] and inverse [18] scattering theory. Its domain of validity has been extensively explored in the literature [40], [39], [58], [95], [77], [78], [47] and compared with experimental results [80], [51].

APPENDIX B MATHEMATICAL FORMULATION OF LINEARIZED DIFFRACTION TOMOGRAPHY

The first Born approximation for the field scattered from the object when illuminated with a plane wave⁷ $\psi_\theta(x) = e^{ik\langle v, x \rangle} = e^{iks}$ propagating in the direction of the unit vector v is computed from the first of (A.2) as

$$\psi_\theta^B(x_0) = -2k^2 \int_{\mathcal{V}} dx' G(x_0 - x') e^{ik\langle v, x' \rangle} f(x'). \quad (\text{A.4})$$

At this point, the Weyl expansion [53] of the Green function G is introduced

$$\begin{aligned} G(t'u + s'v) &= -\frac{i}{4\pi} \int_{-\infty}^{\infty} dp e^{ipt'} \frac{e^{im|s'|}}{m} \\ &\approx -\frac{i}{4\pi} \int_{-k}^k dp e^{ipt'} \frac{e^{im|s'|}}{m} \\ &= G^L(t'u + s'v), \end{aligned} \quad (\text{A.5})$$

where

$$m = \begin{cases} \sqrt{k^2 - p^2}, & \text{if } |p| \leq k \\ i\sqrt{p^2 - k^2}, & \text{if } |p| > k. \end{cases}$$

The expansion in the right-hand side of (A.4) contains both homogeneous (corresponding to $|p| \leq k$) and evanescent (corresponding to $|p| > k$) planewave terms and can be truncated to its homogeneous spectrum only, as indicated by the approximate equality sign in (App. 5), if the corresponding observation point x_0 is taken at least several wavelengths away from the scattering region \mathcal{V} .

Substitution of (A.5) into (A.4) gives

$$\begin{aligned} \psi_\theta^B(t_0 u + s_0 v) &\approx \frac{2ik^2}{4\pi} \int_{\mathcal{V}} dt' ds' \int_{-k}^k dp e^{ipt_0 - t'} \\ &\quad \cdot \frac{e^{im(s_0 - s')}}{m} f(t'u + s'v) e^{iks'} \\ &= \frac{ik^2}{2\pi} \int_{-k}^k dp e^{ipt_0} \frac{e^{ims_0}}{m} \int_{\mathcal{V}} dt' ds' \\ &\quad \cdot e^{-ipt'} e^{-i(m-k)s'} f(t'u + s'v) \\ &= \frac{ik^2}{2\pi} \int_{-k}^k dp e^{ipt_0} \frac{e^{ims_0}}{m} \tilde{f}[pu + (m-k)v] \end{aligned} \quad (\text{A.6})$$

⁷A subscript θ has been introduced to index the incident, total, and scattered waves corresponding to the different tomographic experiments using the classical scan configuration of DT.

in which \tilde{f} denotes the two-dimensional Fourier transform of f . Equation (A.6) defines the “propagation transform” $P_\theta f$ of linearized DT [17]

$$P_\theta f(t_0; s_0) = \begin{cases} \frac{e^{-iks_0}}{ik} \psi_\theta^{(s)}(x_0) & \text{within the Born approximation} \\ \delta W_\theta(x_0) & \text{within the Rytov approximation} \end{cases} \quad (\text{A.7})$$

which relates to the object function f through the convolutional relation [21], [23]

$$P_\theta f(t_0; s_0) = \int_{\mathcal{V}} \int_{\mathcal{V}} dt' ds' \Gamma_\theta(t_0 - t', s_0 - s') f(t'u + s'v) \quad (\text{A.8})$$

for $t_0 \in R^1$, s_0 : fixed, $\theta \in \Theta \subset [0, 2\pi)$, and kernel Γ_θ expressed in spectral form as

$$\Gamma_\theta(t', s') = \frac{1}{2\pi} \int_{-k}^k dp \frac{k}{m} e^{[ipt' + (m-k)s']}. \quad (\text{A.9})$$

Equations (A.8) and (A.9) result in a simple relation when considered in the Fourier domain. This relation, following upon substitution of (A.9) into (A.8), reads

$$\widetilde{P_\theta f}(p; s_0) = \begin{cases} \frac{k}{m} e^{i(m-k)s_0} \tilde{f}[pu + (m-k)v], & \text{if } |p| \leq k \\ 0, & \text{otherwise} \end{cases} \quad (\text{A.10})$$

and is known as the *generalized projection-slice theorem* [102], [21], [23]. Fig. 2 is an illustration of the generalized projection-slice theorem, which in words, implies that the one-dimensional Fourier transform $\widetilde{P_\theta f}$ of the propagation transform is proportional to a semicircular slice through the two-dimensional Fourier transform \tilde{f} of the object function itself.⁸

The above formulation of the inverse problem of DT is compatible with the usual formulation of the inverse problem of conventional Computerized Tomography (CT) and reduces to it in the limiting case of probing radiation of very short wavelength. Indeed,

$$k \rightarrow \infty, \quad \left(\frac{k}{m}\right) \rightarrow 1, \quad (m-k) \rightarrow 0, \quad \text{as } \lambda \rightarrow 0$$

and the kernel $\Gamma_\theta(t', s')$ reduces to

$$\Gamma_\theta(t', s') \approx \frac{1}{2\pi} \int_{-\infty}^{\infty} dp e^{ipt'} = \delta(t'), \quad \text{as } \lambda \rightarrow 0. \quad (\text{A.11})$$

Thus the propagation transform becomes the usual Radon transform

$$\begin{aligned} P_\theta f(t_0) &= \int_{\mathcal{V}} \int_{\mathcal{V}} dt' ds' \delta(t_0 - t') f(t'u + s'v) \\ &= \int_{-\infty}^{\infty} ds' f(t_0 u + s'v). \end{aligned} \quad (\text{A.12})$$

The generalized projection-slice theorem (A.10) has formed the basis for most treatments to the inverse problem of DT, namely, Fourier interpolation [36], [55], [54], [59] and filtered backpropagation [17], [59], [23], while (A.8) formed the basis for the development of iterative algorithms for DT [20], [22],

⁸The remainder of the circular slice is associated with the reflected field, i.e., the scattered field along the measurement line $s = -s_0$.

[44], [43]. Of particular importance to this paper is the filtered backpropagation algorithm [17], [22], which provides a reconstruction \hat{f} that corresponds to a lowpass-filtered version of the unknown object function f . In particular, the filtered backpropagation algorithm estimates \hat{f} as [17]

$$\hat{f}(x) = \frac{1}{2} \frac{1}{(2\pi)^2} \int_0^{2\pi} d\theta \cdot \int_{-k}^k dp |p| e^{ipt} e^{i(m-k)(s-s_0)} \widetilde{P_\theta} f(p; s_0) \quad (\text{A.13})$$

where $x = tu + sv$. It is readily shown that the estimate \hat{f} has the same spatial frequency content as the unknown f over a disk D in Fourier space of radius $k\sqrt{2}$ and zero frequency content outside that disk. Since its first appearance [17], the filtered backpropagation algorithm has been modified and extended to other data acquisition geometries [19] and tested on computer simulated [16], [59] and experimental data [79], [84].

APPENDIX C

ELEMENTS OF THE VOLTERRA THEORY OF NONLINEAR SYSTEMS

A homogeneous Volterra operator (VO) of order $k \geq 1$ is a nonlinear system represented by a functional relation of the form

$$y(\cdot) = \int \cdots \int d\tau_1 \cdots d\tau_k h_k(\cdot; \tau_1, \cdots, \tau_k) x(\tau_1) \cdots x(\tau_k) \quad (\text{A.14})$$

between its input $x(\cdot)$ and the corresponding output $y(\cdot)$. The $(k+1)$ -dimensional function $h_k(\cdot; \tau_1, \cdots, \tau_k)$ is the *kernel* of the homogeneous k th-order VO and, for uniqueness, is assumed symmetric, i.e., its value does not change under a permutation of its arguments. Clearly, a homogeneous VO of order $k = 1$ is a linear system and its kernel $h_1(\cdot; \tau_1)$ is also its impulse response. A homogeneous VO of order k as in (A.14) is a homogeneous polynomial system of order k in the sense that the system response to input $cx(\cdot)$ is $c^k y(\cdot)$ for arbitrary constant c .

A general (inhomogeneous) VO of order N is a nonlinear system consisting of the summation of homogeneous VO's of the form of (A.14) of order less than or equal to N , i.e., a nonlinear system represented by a functional relation of the form

$$y(\cdot) = h_0 + \sum_{k=1}^N \int \cdots \int d\tau_1 \cdots d\tau_k h_k(\cdot; \tau_1, \cdots, \tau_k) x(\tau_1) \cdots x(\tau_k) \quad (\text{A.15})$$

where h_0 is a constant. Clearly, an inhomogeneous VO of order N is a polynomial system of order N in the sense that its response to input $cx(\cdot)$ is a polynomial in c of order N for arbitrary constant c . Equation (A.15) can be generalized further by letting the order N of the inhomogeneous VO become infinite, assuming convergence of the resulting functional series

$$y(\cdot) = h_0 + \sum_{k=1}^{\infty} \int \cdots \int d\tau_1 \cdots d\tau_k h_k(\cdot; \tau_1, \cdots, \tau_k) x(\tau_1) \cdots x(\tau_k). \quad (\text{A.16})$$

In practice, both the number of terms in (A.16) as well as the support of the Volterra kernels have to be truncated. Issues of approximation of nonlinear systems with infinite and truncated Volterra systems have been extensively addressed in the literature [8], [34], [46], [30], [69], [68], [29], [70]. Issues of inverting a given Volterra system are discussed in great length in [71] and in a concise and rigorous manner in [46].

ABSTRACT

In ground penetrating radar (GPR) antipersonnel mine sensing, in which the target is small, shallow and often of low dielectric contrast, detection is challenging. One of the difficulties is that it is hard to distinguish the target signal from the omnipresent random rough ground reflection clutter. In this work, a Monte Carlo computational simulation using 2-dimensional (2-D) transverse magnetic (TM) finite difference time domain (FDTD) with multiple rough surfaces is implemented to investigate single TNT target buries in dispersive soil.

Based on the effects of the random rough surface on an impulse GPR signal and the knowledge of wave propagation differences in different media – air, soil, and TNT – a special background average process using physics based signal processing (PBSP) is performed to remove the ground clutter signal. This procedure first involves shifting and scaling multiple time signals from target-free random rough ground to establish the nominal (average) ground reflection pulse shape. Next, this nominal pulse shape is correlated in time with each trial signal, then shifted and scaled to match the ground surface clutter of that trial signal. Subtracting this shifted scaled clutter signal from the trial signal ideally leaves the target signal (with some additional multiple scattering between the target and ground surface). The PBSP algorithm reapplied in cases for which surface scattering occurs at multiple points. The statistical results of PBSP surface clutter removal indicate that the detection performance degrades with increasing surface roughness and decreasing burial depth. Hypothesis testing on the processed results proved to be successful in a detection and estimation point of view. This paper presents the detection performances in terms of Receiver Operating Characteristics (ROC) for various ground surface roughness and target burial depth cases. Also demonstrated is the performance improvements expected from multiple views: indicating that a multi-bistatic configuration appears to be superior to multistatic transmitter/receiver geometry with minimum combinations.

Keywords: hypothesis testing, FDTD, GPR, ROC, performance, bistatic

1. INTRODUCTION

Detecting buried dielectric targets – such as antipersonnel mines – with GPR is important since million of mines are still be hidden in the ground, a cost and labor effective technique is needed. However, it is also challenging, because the dielectric constant of nonmetallic mine targets are similar to those of the surrounding soil, and because their sizes are comparable to the thickness of soil layer above them. In addition, the soil dielectric constant may not be well characterized, and the ground surface will usually be rough, often with roughness of the order of the target burial depth. The focuses of mine detection addressed in this paper are ground clutter removal and hypothesis testing which qualifies

the detection performance based on 2D TM FDTD model. Although 3D FDTD is more accurate and visible, it is computationally complex and expensive while 2D FDTD can provide much information.

The computational geometry shown in Fig. (1) is typical bistatic geometry based on the Geo-Centers, Inc. EFGPR system¹. The measured Geo-Centers TEMR GPR antenna element radiated signal is used as the excitation, shown in Fig. (2). The TEMR is a wide-band antenna, throughout the 200MHz to 2.0GHz range.

Figure 1. Rough surface computational geometry

Figure 2. incident measured waveform

The impulsive electromagnetic wave propagates through the dispersiver soil and is partially reflected. The received components in time are: the transmitter-receiver coupling signal with much stronger amplitude than the target signal; the ground reflection clutter signal, with distorted shape due to surface roughness; and the target return that is buried in the clutter.

The soil model is Puerto Rican clay loam² with 10% moisture and 1.4g/cc density, with average dielectric constant $\epsilon' = 6.2$. Since the soil is frequency-dependent medium, it is modeled by a single pole conductivity model based on the observation that the frequency variation of the real dielectric constant does not significantly affect either the real propagation constant or the decay rate^{3,4,5}. The probability density function for the random height of the ground surface has a Gaussian distribution with zero mean and standard deviation σ_h . Also, the surface profiles spectrum is assumed Gaussian^{6,7}. Since we interest in the clutter effects on target discrimination, the single scale Gaussian assumption is reasonable⁸. The frequency-independent target is the dry TNT with dielectric constant 2.9, and almost 0 conductivity⁹, and its size is about 10cm by 5cm.

In the FDTD¹⁰ code, the time step used was $\Delta t = 20ps$, which is matched to the 2D excitation time interval, and spatial difference is calculated to be $\Delta = 1.22cm$. The boundary condition used is the perfect matched layer (PML) absorbing boundary condition¹¹, with which the theoretical reflection factor of a plane wave striking a vacuum layer interface can be made insignificant at any frequency and at any incidence angle. In this computation, 16 PML half-layers are used, and it gives good result for incident angle less than 75 degrees¹².

The simulations are implemented for a variety of rough surfaces characterized by standard deviation for height σ_h and correlation length l_c , also for various depths of buried target, and without target as well. In each simulation, 500 random rough surface realizations are generated.

2. SIGNAL AND CLUTTER SEPARATION MODELING AND PROCESSING

The goal of the process is to maximally suppress the clutter and retain the target signature. Since the surface is rough, the statistical rough ground reflection signal is obtained by the cross-correlation model, and eliminated from the received signal. Furthermore, because the shift of target signal is related to the shift of the ground clutter signal, the target signal is enhanced by the alignment procedure.

When the correlation length l_c is large, the received pulse is a shifted and scaled version of transmitted signal. The time shifting and amplitude scaling are due to air/soil partition of the wave propagation path. By identifying these parameters and measuring their statistics separately, much added information about the ground clutter becomes available. The time shifting is found by the correlation function. Cross-correlation function between reference signal ' f ', which is from an ideal soil half-space with a flat boundary, and any realization signal ' i ' is^{7,13}:

$$C_{fi}(m) = \sum_{n=1}^{N-|m|} S_f(n) S_i(n+m) / \sqrt{\sum_{n=1}^N |S_f(n)|^2} \sqrt{\sum_{n=1}^N |S_i(n)|^2} \quad \text{for } m \geq 0 \quad (1)$$

$$C_{fi}(m) = C_{if}(-m) \quad \text{for } m \leq 0 \quad (2)$$

The relative scaling is obtained from:

$$A_i = \sqrt{\sum_{n=1}^N |S_i(n)|^2} / \sqrt{\sum_{n=1}^N |S_f(n)|^2} \quad (3)$$

where $i = 1, 2, \dots, M$ is the rough surface realization index, M is the size of Monte Carlo sample, and N is the total number of time steps. Another way to obtain the scaling factor is to use the maximum correlation normalization instead. Since the energy normalization is superior for rougher surfaces that generate greater pulse distortion, the relative scaling is calculated using Eq. (3). The flow chart of the PBSP is shown in Fig.(3).

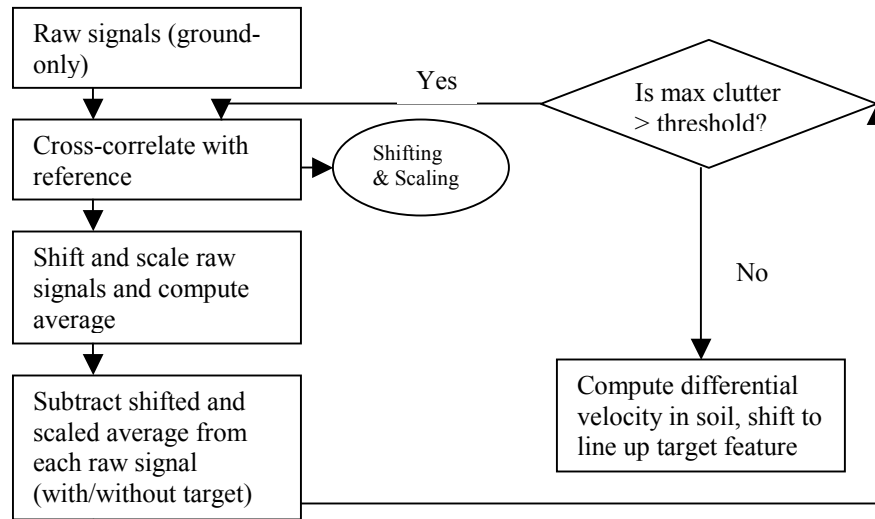

Figure 3. Flowchart of single/multiple PBSP to suppress the ground clutter(s)

The nominal background signal is found by shifting received ground-only signal by $\tau_{gnd,i}$, scaling by A_i , and averaging. The ensemble average gives the best estimate for the local clutter that corrupts the target signal. To reduce ground clutter, the nominal background signal is then shifted back by $\tau_{gnd,i}$, scaled by A_i , and subtracted from each received signal S_i . With the assumption or the knowledge of the depth of the buried target, the path of the scatter signal can be estimated. The wave propagation velocity in soil compared with that of in air is reduced by a factor $1/\sqrt{\epsilon'}$, the shifting factor for the target signal $\tau_{mine,i}$ due to the change of soil amount can be calculated according to the geometry path. Then, the background-subtracted signals are once again realigned to the expected target position^{7,13}. If the surface scattered wave were primarily due to a single specular reflection – as would be the case if l_c were large – then this procedure would suppress most of the surface clutter. However, it is possible that the surface scattering occurs at multiple points. In that case, the cross-correlation/shifts ensemble average/subtraction procedure is repeated.

One hundred computed scattered signals with/without in-ground-target are shown in Fig. (4.a1) and Fig. (4.b1) along with the ± 1 standard deviation confidence interval, with the direct transmitter-receiver coupling signals removed. Those two plots are almost identical. Then, the ground clutter removal procedure is applied, with results shown in Fig. (4.a2) and Fig. (4.b2). Comparing the target-free mean plot to the target-in-ground mean plot, although there are clutter variations involved, there is visible difference in time interval [200 300] – where the target signal would be expected to occur. Therefore, it is possible to distinguish target-in-ground plot from target-free plot. However, it is difficult to localize the target to a certain depth by only looking at Fig. (4.b2), since the clutter amplitudes are comparable to those of the target signal. The realigned signals of the complete PBSP procedure are plotted in Fig. (4.a3) and Fig. (4.b3). The target signals are now well aligned, and the target position can be located by investigating the mean signal in the target-in-ground plot. Furthermore, as expected, the standard deviation is much smaller for the target region of the signal than for the clutter region. The double clutter removal results are shown in Fig. (4.a4) and Fig. (4.b4). Since the clutter due to the second ground reflection has been suppressed, the amplitude of the clutter signal is reduced. Meanwhile, the target signature remains as prominent as expected.

By using the PBSP, most of the ground clutter can be suppressed. However, the processing results are roughness dependent and related to the depth of a buried target. In Fig. (5), the mean signal and STD of several rough surfaces and various depth cases are present.

3. SIMPLE BINARY HYPOTHESIS TESTING

We simplify the mine detection problem to be: whether there is mine at certain depth with the knowledge of the surface roughness. Each of the two answers corresponds to a hypothesis:

H_1 corresponds to the presence of a target (i.e., mine is present)
 H_0 corresponds to the absence of a target (i.e., no mine)

Applying the likelihood ratio test, which is derived to be¹⁴:

$$-\frac{1}{2}(\mathbf{r}^T - \mathbf{m}_0^T)\mathbf{Q}_0(\mathbf{r} - \mathbf{m}_0) - \frac{1}{2}(\mathbf{r}^T - \mathbf{m}_1^T)\mathbf{Q}_1(\mathbf{r} - \mathbf{m}_1) \underset{H_0}{\overset{H_1}{>}} threshold \quad (4)$$

where \mathbf{r} , \mathbf{m}_0 and \mathbf{m}_1 are vectors with N elements, \mathbf{Q}_0 and \mathbf{Q}_1 are $N \times N$ covariance matrices. \mathbf{r} represents the individual background-subtracted signals. \mathbf{m}_0 is the average of realigned no target (clutter) signals; \mathbf{m}_1 is the realigned target signals. The covariance matrices \mathbf{Q}_0 and \mathbf{Q}_1 are the inverses of the diagonal matrices of standard deviations of the clutter and target signals. Since the processed signals are not guaranteed independent of one and another, the diagonal covariance matrices used in the test are approximations. We are investigating the worse case hypothesis test here. 100 out of 500 target signals and 100 out of 500 clutter signals are grouped at test signals. The average signals \mathbf{m}_0 and \mathbf{m}_1 , and standard deviations are obtained from the remaining 400 clutter signals and 400 target signals. The likelihood ratio

test is applied to each test signal associated with a set of trial thresholds. Subsequently, the probability of *false alarm* P_F (*i.e.*, we say the target is present at certain depth when it is not) and the probability of, detection P_D (*i.e.*, we say the target is present at certain depth when it is) are obtained. The performance of the likelihood ratio test is evaluated by receiver operating characteristic (ROC) curve¹⁴. The ROC curves for a variety of rough surfaces and different depths are shown in Fig. (6). As the depth increases, the performance improves, *i.e.*, when a buried target is close to the surface, it is hard to distinguish the ground clutter from the target signal since the ground clutter signal and target signal are too close to remove the clutter signal without affecting the target signal. The detection performance degrades as the standard deviation increases. Thus, the detection becomes difficult as expected when the surface is rough and the target is shallow buried.

By relating signals associated with certain depth to several average signals for different depths, it has been found that the best performance always occurs for the correct depth estimate. An example is shown in Fig. (7). The test signals for depth 8.5cm were related to the average signals and corresponding standard deviation that are belong to the same roughness family. Thus, the correct target depth will be obtained by testing sample signals with stored statistics of various families with same surface roughness. Interestingly, the ROC curves for close but not exact depths are worse than those for much deeper or shallower depth estimates.

The previous results are based on the geometry shown in Fig. (1) -- the target is centered beneath the transmitter-receiver (TR) pair. Recall that the detection performances decrease for rougher surfaces. In order to improve the performance, multi-bistatic and multistatic geometries are investigated. Now, in addition to then single centered TR pair position, we used four more TR positions for multi-bistatic geometry: 12.2cm and 24.4cm to the left and right of the center. As the pair moves away from the target, the test performance degrades. Also, the amplitude of the average target signal drops. However, the combination of three TR positions improves the detection performance significantly. With five TR views, the performance is even better. It is also true for the multistatic case with fixed transmitter and multiple receiver views. The improvements of using three/five TR pairs and three/five receiver views are shown in Fig. (8.a) and Fig. (8.b). Although performance increases with the number of views, the combinations of three TR positions, or three receiver views, each spaced 12.2cm apart to the left and right, appear to give excellent results.

4. CONCLUSION

The computational study of 2D TM FDTD is presented to investigate a single dry TNT target at certain depth buried in dispersive soil with the presence of a random rough surface. The dispersive FDTD algorithm is used to incorporate the frequency-dependent complex conductivity media – Puerto Rican clay loam. The air/soil interface is characterized by Gaussian roughness, since the single scale roughness is well described by Gaussian process. The GPR impulse used is based on a measured transmitter pulse, with a wide-band width and the capability of exploring target in the presence of a lossy medium. The PML boundary is employed to terminate the computational grid.

The simulated result is processed using a background average procedure – PBSP, which even works for a shallow buried target. The ground clutter is mostly removed by the ensemble average and subtraction procedure. Also, shifting and scaling the individual received signal back and forth according to the transmission path in the air and the soil enhance the target signature. The statistical results of the PBSP indicate that the quality of target signals depends on the roughness of the surface and the depth of a buried target.

In addition to examining the statistics of fields scattered from a Gaussian rough surface, we investigate the worse case target detection performance by using the classic detection theory. Applying the binary hypothesis tests to the processed signals, the target can be localized at certain depths even under rough ground surfaces. Furthermore, the spatial combinations of TR position will improve the detection performance.

ABSTRACT

The use of ground penetrating radar (GPR) is one of the most popular techniques for the detection of anti-personnel mines and therefore it is desirable to accurately model such systems. For many GPR applications, FDTD models used to simulate the system are two-dimensional, because they are simple to implement and computationally inexpensive. However, a three-dimensional model is more accurate and allows complete freedom for the location of the object relative to the receivers. Instead of fully modeling the transmitter and receiver elements, and adding significant complexity, the transmitted field in this study is experimentally measured and used as the model's excitation. The model developed simulates a GPR system consisting of a parabolic reflector transmitter and a multi-static receiver array. The model is tested for both flat and rough ground with a Gaussian variation. The results are compared with experimental data and are found to be very accurate. The validation of this approach makes the model a powerful tool that can be used in different applications, where the exciting field is computationally or experimentally specified.

Keywords: FDTD, modeling, ground-penetrating radar, mine detection, parabolic reflector

1. INTRODUCTION

Land mine detection using ground-penetrating radar (GPR) has been a topic of research for many years, and research has shown that it is a challenging problem with no unique solution. The properties of the transmitting and receiving antennas used, the geometry of the system, and the signal processing algorithms employed for the processing of the data are all important aspects of the problem. A description of these design parameters and a summary of some of the most popular GPR systems can be found in [1].

Among the several different techniques, the forward-looking parabolic reflector transmitter GPR aims to reduce the clutter from the ground surface and thus make the detection of the object an easier task. This system, which was designed by Northeastern University and fabricated at Geo-Centers, Inc., has been described in previous work^{2, 3, 4}. The parabolic reflector transmitter illuminates the ground with a forward propagating, quasi-planar wave. A significant amount of the ground clutter will scatter away from the ground surface, and therefore the relatively isotropic scattered signal from a buried object has a higher probability of being detected by the receivers, positioned in the backscattered direction. The possibility of detecting the small signal scattered from the object depends on the electromagnetic properties of the material, its position relative to the receivers and how deep it is buried into the ground. Using a short-duration excitation impulse and a multi-static array receiver system, the detection performance for shallow buried targets is enhanced³.

In order to simulate this system, we can measure the transmitted field voltages and find a way to extract the electric field that will be used as an input to the model. The modeling is performed using the Finite-Difference Time-Domain numerical method. The system has been compared with previous 2D models², but here a fully three-dimensional model is developed, which simulates the incident quasi-planar wave, propagation in frequency dependent soil, the ground clutter for flat and rough cases, and the signal scattered by the object, resulting in the signal received by the four-receiver multi-static array.

2. GPR SYSTEM MODELING

The FDTD method is one of the most popular numerical techniques for electromagnetic problems. It is based on discretizing Maxwell's equations in time and space using a difference scheme for the approximation of the derivatives, on edges of the so-called Yee-cell⁵. Several issues related to the numerical implementation of the FDTD technique, such as stability and dispersion⁷, together with geometry considerations, play an important role in determining the size of this cell, which is chosen to be uniform for the present application.

A fully three-dimensional FDTD model would include the transmitting and receiving antennas, the parabolic reflector, the air/ground interface and the buried object. In addition, the transfer functions that convert voltages to electric fields are also necessary in order to compare the simulation results to measured data. Alternatively, we can use a more simplified approach if we make certain assumptions for our system. First of all, if the receiving antenna is located in the far-field of the transmitting system, there are no significant ringing effects and therefore the knowledge of the transmitting fields is sufficient for use as an excitation model. Moreover, if we consider the system to be linear and time-invariant (Fig.1), then we can interchange the order of the “boxes” in figure 1. Then, we can measure the voltages with the receiver before the channel, and use these voltages as input to get output voltages, which can be directly compared to the data.

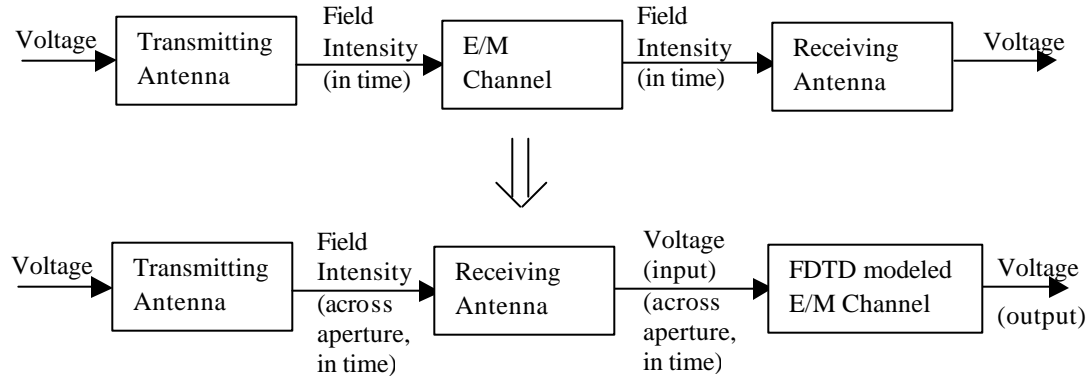

Fig. 1: Transition from the physical system to the equivalent model by interchanging the order of processes.

Based on these assumptions, we can consider a plane in the 3D grid that is excited by field values that are experimentally measured and then let this incident quasi-planar wave propagate, encounter the soil and the object, and record the signal at the points where the receivers are located. The geometry of the model is depicted in figure 2. The procedure followed to derive the input excitation by the measured values is described in the next section. Here we briefly discuss our approach towards some of the most important issues that are related to the FDTD method. These include the modeling of lossy, dispersive soil and the absorbing boundary conditions. A more detailed analysis can be found in [6].

Any FDTD analysis should account for the frequency dependence of the soil's electrical properties. There are several methods that are developed to model this dispersion based on fitting parameters to match measured data for a range of

frequencies^{10,11}. The present model uses a z-transform method based on a single-pole, two-zero conductivity model, which leads to good agreement with measured soil data over two decades in frequency⁸. This one-pole approach requires storage of only two previously computed field values and leads to very simple equations for the propagation in soil that use these past values and some additional constants.

Due to the ground's abnormalities and the presence of other possible scatterers, such as rocks or metal objects, it is also necessary to introduce ground roughness in the FDTD model. For the 3D geometry, a rough surface is generated using a height variation that has a joint, zero-mean Gaussian distribution in both x and y dimensions¹³.

Fig. 2: Geometry of the 3D FDTD grid that simulates the GPR system and the four-receiver plane.

Terminating the grid with an effective absorbing boundary condition (ABC) that will significantly reduce unwanted reflections is one of the most important objectives for any FDTD application. In the literature, the perfectly matched layer (PML) absorbing boundary condition¹⁴ has been extensively studied and its modified versions can be used for a 3D model that includes free space and lossy, dispersive soil. An alternative approach is to use the Mur absorbing boundary conditions¹⁵. Although the PML performance in free-space is superior to the Mur ABC, in the frequency-dispersive soil it is comparable to a Mur-type ABC that uses the single-pole conductivity model mentioned above^{6,9}. Using a point-source excitation, this 3D Mur-type ABC has been tested in Puerto-Rican clay loam with 1.4 g/cc density and 10% moisture and resulted to a maximum 5% reflection on the edges of the grid⁶, and testing for 1D cases for 5% moisture with a 1GHz Gaussian exciting pulse has shown that up to a 15° angle, this Mur-type ABC behaves better than the PML⁹. For an approximately 45° incident plane wave, the angle of propagation in the soil is within this 15° range, making this Mur-type ABC preferable to the PML. In addition, using Mur-type ABC in the model is much simpler to implement and faster than a 3D air/soil PML. As for the reflection in the free-space region, the planes of excitation and receivers in the 3D grid (figure 2) are located closely enough to the ground that these reflections occur later than the ground clutter and mine signal⁶.

3. PARABOLIC REFLECTOR'S INCIDENT WAVE

The offset paraboloidal reflector antenna generates a quasi-planar wave of approximately 45° of incidence that can be considered fairly uniform in the ground region of interest (figure 3). The offset section is necessary to avoid the blockage of rays by the feed structure. The reflector collimates rays from an ultra-wideband transmitting feed. A detailed description of the necessary design considerations and the characteristics of the system can be found in references [4] and [12]. Here we are interested in describing the procedure that was followed in order to use the wave generated by this system as the excitation for the FDTD model, based on measured data. Figure 3 shows the geometry of the performed experiment.

In order to simulate this system, we experimentally measured the transmitted field. Turning the parabolic antenna upside down, we measured amplitudes and delays on the xy plane, using a Styrofoam sheet as physical support for the measurement. The measurements were taken every two inches in the x -direction for the interval $[-10'', 10'']$ and every three inches in the y -direction for the interval $[-9'', 9'']$, where the center $(0,0)$ corresponds to the beam center of the parabolic antenna, as shown in figure 3. In addition, the waveforms of the incident field were recorded for the center and the corners of the x - y plane. These nine positions are marked in the figure.

Fig. 3 Experiment for measuring the field wave generated by the parabolic reflector. On the left, the actual system facing the ground is depicted and on the right, the system is turned upside-down in order to measure the transmitted field as function of time position on the x - y plane.

In order to derive the field values for every grid cell from the recorded waveforms and the measured amplitudes and time delays, we first need to interpolate these measured values for the intermediate points according to the length of the cubic cell's sides that are used in the simulation. The time step of the recorded waveforms also needs to be equal to the one used in the simulation. Then an interpolation algorithm performs the following steps:

1. Take the waveforms at $(0, 0)$ and $(0, +9)$ to derive the waveforms for all points along $(0, y)$.
2. Repeat for $(+10, 0)$ and $(+10, +9)$ to derive waveforms along $(+10, y)$.
3. Use $(0, y)$ and $(+10, y)$ to derive the waveforms for all the points (x, y) with $x \in [0, +10]$, $y \in [0, +9]$.
4. Repeat steps 1-3 for the three remaining blocks of data.
5. Unify the results to produce the interpolated field for (x, y) , $x \in [-10, +10]$, $y \in [-9, +9]$ and for an x (y) increment that corresponds to the Δx (Δy) of the simulation.

The fields that are obtained using this method are shown in figure 4, where cuts along the x and y -axis through the center are presented. For display purposes the field values in these figures have been under-sampled both in space and time. These figures verify that the measured transmitted field possesses the characteristics desired for land-mine detection applications, being relatively planar, tilted 45° to vertical in the xz plane and having a gradual amplitude taper away from the center of the beam. The wave transmitted by the parabolic reflector is only an approximation to a 45° incident plane wave. These plots, though, illustrate that this approximation is realistic.

Figure 4 also shows the result of exciting the E_x component of the electric field with the above values in a 3D FDTD grid. The H_y magnetic field component on the xz surface that passes through the center of the grid is plotted for three different time steps, in the vicinity of the air/ground interface. The output of this simulation further illustrates the validity of the plane-wave approximation, especially locally, in the air/ground region that includes the plane of the receivers and the mine target.

Fig. 4: Parabolic reflector's wave that excites the 3D FDTD grid. The cuts along the x and y-axis through the center illustrate the characteristics of the incident wave. As the wave propagates in the grid, it locally resembles a plane wave with 45° incident angle.

4. RESPONSE OF REALISTIC SOIL USING GPR SIMULATIONS AND DATA

The parabolic transmitter shown in figure 3 was used in an outdoor experiment in Northeastern 's Dedham Campus outdoor track. The GPR receiver array consists of two forward and two rear antenna elements, positioned close to the ground, behind the focal point of the transmitting antenna. The parabolic antenna system is put on a survey cart that can travel along-rails down-track. Several plastic and metallic objects are buried along the track (figure 5). The soil can be approximately considered as clay loam with 1.4 g/cm^3 density. We use measured soil values for Puerto-Rican clay loam¹⁶. The statistical characteristics of the roughness of the ground are not expected to change significantly along the track. As the cart moves along, the received signal at each of the four receivers is measured for every half inch. Starting with the center of the system (beam center) being in the center in the y (cross-track) direction and moving it along the x (down-track) direction, the process is repeated for every two inches left and right (y-direction) to the center.

Fig. 5: Photograph of the GPR system and diagram of the outdoor track

In order to compare simulated and experimental data, a scan corresponding to a track location with no object beneath the ground was considered. To simulate the ground response recorded at this scan, the three-dimensional FDTD model was

run for both flat and rough ground cases, and the planes of excitation and receivers were placed as in figure 2, with the receivers' height equal to their distance from the ground in the outdoors experiment. The ground roughness parameters are set to be 10.0 cm for the correlation length and 1.0 cm for the mean square height. These parameters are chosen to correspond to a moderate rough case.

In order to get the ground response from the scanned signal, we first need to determine the direct signal from transmitter to receiver and subtract it. It is important and rather difficult to capture an accurate reference signal in an outdoor experiment due to reflections from the surrounding environment. Furthermore, since this signal will determine the time alignment of the data, finding the starting time is also critical. For this reason, an air-shot signal was recorded four times for each receiver, the four waveforms were aligned and their average was used as the reference direct signal for each receiver. The air-shot signals were taken by turning the system upside-down to minimize ground reflections. The reflection caused by the surrounding environment can be considered as part of the direct signal. Then the reference direct signal for each receiver was subtracted from the scanned signal and the result was normalized. For each receiver, the total number of samples in the scanned data is 512, but the sampling rate is slightly different, namely 38.2, 37.1, 33.3 and 37.5ps for receivers 1,2,3, and 4 respectively. Thus, the time window is slightly different for each receiver. The starting time is determined by time alignment based on the air-shot signal.

For the FDTD simulations the direct signal can be easily obtained by removing the ground and recording the signal at the four receivers. This stored signal is then subtracted by the ground signal and, after normalizing, the ground response for flat and rough ground is obtained. The starting time, as with the experimental data, is arbitrary. The simulated signal was normalized to the maximum value of the experimental signal for comparison. The soil was modeled to simulate the Puerto Rican clay loam that is considered for the experiment. The time step for the simulations was 10ps, so the simulated data was extrapolated to match the time steps of the four receivers in the experiment. As mentioned above, due to this difference in the sampling rate, the time windows for the four receivers are slightly different.

Fig. 6: Realistic soil response (measured data vs. FDTD model). The x-marked line corresponds to the measured data, the solid and dash-dotted lines to the simulation results for flat and rough ground respectively. The ground roughness follows a Gaussian distribution with parameters 10.0 cm for the correlation length and 1.0 cm for the mean square height.

The ground response of the simulation model vs. the experimental data is shown in figure 6. The figure shows a very good agreement of the three-dimensional model with the data. The ground roughness effect is mostly apparent at the fourth receiver, and the measured data lies between the flat and rough ground simulation response for the time interval where these two responses are remarkably different. For the rest of the receivers, the measured data is in very good agreement especially in the interval where the main peak occurs, and only at receiver 3 there is a time delay after the main peak for the simulation response in comparison to the data, which may be attributed to experimental errors or non-predicted roughness effects.

5. SCATTERING FROM METALLIC OBJECT

An analysis of the 3D model's predicted scattered signal from plastic and metallic mines and a comparison with two-dimensional models can be found in [6]. However, in order to further confirm the validity of the three-dimensional model, we performed an additional test for which reliable experimental data was available.

This test involves the scattered signal for an aluminum sphere placed in the center of the grid. The simulation results are compared with measurements performed inside, where the sphere was placed on the center of the Styrofoam sheet (figure 3). Here there is no air/ground interface and thus no ground signal and the waveforms were recorded in the experiment with the direct signal subtracted. The transmitting pulse is different and so is the recording time window. The rest of the geometry remains the same. As with the experimental waveforms, the direct signal is recorded and subtracted for the simulation runs. Here, the sampling rate is the same for the four receivers and the starting time is arbitrary, and it is chosen for the simulations so that the signal peaks are aligned. The results are shown in figure 7, with the simulation output having been normalized to the maximum value of the measured output.

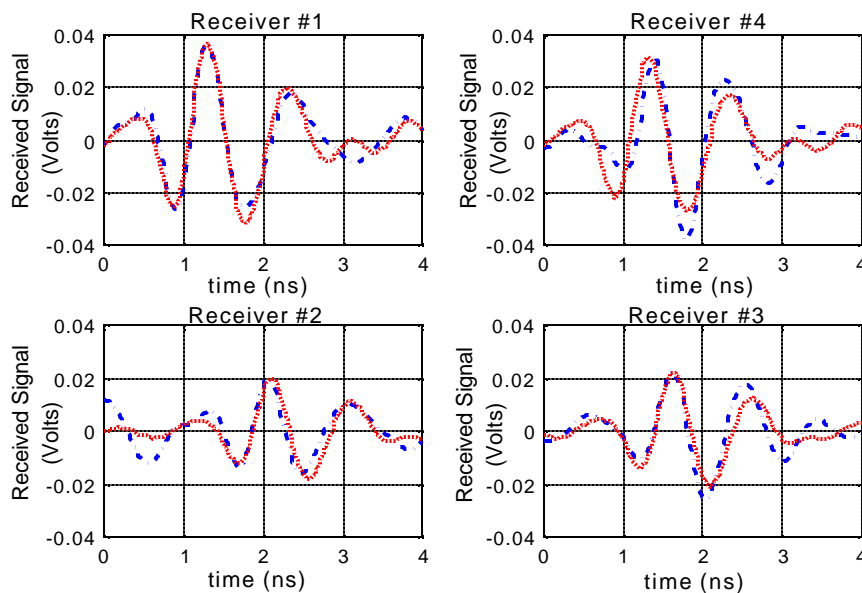

Fig. 7: Scattered signal from an aluminum sphere in free-space (measured data vs. FDTD model). The dash-dotted line corresponds to the measured data, and the solid line to the simulation results.

Figure 7 further illustrates the validity of the three-dimensional FDTD model. Using a different excitation pulse for the parabolic reflector transmitter, the agreement is very good with a small difference only for receiver #4. The scattered

signal is higher at the front receivers 1 and 4, as expected since the ball is located closer to them (beam center of figure 2). The peak occurs later for the rear receivers 2 and 3, due to the propagation time delay.

6. CONCLUSIONS

The three-dimensional FDTD model can accurately simulate a GPR application, such as land mine detection using a parabolic reflector system, which is studied in this work. Following an approach that aims to simplify the complexity of the model as much as possible, we based our excitation on experimental measurements and an interpolation procedure and used simple one-pole models for the soil equations. Mur-type absorbing boundary conditions were chosen for their simplicity and good performance in soil. Placing the receivers close to the ground, the unwanted reflections from the upper sides of the grid occur later than the examined signal.

The model was tested in two different experiments. Using the Geo-centers, Inc. radar pulse as excitation, the ground signal at the four receivers was compared to experimental data taken using the parabolic reflector system at Northeastern's outdoor track. The measured data was found to lie between the flat and rough ground simulated data. Then, for a different pulse transmitter signal, the scattered signal from an aluminum ball was compared to data taken in an inside experiment. The very good agreement for these two different cases is a very strong proof for the validity of the model.

In [6], a study of the ground response with and without plastic and metal mines is studied as a function of position, and the results are compared to two-dimensional cases and conclusions on the ability to detect a plastic non-antipersonnel mine are drawn, based on this FDTD model. It is our objective to test these conclusions with additional reliable data in the future. The validation of this model makes it a powerful tool since, if modified, it can be used for a variety of applications and different systems, once the incident wave is accurately calculated. In other words, the model can be used to break up a larger problem, provided that we are in the far-field of the transmitting antenna and effects of ringing between transmitting and receiving antennas are negligible.

Abstract

Ground surface roughness is problematic when using a radar impulse to detect and locate land mines. Waves scatter from a random rough ground surface in unpredictable ways, contributing to clutter that is particularly hard to suppress. This clutter has proven experimentally and computationally to distort and obscure the desired scattered field from a buried target. To overcome this effect we have developed a lightweight, artificial dielectric that can be placed over a chosen area that will mimic flat ground and mitigate clutter effects.

An artificial dielectric of close-packed array of small insulated metal-coated plastic spheres and lossless uniform plastic spheres can be formulated to match the dielectric properties soil. The ratio of these two spheres in the collection is adjusted to match a particular soil type and the moisture content. Placing them in a conformable bag and ensuring a flat upper interface with the air, ground reflections from an impulse radar can effectively be removed to reveal a target scattering signature. Furthermore, a matched filter can be used to distinguish between a landmine and a false alarm (such as a rock).

The artificial dielectric was matched by running experiments in the frequency and time domains. A 1 GHz center frequency impulse ground penetrating radar was used to collect time signals and compare different cases: flat ground, rough ground and rough ground with artificial dielectric. Results indicate excellent rough surface reflection removal and target signal enhancement.

Keywords

mine detection, artificial dielectrics, ground penetrating radar, coupling, impedance matching

Introduction

Detection of an anti-personnel land mine using ground penetrating radar (GPR) depends on recognizing a reflection from an object buried shallowly below the ground surface. Often the dielectric constant of the target materials (RTV, nylon, TNT, etc.) is in the range of dry soil¹. Mines buried in moist soil offer a slightly lower dielectric constant than their surroundings. This scattering from a low contrast object is compared to a ground signal without an object and a positive or negative decision is made.

The background reference signal that is compared to the test signal will usually be taken over flat ground without a target. If the test signal is obtained over flat ground, a reflection from an object can be seen by subtracting the background signal. However, in realistic environments the ground surface is not flat. Scatter resulting from a rough ground surface can obscure the desired scattered field from the buried target. The undesirable clutter, as it is known, is unpredictable and therefore difficult to remove in processing². Time gating the received signals is not feasible as the targets are usually buried very close to the ground surface³ (most AP mines are between 2cm and 10cm). The clutter will affect the ground reflection and disturbs the signal in the time range where the mine reflection is likely to occur.

Simulations were performed using a three dimensional finite difference time domain model³ to show the effects of rough ground on the propagating fields. A modulated Gaussian pulse was used as the source. Figure 1 displays the incident plane wave coming from the right at a 30 degree angle on flat ground, and the subsequent transmitted and reflected fields. Figure 2 illustrates how clutter is introduced into the reflected field when the ground is rough. The ground roughness follows a Gaussian distribution with a mean height of 1 cm and a correlation length of 10 cm⁷.

Figure 1: Propagating fields from flat ground

Figure 2: Propagating fields from rough ground

Figure 3: Isotropic effect develops from rough ground

Figure 3 shows the propagating fields of the same rough ground simulation as Figure 2 at a later time. There is no buried target in this simulation. Here we can see an isotropic effect develop near the center of the figure. This might be incorrectly interpreted as the return from a buried target. Thus rough ground clutter not only reduces the probability of detection but also increases the probability false alarms.

Although rough ground presents a complicated problem in detecting subsurface objects, a physical means is implemented to overcome this obstacle. A lightweight artificial dielectric is placed over a test area that will mimic flat ground and mitigate clutter effects. The material must be electromagnetically similar to the ground, taking into account the soil type and moisture content. Also it must physically conform well to the test area and retain a flat interface with the propagating fields from the transmitter. Experiments were performed to find a suitable artificial dielectric to match a particular soil. Subsequent experiments using ground penetrating radar have proven that the detection process is improved using the artificial dielectric.

Artificial Matching Layer

An artificial dielectric (AD) layer fills voids and lessens the effects of bumps in the ground surface. The purpose of this layer is to soften and planarize the interface rather than act as an impedance transformer between the air and the soil. The relative permittivity of the layer is for the most part constant and cannot be perfectly matched to the soil during use. The dielectric constant of soil is a function of the soil type, moisture content and density – the latter two can vary widely over a test area. The background reference signal is obtained using the AD over flat ground with a nominal moisture content and density. The background signal will have a reflection from the top, flat surface of the dielectric and a later reflection from the AD/ground interface. We will see that this second reflection is more stable under various rough surfaces when compared to the direct air/ground interface.

Conducting spheres that are spatially separated have been used as artificial dielectrics for many years⁴. However, solid metal spheres are too heavy for land mine use and separating them in a fixed matrix is clearly not feasible. The same goal is achieved with the use of lightweight plastic spheres with a thin metallic coating. The spheres also have an outer plastic film that isolates them from one another. These 6mm beads are available in bulk from an arts and crafts manufacturer as decorations.

For the GPR experiment a soil tank was built and filled with clay-loam topsoil. At 1 GHz, the complex dielectric constant of clay-loam will vary between 6 and 20 depending on the moisture content and the density. For conducting spheres, the effective impedance depends on the geometry of the array and the proximity of the spheres. The separation can be computed in terms of volume packing fraction of the spheres in space. The volume packing fraction is given as:

$$p = Kv_S / v_{TOTAL}$$

Where K is the number of spheres in a total volume (v_{TOTAL}) and v_S is the volume of a sphere ($\frac{4}{3}\pi r^3$).

The effective impedance (ϵ_r) can be approximated as a function of packing fraction by the following formulas⁴:

$$\left. \begin{matrix} \epsilon / \epsilon_0 \\ m / m_0 \end{matrix} \right\} = 1 + 3p/A(p)$$

and

$$h_r = \sqrt{\frac{m_r}{\epsilon_r}}$$

where for simple cubic (sc) packing,

$$A(p) = -1/R_1 - p + 1.3047R_3 p^{10/3} + 0.0723R_5 p^{14/3} - 0.5289R_3^2 p^{17/3} + 0.1526R_7 p^6$$

and for face centered cubic (fcc) packing,

$$A(p) = -1/R_1 - p + 0.0753R_3 p^{10/3} + 0.2420R_5 p^{14/3} + 0.0558R_3^2 p^{17/3} + 0.0231R_7 p^6$$

and,

$$R_n = \begin{cases} -1, & \text{for } \mathbf{e}_r \\ n/(1+n), & \text{for } \mathbf{m}_r \end{cases}$$

The effective impedance for both structures is plotted in Figure 4.

Figure 4: Effective Impedance vs. packing fraction

In practice we would expect the random distribution of spheres to favor that of an fcc structure. The volume density of the 6mm beads was found to be 0.565 which yields an approximate impedance of 0.26Ω . The impedance of soil is found using only the relative permittivity, with the permeability assumed to be that of free space. The impedance for clay loam usually varies between 0.22Ω (at 20% moisture) and $0.41\Omega^5$. We see that the impedance of the AD falls in the range of loamy soils with moisture contents of 12% to 20%.

For an impulse GPR system with a bandwidth of 700 MHz to 1.3 GHz the wavelength of the pulse in the dielectric varies between $33\text{ cm} < \lambda < 18\text{ cm}$. The values are significantly larger than the 6mm diameter spheres and therefore the impedance calculations assume frequency independence.

To better match the AD to a particular soil, the volume packing fraction is reduced, i.e. the spacing among the metallic beads is increased. This is done by uniformly distributing all-plastic beads among the conducting spheres. In order to ensure a uniform mixture of the AD, 8mm non-metallic beads were used because they are similar in weight and size. Measurements were taken in the frequency domain using a microwave network analyzer. Clay loam soil at ~15% moisture was compared to varying the ratios of the two types of beads. The contents were placed in a paraffin cavity and the S11 frequency response was recorded. Figure 5 shows the frequency response of the soil (solid dark) compared to two different ratios of the artificial dielectric. We see that a relatively good match (+) is achieved with the AD when the ratio is 1:2 (by volume 8mm/6mm). The response of dry sand is shown for contrast.

Figure 5: Frequency response of clay loam (solid dark), artificial dielectric (o,+) and sand (--)

Figure 6: Flat ground (solid), roughened surface (dotted), AD fill (dashed)

A comparison was also performed in the time domain using ground penetrating radar. Looking at Figure 6 the solid line indicates flat ground, the dotted is ground with a roughened surface, and the dashed line is surface filled with AD. The ratio that best fit the flat ground response was also 1:2 (by volume 8mm/6mm).

Experiment

Ground penetrating radar experiments are performed at GeoCenters, Inc. in Newton, MA. An indoor wooden soil tank 3ft x 3ft x 2ft provides a controlled testing environment. The pulser (Picosecond Pulse Labs, Inc., model 1000D) excites the GPR system with a Gaussian pulse with a center frequency of 1 GHz and a -3dB bandwidth of 0.6 GHz. The transmitter and receiver are GeoCenters' 7 3/8" TEM horn rolled edge antennas. The rolled edge is implemented to minimize edge reflection, i.e. to better match the impedance of air. A diagram of the setup is seen below in Figure 7a along with a photograph in Figure 7b.

Figure 7a

Figure 7b

The AD is placed in a conformable mesh bag and attached to a ¼” thick lossless Plexiglas (22in x 22in) to ensure a flat interface with the air. The 6” diameter target used in the experiment is an anti-personnel land mine with a material substitute for TNT that has similar electromagnetic properties.

The received signal can be modeled as follows:

$$r(t) = d(t) + n(t) + g(t-t_1) + c(t-t_2) + m(t-t_3)$$

Detection is based on deciding if the signal $m(t)$ is present or not in $r(t)$ among the other contributions. The targets are positioned below the antennas at varying depths and ground surfaces. The direct signal $d(t)$ is acquired by storing an air shot on the oscilloscope, making sure all objects that will reflect energy in the time range (a 4 ns window) of the experiment are removed. This is then subtracted from all test signals. The high frequency noise $n(t)$ is numerically suppressed using an FIR low-pass filter⁶ with a cutoff frequency $\omega_h = 0.06$. The flat ground signal $g(t)$ is a density-dependent version of the impulse that varies in delay and amplitude according to how the soil is packed (assuming that the moisture content is constant over a test period). The clutter $c(t)$ is dependent on the surface roughness and thus will vary in unpredictable ways. This distorts the return from the mine, $m(t)$, which, like $g(t)$, is also an attenuated and delayed version of the impulse.

The ground signal is removed by first obtaining a reference flat ground, no target signal. The permittivity and conductivity of the soil will change with density, which affects the amplitude of the ground impulse. Also the nominal distance between the antennas and the ground changes slightly throughout the test, affecting delay. As a result, a series of flat ground signals are acquired. The signals are aligned and scaled according to the average time reference and average amplitude of their peak values (the reflection of the impulse from the ground). These normalized signals are then averaged to produce a single background reference signal that will be compared to subsequent test signals.

This process is also performed to produce one background reference signal using the artificial dielectric. This signal is compared to test signals that use the AD.

Figure 8a shows samples of flat, no target signals (dotted) with the average background reference overlaid (solid). Figure 8b is the same for the AD background. The first peak in Figure 8b is the impulse return from the top of the AD. The second peak is the addition of the first pulse shape and the return from the AD/soil interface (resulting from the dielectric constants not being perfectly matched).

Figure 8a: Various flat ground reference signals (dotted); averaged background reference (solid)

Figure 8b: Using the AD

A new test signal will be compared to the background signal. To account for soil density and height changes, the test signal is aligned to the background signal's peak amplitude. If clutter from the ground roughness is very low, subtracting the background reference should reveal a target reflection. Using the artificial dielectric we will be able to reduce this clutter enough on moderately rough surfaces to still yield a correct decision. The following figures illustrate the effect of two different rough ground cases. We see in Figure 9a the variation in the received rough ground signals (dashed) compared to the flat ground reference (solid). Signals of the same rough ground cases were compared to the reference using the AD and a significant reduction in variance is noted. The markers on the plots indicate the time range of interest, i.e. when a target reflection will show up if it is buried from 2 cm to 10 cm.

Figure 9a: Flat background reference (solid), two different rough ground signals (dashed)

Figure 9b: Using the AD reduces the variance of rough ground signals compared to the reference

The cross correlation of the flat reference signal with the test signal, normalized to the square root of its energy can be found as follows⁷:

$$C_{fi}(m) = \frac{\sum_{n=1}^{N-|m|} S_f(n) S_i(n+m)}{\sqrt{\sum_{n=1}^N |S_f(n)|^2} \sqrt{\sum_{n=1}^N |S_i(n)|^2}}, \text{ for } m \geq 0$$

$$C_{fi}(m) = C_{if}(-m), \text{ for } m < 0$$

The maximum of the flat reference autocorrelation normalized by its energy will be unity. The difference between the maximum value of $C_{fi}(m)$ and 1 is a good metric to use for characterizing how well the rough ground test signal resembles the flat reference, i.e. the error between the reference and test signals. The average error when using the AD for 9 signals of varying ground roughness is found to be 0.0096, with a variance of 7.365×10^{-5} . When not using the dielectric the average is 0.0222 with a variance of 1.533×10^{-4} . The lower mean value and variance of this metric illustrates an improvement in the stability of the test signals when using the artificial dielectric. Thus the probability of detecting a slight signal variation due to a small, plastic object is enhanced.

A simple method for detection without the AD is given in the following diagram.

Figure 10: The impulse from a metal target is visible after background subtraction

The plots in Figure 10 show an example detecting a subsurface object using this method. The object is a metal sphere buried 5cm below flat ground. The average background signal (solid) is seen in the first two plots on the left along with the test signal (dashed). After scaling and aligning the background signal is subtracted, revealing an version of the impulse scattered from the object (scaled in the plot on the right).

The method becomes less effective when the object's dielectric constant is similar to the soil and when the ground surface is not flat. In Figure 11a we see a signal with a buried dielectric target (dashed) in flat ground, a buried target signal in rough ground (dotted) and a no-target signal in rough ground (dash-dot). Subtraction in Figure 11b reveals the target in flat ground but a determination of the same target in rough ground is much more challenging. Furthermore the no-target and target signals in rough ground are difficult to distinguish. In this case the chance of a false alarm is increased.

Figure 11a: Target signals in flat (dashed) and rough (dotted) ground; no-target signal in rough (dash-dot); background (solid)

Figure 11b: Subtraction shows the plastic target at 2.75 ns in flat ground (dashed), but roughness obscures the target (dotted) and no-target (dash-dot) signals

Figure 12: AD target signals; flat (dashed) and rough (dotted) compare similarly to the reference

Figure 13 displays the result of this algorithm with the object seen at 2.6 ns in flat (solid) and in rough ground (dashed and dotted). A test signal without a target (dash-dot) is also displayed to show a case where a false alarm can be avoided.

The procedure was tried for mines at various depths and preliminary assumptions show that the artificial dielectric offers improvement during cases of rough ground, especially at the more shallow target depths (2 cm – 5cm)

Figure 14: Target detected in flat ground (solid) and two rough ground cases (dashed, dotted); a no-target response is also visible (dash-dot)

Conclusions

The artificial dielectric placed over the ground area to be tested has proven to facilitate the mine detection process. This is true for several cases examined with the 6" diameter plastic AP mine buried between 2cm and 8cm in various rough ground interfaces. Even for flat ground it appears that the AD reduces whatever clutter is added to the received signal due to soil density changes.

As more data is collected one might expect improvements in the detection algorithm as the reduced clutter is better characterized and removed. Also receiver operating characteristics can be developed to optimize the probability of detection for a given false alarm rate.

Abstract

Scattering of electromagnetic waves from multilayered random rough surfaces is crucial for subsurface sensing applications. A multiple interaction method of moments (MoM) model is used in this work to analyze scattering from two-dimensional multilayered random rough ground (3-D scattering problem) especially when the underground layer is deeply buried under the air/ground interface. The presented model removes a barrier and enables the application of the Steepest Descent Fast Multipole Method (SDFMM) to certain 3-D non-quasi-planar structures. The conventional SDFMM has been used to analyze electromagnetic wave scattering from quasi-planar structures where the scatterer's height is a fraction of a free-space wavelength. The presented model is based on multiple interactions mechanism between the air/ground interface and the buried underground layer. The basic idea of the proposed multiple scattering model is to decompose the non-quasi-planar multilayered ground into two quasi-planar scatterers where the conventional SDFMM can be applied separately to each one. The interactions between the sub-quasi-planar scatterers are calculated using the electromagnetic vector potentials near-field expressions. This model is tested and validated with the MoM on a variety of geometries. The results show that the strongest signature of the buried scatterer is mainly due to the first multiple interaction mechanism (ground-object-ground) while the contributions from repeating this mechanism become insignificant even for lossless and/or slightly lossy underground.

I. INTRODUCTION

Electromagnetic subsurface sensing has recently become an attractive research area due to its wide civil and defense applications. There are numerous unfound buried objects; these objects could be, but are not limited to, the location of underground water, gas and/or water lines, identifying cracks in asphalt roads, cancerous tumors in the human breast, plastic anti-personnel or metallic anti-tank mines, or the location of hazardous environmental wastes, etc. In reality, these complicated scattering problems have three-dimensions (x , y and z) that cannot be solved in closed forms but rather can be solved using computational techniques, in particular using fast algorithms. Few fast computational techniques were developed in the literature, e.g., the Fast Multipole Method (FMM) [1]-[3], the Steepest Descent Fast Multipole Method (SDFMM) [4]-[6], the Sparse Matrix/Canonical Grid Method (SMCG) [7], [8], and the Spectral Algorithm combined with the Forward-Backward Method (FB/NSA) [9]. These fast techniques have shown superiority regarding the CPU time and memory requirements over the conventional methods (e.g. the method of moment (MoM), the finite-difference methods (FD) and the finite-element method (FEM)). Recently, the SDFMM has been adopted to analyze the scattering from penetrable shallow objects buried under two-dimensional random rough ground [10]-[11]. The SDFMM has the great advantage of $O(N)$ computational complexity for both the CPU time and computer memory, where N is the total number of electric and magnetic surface current unknowns. However, there is a barrier that prohibits using the SDFMM in some potential applications; the scatterer should have a quasi-planar structure with total height equal to a fraction of a free-space wavelength. On the other hand, there are several potential geometries that have non-quasi-planar structures such as (i) multilayered ground where the burial depth of

the underground layer is larger than the wavelength [12], (ii) a non-quasi-planar object buried under the quasi-planar rough ground, (iii) utility cylindrical pipes deeply buried under the rough ground, etc.

The basic idea of the multiple scattering model is to decompose a non-quasi-planar structure into two quasi-planar scatterers as shown in Fig. 1 where the conventional SDFMM can be applied separately to each one. The interactions between the sub-quasi-planar scatterers, e.g. between the ground and the buried object in Fig. 1, are calculated directly using the electromagnetic vector potential expressions for the electric and magnetic near-fields [13]. The proposed model sheds light on the physics involved in the subsurface scattering mechanism [12], [14]. In this work, we are emphasizing on (i) presenting and validating the multiple scattering model on a variety of geometries as shown in Fig. 2 and (ii) using the SDFMM in the proposed multiple scattering model for non-quasi-planar structures aiming to speed up the calculations by exploiting the superior $O(N)$ computational complexity of the SDFMM.

The proposed model algorithm will be described in Section II, numerical results are presented in Section III and concluding remarks are given in Section IV.

II. FORMULATION

The four integral equations describing the unknown equivalent electric and magnetic surface currents for the problem of a single object buried beneath two-dimensional rough ground were derived in [10]-[11]. Upon applying Galerkin's method for testing and using the RWG vector basis functions for approximating the surface currents [15], these integral equations are transformed into a set of linear system of equations $\bar{\bar{Z}}\bar{\bar{I}} = \bar{\bar{V}}$ given by [10]:

$$\begin{pmatrix} \bar{Z}_{g.g} & \bar{Z}_{g.obj} \\ \bar{Z}_{obj.g} & \bar{Z}_{obj.obj} \end{pmatrix} \begin{pmatrix} \bar{I}_g \\ \bar{I}_{obj} \end{pmatrix} = \begin{pmatrix} \bar{V}_g \\ 0 \end{pmatrix} \quad (1)$$

where $\bar{Z}_{g.g}$ is a submatrix representing interactions between elements only on the ground surface; $\bar{Z}_{g.obj}$ is a submatrix representing interactions between elements on the ground surface and elements on the object surface; $\bar{Z}_{obj.g}$ is a submatrix representing interactions between elements on the object surface and elements on the ground surface; and $\bar{Z}_{obj.obj}$ is a submatrix representing interactions between elements only on the object surface. It was shown in [10] that the total matrix $\bar{\bar{Z}}$ has order of $2(N+P) \times 2(N+P)$, where N is the number of vector basis functions on the ground and P is the number of vector basis functions on the object. The factor of two is to account for both the electric and magnetic surface currents. Moreover, $\bar{Z}_{g.g}$ (and $\bar{Z}_{obj.obj}$) is exactly the impedance matrix obtained in the PMCHW integral equations [16]. The vector \bar{V}_g is composed of the tested tangential incident electric field \bar{E}_g^{inc} and the tested normalized magnetic field $\eta_1 \bar{H}_g^{inc}$ on the ground surface. The unknown current coefficients \bar{I}_g and \bar{I}_{obj} were solved for in [10] and [11] by applying the SDFMM directly to Eq. 1. Conversely, in this work, the multiple scattering model will be used to iteratively solve for the unknown current coefficients in

$$\bar{Z}_{g.g} \bar{I}_g^{(n)} = \bar{V}_g^{(n)} \quad (2a)$$

$$\bar{Z}_{obj.obj} \bar{I}_{obj}^{(n)} = \bar{V}_{obj}^{(n)} \quad (2b)$$

where $n = 1, 2, 3, \dots$ is the number of iterations or the number of multiple scattering mechanisms between the ground and the buried object as shown in Fig. 2b. The mechanism of the multiple scattering model begins by calculating the incident waves from the source (transmitting antenna) on the rough ground $\bar{V}_g^{(0)}$ with the assumption that there are no buried objects under the ground. Then the SDFMM is used to calculate the induced electric and magnetic surface currents on the ground as $\bar{J}_g^{(0)}$ and $\bar{M}_g^{(0)}$, respectively. In return, these currents are used to induce incident electric and magnetic fields on the surface of the

buried scatterer $\bar{V}_{obj}^{(1)}$, which are calculated directly using the near-field expressions [13]. Depending on the geometry of the buried object, the SDFMM or the MoM is used to calculate the induced electric and magnetic surface currents on the buried object, $\bar{J}_{obj}^{(1)}$ and $\bar{M}_{obj}^{(1)}$. Finally, these currents are used to induce electric and magnetic fields on the ground surface as $\bar{V}_g^{(1)}$ using [13], and the SDFMM can be used to solve for the induced electric and magnetic currents on the ground, $\bar{J}_g^{(1)}$ and $\bar{M}_g^{(1)}$, respectively. This completes one multiple scattering mechanism (e.g. ground-object-ground). The process is to be repeated till the solution of currents on the ground and on the buried object converges.

As will be shown in the following section, a significant reduction in the CPU and memory requirements is anticipated upon using the multiple scattering mode where only $\bar{Z}_{g,g}$ and $\bar{Z}_{obj,obj}$ are used in the iterative calculations while in the conventional SDFMM and/or the conventional MoM, the four matrices $\bar{Z}_{g,g}$, $\bar{Z}_{obj,obj}$, $\bar{Z}_{g,obj}$ and $\bar{Z}_{obj,g}$ are to be used. In many applications $\bar{Z}_{g,obj}$ and $\bar{Z}_{obj,g}$ have the same order as $\bar{Z}_{g,g}$ and $\bar{Z}_{obj,obj}$ as will be demonstrated in Section III.

III. NUMERICAL RESULTS

A variety of geometries represented by five examples are used in this section to test and validate the proposed multiple scattering model with the conventional MoM. The numerical results will present (i) the electric and magnetic surface currents on the ground, (ii) the electric and magnetic surface currents on the buried scatterer, and (iii) the scattered electric field above the ground due to just the buried scatterer (i.e., scatterer's signature). In all results presented in this section, the incident wave is assumed a Gaussian beam tapered towards the edges of the ground [17] with horizontally polarized incident electric field (i.e., in the y -direction) and due to just the air/ground interface as well. The half beam width of the beam is $L/5$ where the ground has dimensions $L \times L$.

In Example 1 shown in Fig. 2a-b, the flat ground has dimensions $3.04\lambda_o \times 3.04\lambda_o$ with an x -directed horizontal cylinder of length $b = 3.04\lambda_o$, radius $a = 0.15\lambda_o$, and burial depth $z = -0.65\lambda_o$ measured from its center, where λ_o is the free-space wavelength. The relative dielectric constant of the ground and the buried cylinder are assumed $\epsilon_{2r} = 2.5 - j0.18$ and $\epsilon_{3r} = 7.9 - j0.0029$, respectively. The incident angle in this example is $\vartheta^i = 0$. Excellent agreement between the multiple scattering model and the MoM for the electric and magnetic surface currents on the flat ground and on the buried cylinder is shown in Figs. 3a-d. For qualitative comparisons, the magnitudes of the surface currents are plotted versus the y -direction at $x = 1.52\lambda_o$ in these figures. Four multiple scattering mechanisms, as described in Fig. 2b, are used to obtain these results. Similar agreement is observed for results plotted versus the x -direction at $y = 1.52\lambda_o$. An insignificant error is observed in Figs. 3c and 3d that could be due to the error introduced in approximating the cylindrical surface with triangular patches. As shown in these figures, the presence of the buried cylinder caused a significant change in the initial ground currents $\bar{J}_g^{(0)}$ and $\bar{M}_g^{(0)}$ only after the first multiple scattering mechanism. Similarly, Fig. 4a shows the convergence of the magnetic surface current on the upper half of the buried cylinder, plotted versus the x -direction at $y = 1.52\lambda_o$, while Fig. 4b shows the convergence of the magnetic surface current on both the upper and lower halves of the buried cylinder, plotted versus the y -direction at $x = 1.52\lambda_o$. The results confirm that the surface currents converge after only one ground-object-ground scattering mechanism, as described in Fig. 2a.

In Example 2, the geometry is a multilayered flat ground as shown in Fig. 2c, where the ground has dimensions $3.04\lambda_o \times 3.04\lambda_o$ and the underground layer has burial depth of $z = -0.45\lambda_o$. The relative dielectric constant of the ground and the underground layers are assumed $\epsilon_{2r} = 2.5 - j0.18$ and

$\epsilon_{3r} = 4.2 - j0.29$, respectively. The incident angle in this example is $\vartheta^i = 10^\circ$. All results show excellent agreement with the MoM (not presented here).

In Example 3, the geometry is a multilayered rough ground with flat underground layer as shown in Fig. 2d. The ground dimensions, the burial depth of underground layer, the relative dielectric constants, and the incident angle are the same as in example 2. The roughness parameters of the upper rough air/ground interface are given by the rms height and the correlation length of the random rough surface as $\sigma = 0.08\lambda_0$ and $l_c = 0.5\lambda_0$, respectively. All comparisons with the MoM strongly validate the multiple scattering model used in this example similar to previous examples (not presented here).

In Example 4, the geometry is flat ground with a buried sphere as shown in Fig. 2e where the dimensions of the ground are $4.08\lambda_0 \times 4.08\lambda_0$. The sphere has radius of $a = 0.5\lambda_0$ and is buried at $z = -0.75\lambda_0$ measured from its center. The relative dielectric constants of the ground and the buried sphere are assumed $\epsilon_{2r} = 2.5 - j0.18$ and $\epsilon_{3r} = 4.5 - j0.029$, respectively. The incident angle in this example is $\vartheta^i = 0$. In Figs. 5a and 5b, the magnitude of magnetic surface current on the air/ground interface is plotted versus the x -direction at $y = 2.04\lambda_0$. Three solutions are presented in Figs. 5a; (i) solution obtained using the conventional MoM for the whole scatterer (hollow circles), (ii) solution obtained by employing the MoM in the multiple scattering model (solid circle), (iii) solution obtained by employing the SDFMM in the multiple scattering model (+ symbol). The results show excellent agreement between these three methods. Moreover, validations based on the scattered electric fields observed above the ground at $z = 0.5\lambda_0$ and due just to the buried sphere are shown in Fig 5b where results are plotted versus the x -direction at $y = 2.04\lambda_0$. Excellent agreement between the three methods is also observed in these figures. However a slight difference between the multiple scattering model and the conventional MoM results is observed in Fig. 5b. This slight difference can be attributed due to the definition of the scattered fields due to just the buried object in both methods. In the conventional MoM method we calculated the total scattered electric fields twice; once with the buried sphere and once without the buried sphere, then the results are subtracted from each other using complex vectors [10]-[11]. On the other hand, for the multiple scattering model we use the obtained surface electric and magnetic currents on the ground due to only the presence of the sphere, i.e., $\bar{J}_g^{(1)} + \bar{J}_g^{(2)} + \bar{J}_g^{(3)}$ and $\bar{M}_g^{(1)} + \bar{M}_g^{(2)} + \bar{M}_g^{(3)}$, and use the near-field expression in [13] to compute the scattered electric fields. Notice that the quantities $\bar{J}_g^{(0)}$ and $\bar{M}_g^{(0)}$ represent the surface currents on the ground with the assumption that there is no buried objects, i.e., only the ground is present and are not used to calculate the signature of the buried sphere.

In Example 5, the geometry is a multilayered rough ground as shown in Fig. 2f where the dimensions of the ground and the incident angle are the same as in example 4. The underground rough layer has a burial depth of $z = -0.95\lambda_0$ measured from its mean plane to the rough air/ground interface mean plane. The relative dielectric constants of the ground and the underground layer are assumed $\epsilon_{2r} = 2.5 - j0.18$ and $\epsilon_{3r} = 3.7 - j0.2$, respectively. The roughness parameters of the air/ground interface are $\sigma_1 = 0.06\lambda_0$ and $l_{c1} = 0.5\lambda_0$ while they are $\sigma_2 = 0.05\lambda_0$ and $l_{c2} = 0.4\lambda_0$ for the underground layer. In Fig. 5a, the magnitudes of the magnetic surface currents on both the rough air/ground interface and the underground rough layer are plotted versus the y -direction at $x = 2.04\lambda_0$. The results show an excellent validation between the model using the MoM and the model using the SDFMM. In Fig. 5b, the scattered electric fields observed above the ground at $z = 0.5\lambda_0$ are plotted versus the y -direction at $x = 2.04\lambda_0$. The scattered fields due to just the rough air/ground interface are calculated using only the surface currents $\bar{J}_g^{(0)}$ and $\bar{M}_g^{(0)}$ while the scattered fields due to just the underground layer are calculated using only the

surface currents $\bar{J}_g^{(1)} + \bar{J}_g^{(2)} + \bar{J}_g^{(3)}$ and $\bar{M}_g^{(1)} + \bar{M}_g^{(2)} + \bar{M}_g^{(3)}$. As expected, the results in Fig. 5b show that the signature of the air/ground interface is significantly larger than that of the underground layer. Moreover, the results of this example clearly confirm the previous observations that the solution converges after the first multiple scattering mechanism (i.e., air/ground interface-underground layer-air/ground interface).

It should be mentioned that the relative residual error used in the TFQMR solver is 10^{-5} in all results of this section. For efficient results, the multiple scattering model should not be used when the buried objects are very shallow due to the inaccuracy of the near-field expressions in [13], but instead, the complete SDFMM, which has been successfully used in analyzing these structures [10]-[11], should be used.

IV. CONCLUSIONS

A new multiple scattering model to compute the signature of non-shallow objects buried under the rough ground (3-D scattering problem) is presented and validated in this work. The advantages of this model is (i) superior computational requirements than using the conventional MoM especially when the SDFMM is employed in the model and (ii) removing a barrier in the conventional SDFMM since it should be only applied to quasi-planar structures. It has been shown in this work that upon using the proposed multiple scattering model, certain potential non-quasi-planar structures, e.g., three multilayered ground, are decomposed into two quasi-planar layers where the SDFMM is separately applied. Interestingly, all obtained results show that both the electric and magnetic surface current solutions converge after only a single multiple scattering mechanism (i.e., from air/ground interface to buried object and then back to air/ground interface). This assures that no extra CPU time is needed to achieve the correct solutions.

ABSTRACT

The computational solution of large-scale linear systems of equations necessitates the use of fast algorithms but is also greatly enhanced by employing parallelization techniques. The objective of this work is to demonstrate the speedup achieved by the MPI (Message Passing Interface) parallel implementation of the Steepest Descent Fast Multipole Method (SDFMM). Although this algorithm has already been optimized to take advantage of the structure of the physics of scattering problems, there is still the opportunity to speed up the calculation by dividing tasks into components using multiple processors and solve them in parallel. The SDFMM has three bottlenecks ordered as (1) filling the sparse impedance matrix associated with the near-field Method of Moments interactions (MoM), (2) the matrix vector multiplications associated with this sparse matrix (3) the far field interactions associated with the fast multipole method. The parallel implementation task is accomplished using a thirty-one node Intel Pentium Beowulf cluster and is also validated on a 4-processor Alpha workstation. The Beowulf cluster consists of thirty-one nodes of 350MHz Intel Pentium IIs with 256 MB of RAM and one node of a 4x450MHz Intel Pentium II Xeon shared memory processor with 2GB of RAM with all nodes connected to a 100 BaseTX Ethernet network. The Alpha workstation has a maximum of four 667MHz processors. Our numerical results show significant linear speedup in filling the sparse impedance matrix. Using the 32-processors on the Beowulf cluster lead to achieve a 7.2 overall speedup while a 2.5 overall speedup is gained using the 4-processors on the Alpha workstation.

INTRODUCTION

The calculation of the scattered electric and magnetic fields from a three-dimensional problem using the conventional techniques (e.g., the Method of Moments

(MoM), the Finite Element Method (FEM), or the Finite Differences in the time or frequency domains (FDTD or FDFD)) is a computationally intensive undertaking, especially for soils having a large dielectric constant. Moreover, the computational complexity of the problem dramatically increases upon inserting penetrable objects under the rough ground. Therefore, there was a necessity to use the fast computational algorithms to deal with this complex scenario. There exist few fast algorithms in the literature: the Fast Multipole Method (FMM) [1]-[3]; the SDFMM [4]-[6]; and the Sparse Matrix/Canonical Grid Method (SMCG) [7]-[8]. Basically, the standard FMM, the SDFMM, and the SMCG fast methods have the great advantage of converting the dense matrix obtained using the MoM into a sparse matrix leading to a dramatic reduction in the CPU time and computer memory requirements. In addition the fast algorithm, the Spectral Algorithm combined with the Forward-Backward Method (FB/NSA) [9], has shown to be an efficient iterative MoM for 3-D scattering problems.

In this work we adopted the SDFMM due to its superiority over the other fast algorithms in treating quasi-planar structures. The SDFMM is an integral equation-based fast algorithm that is a hybridization of (1) the Method of Moments (MoM), (2) the Fast Multipole Method (FMM), (3) the Steepest Descent Integration path (SDP) [4]-[6]. Recently the SDFMM has been successfully implemented to handle subsurface sensing applications, in particular, the scattering from a landmine modeled as a PEC and/or penetrable spheroid buried under a two dimensional randomly rough ground [10]-[11]. The SDFMM has computational complexity for the CPU time and for the memory requirement equal to only $O(N)$ per iteration versus $O(N^2)$ for the MoM, where N is the total number of the unknowns [4]-[6]. The reduced complexity of the SDFMM over several other computational electromagnetics techniques has helped in achieving a

fast and successful running for the Monte Carlo simulations [11]. However, the Monte Carlo sample needs in some cases to be greatly increased, e.g. when the ground random roughness increases the size of the Monte Carlo sample needs to be increased to achieve a converging solution. This could dramatically increase the required run time, especially when the dielectric constant of the ground is large and/or the penetrable buried object is electrically large. This necessitates more acceleration to the SDFMM computer code by using the MPI parallel implementation [8],[12],[13].

In this work, we used the MPI library for the parallel implementation of the SDFMM code [14]-[15]. The advantage of using the Beowulf cluster is that the system can be completely dedicated to the parallelization task, which is demonstrated in this work by executing small-scale cases due to memory limitations. Our emphasis is to demonstrate the overall speedup that can be achieved using the thirty-two processors. Porting the parallelized code to the national supercomputers, where hundreds of processors and adequate RAM are available, will potentially facilitate the computations of large-scale problems.

PARALLELIZATION METHODOLOGY

The SDFMM makes use of the equivalence theorem to calculate the electric and magnetic fields inside and outside a 3-D penetrable object buried under the rough surface interface [10]-[11]. The 3-D arbitrary object is modeled by scatterer R_3 that is immersed in scatterer R_2 which represents the rough ground which is immersed in the free space region represented by R_1 . The three regions, R_1 , R_2 and R_3 have permittivity and permeability given by ϵ_1 and μ_1 , ϵ_2 and μ_2 , and ϵ_3 and μ_3 , respectively, representing free space, soil medium and penetrable buried object. There are two final sets of unknown equivalent electric and magnetic surface currents in the following formulations. They are \bar{J}_1, \bar{M}_1 on the exterior of the rough ground interface between R_1 and R_2 , and \bar{J}_3, \bar{M}_3 on the exterior of the buried object interface between R_2 and R_3 . Upon applying the boundary conditions, continuity of tangential components of the electric and magnetic fields on these interfaces, new integral equation formulations are obtained as [10]-[11]:

$$\bar{E}^{inc}(\bar{r})\Big|_{\text{tang.}} = [(L_1 + L_2)\bar{J}_1 - (K_1 + K_2)\bar{M}_1 - L_3\bar{J}_3 + K_3\bar{M}_3]_{\text{tang.}} \quad (1a)$$

$$\bar{H}^{inc}(\bar{r})\Big|_{\text{tang.}} = \left[(K_1 + K_2)\bar{J}_1 + \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{M}_1 - K_3\bar{J}_3 - \frac{L_3}{\eta_2^2} \bar{M}_3 \right]_{\text{tang.}} \quad (1b)$$

$$0 = [-L_2\bar{J}_1 + K_2\bar{M}_1 + (L_3 + L_4)\bar{J}_3 - (K_3 + K_4)\bar{M}_3]_{\text{tang.}} \quad (1c)$$

$$0 = \left[-K_2\bar{J}_1 - \frac{L_2\bar{M}_1}{\eta_2^2} + (K_3 + K_4)\bar{J}_3 + \left(\frac{L_3}{\eta_2^2} + \frac{L_4}{\eta_3^2} \right) \bar{M}_3 \right]_{\text{tang.}} \quad (1d)$$

In which the integro-differential operators L_i and K_i , $i=1, 2, 3$ and 4, are given in detail in [11]. In Eqs. 1a-d, the unknown surface electric and magnetic currents are \bar{J}_1 , \bar{M}_1 , \bar{J}_3 , and \bar{M}_3 , while the tangential components of the incident electric and magnetic fields on the rough surface are given by $\bar{E}^{inc}(\bar{r})\Big|_{\text{tang.}}$ and

$\bar{H}^{inc}(\bar{r})\Big|_{\text{tang.}}$, respectively. The intrinsic impedance in

each region is $\eta_i = \sqrt{\mu_i / \epsilon_i}$, $i=1, 2$, and 3, where the dielectric permittivity and permeability in each region are ϵ_i and μ_i , respectively. The equivalent electric and magnetic currents are approximated using the Rao, Wilton and Glisson (RWG) vector basis functions [16]-[17]. Upon applying Galerkin's method for testing and substituting the RWG surface current approximations

in 1a-d, the original integral equations are transformed into a set of linear system of equations given by [10]-[11]:

$$\bar{\bar{Z}} \bar{\bar{I}} = \bar{\bar{V}} \quad (2a)$$

The impedance matrix $\bar{\bar{Z}}$ has order of $2(N+P) \times 2(N+P)$. The vector $\bar{\bar{V}}$ is a matrix of order $2(N+P) \times 1$ and composed of a submatrix of the tested tangential incident electric field \bar{E}^{inc} of order $N \times 1$ and a submatrix of the tested normalized magnetic field $\eta_1 \bar{H}^{inc}$ of order $N \times 1$, and a null submatrix of order $2P \times 1$. The quantities N and P are the numbers of basis functions (total number of edges of the triangular patches) on the surfaces of the rough ground and the buried object, respectively. If the MoM

is used to formulate and solve Eq. (2a), the computation and storage of all the elements of the matrix $\bar{\bar{Z}}$ are required. Furthermore, if an iterative solution process is used, matrix-vector products involving multiplying $\bar{\bar{Z}}$ by a vector \bar{I} are required. However, upon using the SDFMM [4]-[6],[10],[11] the matrix $\bar{\bar{Z}}$ becomes sparse and the system of equations in (2a) can be written as:

$$\bar{\bar{Z}}' \bar{I} + \bar{\bar{Z}}'' \bar{I} = \bar{V} \quad (2b)$$

where the matrix $\bar{\bar{Z}}'$ is a sparse matrix whose non-zero elements need to be calculated and stored using the conventional MoM and then multiplying them by the vector \bar{I} (near field interactions) while the matrix-vector multiply $\bar{\bar{Z}}'' \bar{I}$ is computed in one step without calculating or storing any elements of the matrix $\bar{\bar{Z}}''$. This was achieved by hybridizing the FMM with the SDP leading to the SDFMM [4]-[6]. There are three bottlenecks in the SDFMM computer code: (i) the subroutines that calculate the elements of the sparse matrix $\bar{\bar{Z}}'$; (ii) the subroutine that executes the matrix vector multiplication $\bar{\bar{Z}}' \bar{I}$ in every iteration; (iii) the subroutine that executes the fast multipole method for $\bar{\bar{Z}}'' \bar{I}$ (far-field fast multipole interactions). These three bottlenecks in the serial SDFMM computer code are separately parallelized in the current work as pictorially described in Fig. 1 [18].

The key data structure of bottleneck (i) is the sparse matrix $\bar{\bar{Z}}'$ which is originally stored in the serial SDFMM computer code as blocks of nonzero elements. These elements represent the near-field interactions in the conventional MoM. The computations of these blocks are independent and therefore are parallelized in a straightforward manner by distributing them among all processors with no additional communication. When this routine is parallelized we achieved almost a linear speedup for bottleneck (i) on 32 processors. It is necessary to mention that the elements of $\bar{\bar{Z}}'$ remain distributed among the processors at the end of parallelizing bottleneck (i).

In the second bottleneck (ii) in the serial SDFMM computer code, the matrix-vector multiplication $\bar{\bar{Z}}' \bar{I}$ is executed every iteration of the transpose-free quasi-minimal residual (TFQMR) iterative solver [19]. This multiplication is parallelized by distributing the vector \bar{I} to all processors similar to the elements of the sparse matrix $\bar{\bar{Z}}'$ in bottleneck (i). Therefore, the multiplication proceeds in parallel without additional communications and the vector components that result

from the multiplication are then distributed to all processors.

In the third bottleneck (iii) in the serial SDFMM computer code, the fast multipole part for the matrix vector multiplication represented by $\bar{\bar{Z}}'' \bar{I}$ in (2b) is computed for every iteration of the TFQMR iterative solver. This part of the serial code includes the computations of the Green's function approximations for the air and for the medium (e.g. soil). These two approximations of the Green's function are independent and are represented in the serial computer code by two separate subroutines; therefore they are executed concurrently as a first parallelization phase of bottleneck (iii). The load balance between these two subroutines is achieved using a detailed performance model based on the serial execution time of each routine, the time required for collective communication operations, and the amount of communication overhead needed. Moreover, in the serial computer code each one of these two subroutines includes all the multi-level FMM computations such as the inhomogeneous plane wave expansions and the dipole interactions at the finest level (aggregation), all interactions going up the tree, all the multi-level translation operations, all interactions going down the tree and finally the disaggregation process at the finest level which concludes the far-field interactions producing $\bar{\bar{Z}}'' \bar{I}$ [1]-[6]. As a second phase of parallelizing bottleneck (iii), each Green's function approximation subroutine is parallelized but only at the finest level. In this work, no parallelization was conducted for the multi-level portion in these subroutines due to the existing complex interdependencies in the serial computer code. More parallelization future work is needed for this part.

NUMERICAL RESULTS

We evaluated the parallel implementation of the SDFMM computer code on a 32-node Intel Pentium-based Beowulf cluster. Thirty one nodes of the Beowulf cluster are 350MHz Intel Pentium IIs with 256 MB of RAM in addition to one node of a 4x450MHz Intel Pentium II Xeon shared memory processor with 2GB of RAM. The nodes are connected to a 100 BaseTX Ethernet network and they use the SuSE 6.1 operating system with Linux kernel 2.2.13, and the MPICH 1.2.1 implementation of the MPI library. Moreover, we tested the parallelized code on a 4-node shared memory Compaq Alpha-based workstation (667Mhz Alpha 21264) of 16GB total RAM. The processor uses the UNIX OSF/1 V5.1 operating system with the MPICH 1.1.2 MPI library. Our benchmark includes three small-scale cases executed on the 256MB Intel cluster, and in addition

one moderate-scale case that is executed on the Alpha workstation. To evaluate the speedup achieved by the parallel code, we considered a range of values for the ground roughness and/or for the buried object. All results obtained by executing the parallel version of the code are validated with those computed by the serial version of the code [10]-[11]. In all computations a 10^{-3} tolerance is assumed for the TFQMR iterative solver [19]. The scattering problem configurations used in [11] are employed here, but for only one rough surface realization as shown in Fig. 2. The rough ground is characterized by Gaussian statistics with zero mean for the height, thus the roughness parameters can be described by the rms height σ and the correlation length l_c . In all cases, the relative dielectric constant of the ground soil and the penetrable buried object (anti-personnel mine) are $\epsilon_r = 2.5 - j0.18$ and $\epsilon_r = 2.9 - j0.0092$, respectively. A Gaussian beam with horizontal polarization is employed for the incident waves at normal incidence for Cases 1-3 and at 10° from normal direction for Case 4 [11].

In the small-scale Cases 1-3, the dimensions of the modeled ground are assumed to be $3\lambda_0 \times 3\lambda_0$ leading to almost 8,800 of total number of surface current unknowns, while these dimensions are increased to be $8\lambda_0 \times 8\lambda_0$ for the moderate-scale Case 4 leading to 60,320 unknowns, where λ_0 is the free space wavelength. In Case 1, the scattered electric fields from a rough ground alone (no buried target) with $\sigma = 0.3\lambda_0$ and $l_c = 0.5\lambda_0$ are calculated at height of $1.2\lambda_0$ above the ground. In Case 2, the scattered electric fields from a rough ground with a buried penetrable sphere are calculated at height of $0.5\lambda_0$ above the ground. The ground roughness is assumed to be $\sigma = 0.1\lambda_0$ and $l_c = 0.5\lambda_0$ and the sphere has radius of $a = 0.16\lambda_0$ with burial depth equal to $z = -0.32\lambda_0$ measured from its center to the mean plane of the ground. The sphere in Case 2 is replaced by a spheroid of dimensions $a = 0.3\lambda_0$ and $b = 0.15\lambda_0$ in Case 3 that is buried at $z = -0.3\lambda_0$ with ground roughness equal to $\sigma = 0.04\lambda_0$ and $l_c = 0.5\lambda_0$.

Both the overall speedup and the initial speedup (filling matrix $\bar{\bar{Z}}'$) are plotted versus the number of processors for Cases 1, 2 and 3 in Figs. 3a, 3b and 3c, respectively. The speedup is defined as the ratio of the serial runtime to the parallel runtime. The results in these figures show the significant speedup in the initial time (set up) that is consumed to fill the sparse matrix $\bar{\bar{Z}}'$ as explained in Section II. This initial speedup

dramatically affects the overall speedup of the code as shown in these figures. In addition, the results show that almost the same overall speedup can be achieved by employing only twelve instead of thirty-two processors.

The efficiency for a given number of processors is defined as the ratio of the speedup to the number of processors. In each case, the peak speedup is achieved when running on 32 processors, where for case 1, the peak speedup is 7.1 as shown in Fig. 3a, with a reduction in runtime from 99 minutes on one processor to 14 minutes on 32 processors. For Case 2, the peak speedup is 6.2 as shown in Fig. 3b, with a reduction in runtime from 90 minutes to 14 minutes while for Case 3, the peak speedup is 7.2 as shown in Fig. 3c, with a reduction in runtime from 88 minutes to 12 minutes. Over these three cases, the average speedup on 32 processors is 6.8, giving an efficiency of 0.21. Based on the serial runtimes, 88% of the code is executed in parallel. Therefore by Amdahl's Law [20], the peak speedup achievable is 8.3. We conclude that communication overhead and load imbalance among the processors account for the reduction in speedup from 8.3 to 6.8. An interesting comparison between the speedup achieved in each one of the bottlenecks (i)-(iii) mentioned in Section II, is shown in Fig. 4. These results show that the matrix-vector multiplication $\bar{\bar{Z}}'\bar{T}$ (that is the bottleneck (ii)) governs the overall speedup of the parallelized computer code.

In the second set of experiments, we solved the moderate-scale problem of Case 4 (60,320 unknowns) on the Alpha SMP using all four available processors. The penetrable spheroid of dimensions $a = 0.3\lambda_0$ and $b = 0.15\lambda_0$ is buried at $z = -0.3\lambda_0$ under the $8\lambda_0 \times 8\lambda_0$ rough ground with $\sigma = 0.04\lambda_0$ and $l_c = 0.5\lambda_0$. The magnitude of the total scattered electric field from the ground with the buried target is shown in Fig. 5. The magnitude of the scattered electric fields for just the buried spheroid is computed by subtracting the return from the rough ground using complex vector representation from the total return from the ground with the buried target [10]-[11]. The output is shown in Fig. 5b. The results of Fig. 5a and 5b clearly demonstrate that the signature of the buried plastic landmine is relatively small compared with the return from the ground which is considered a major source of clutter in landmine detection application. Moreover, the distortion observed in Fig. 5b is due to the roughness of the ground which is modeled here as only one random rough surface realization, however the Monte Carlo simulations case was presented in [11]. The serial version took 96 minutes to run this case

while the parallel version took 37 minutes, giving a speedup of 2.5 and an efficiency of 0.63. The predicted peak speedup on the four processors is 2.9. This implies that executing the parallel code on the 4-Alpha 667MHz processor gives a remarkable reduced absolute runtime for this moderate-scale case. This achievement can be exploited to execute large-scale

scattering problems as mentioned in Section II. For the memory requirements, the serial version of the code requires 950MB of RAM while the parallel version requires 1154MB of RAM distributed over the four processors as 288, 290, 289 and 287MB, respectively. Table I summarizes the parameters and output results for all cases presented in this section.

Table I Overall speedup

Case #	Number of Unknowns	σ	Object	System	Number of Processors	Serial/Par. time (min.)	Speedup (overall)
1	8,800	$0.3\lambda_0$	None	Cluster	32	99/14	7.1
2	8,800	$0.1\lambda_0$	Sphere	Cluster	32	90/14	6.2
3	8,800	$0.04\lambda_0$	Spheroid	Cluster	32	88/12	7.2
4	60,320	$0.04\lambda_0$	Spheroid	Alpha Server	4	96/37	2.5

The results described in this section demonstrate that by implementing the fine grained parallelism, we have achieved good speedups when using a single rough surface realization (one run of the code). This achievement is suitable for some subsurface scattering configurations where we may need to obtain multiple views of a target buried under the same rough surface realization [10]. This requires running the code several times. However, the current speedup is not suitable when the number of rough surface realizations is much larger than the number of available processors, e.g. Monte Carlo simulations, due to the saturation occurs in the speedup of the second and third bottlenecks.

CONCLUSIONS

Good overall speedup has been achieved as the SDFMM computer code is parallelized using the MPI library. The linear speedup obtained for the first bottleneck associated with filling the sparse impedance matrix is significant. Sensible speedups are obtained for the second and third bottlenecks associated with the matrix vector multiplication in the near-field and the far-field FMM approximations, respectively. However, the later speedups saturate upon using only 12 processors out of the 32 nodes available on the system. This saturation affects the overall speedup of the computer code and limits its application. More parallelization work is needed to enhance the speedup to be used for large Monte Carlo simulations.

ACKNOWLEDGMENTS

This research was sponsored in part by the Army Research Office Demining MURI grant # DAA 0-55-97-0013, in part by the Engineering Research Centers

Program of the NSF under award number EEC-9986821, and in part by the College of Engineering at the University of Arkansas. This work benefited from the allocation of time at the Joulian Cluster and at the Advanced Scientific Computation Center (NU-ASCC) at Northeastern University. The SDFMM was originally developed by V. Jandhyala, E. Michielssen and W. Chew at the UIUC.

Magda El-Shenawee received the Ph.D. degree in electrical engineering from the University of Nebraska-Lincoln in 1991. In 1992, she worked as a Research Associate in the Center for Electro-Optics at the University of Nebraska. In 1997, she worked as Visiting Scholar at the University of

Illinois at Urbana-Champaign and in 1999, she joined the Center for Electromagnetics Research at Northeastern University, Boston. Currently, Dr. El-Shenawee is an assistant professor in the Department of Electrical Engineering at the University of Arkansas, Fayetteville. Her research areas are rough surface scattering, computational electromagnetics, subsurface sensing of buried objects, breast cancer modeling, numerical methods, and micro-strip circuits. Dr. El-Shenawee is a member of Eta Kappa Nu electrical engineering honor society.

Carey M. Rappaport received five degrees from the Massachusetts Institute of Technology: the SB in Mathematics, the SB, SM, and EE in Electrical Engineering in June 1982, and the PhD in Electrical Engineering in June 1987. Prof. Rappaport has

worked as a teaching and research assistant at MIT from 1981 until 1987, and during the summers at COMSAT Labs in Clarksburg, MD, and The Aerospace Corp. in El Segundo, CA. He joined the faculty at Northeastern University in Boston, MA in 1987. During Fall 1995, he was Visiting Professor of Electrical Engineering at the Electromagnetics Institute of the Technical University of Denmark, Lyngby, as part of the W. Fulbright International Scholar Program. He has consulted for Geo-Centers, Inc., PPG, Inc. on wave propagation and modeling, and microwave heating and safety. He is Principal Investigator of the ARO Multidisciplinary University Research Initiative in Humanitarian Demining and Co-Principal Investigator of the Center for Subsurface Sensing and Imaging Systems (CenSSIS) Engineering Research Center. Prof. Rappaport has authored over 180 technical journal and conference papers in the areas of microwave antenna design, electromagnetic scattering computation, and bio-electromagnetics, and has received two reflector antenna patents, two biomedical device patents and three subsurface sensing device patents. He was awarded the IEEE Antenna and Propagation Society's H.A. Wheeler Award for best applications paper of 1985. He is a member of Sigma Xi and Eta Kappa Nu professional honorary societies.

Desheng Jiang received the BS degree in Chemistry from Jiangxi Normal University in 1993, the MS in Oceanography from Texas A&M University in 1999, and the MS in Electrical Engineering from Northeastern University in 2001, respectively. He is currently a

Software Engineer with Openwave Systems Inc.

Waleed M. Meleis received the BSE degree in electrical engineering from Princeton University in 1990 and the MS and PhD degrees in computer science and engineering from the University of Michigan in 1992 and 1996, respectively. He is an assistant professor in the Department of

Electrical and Computer Engineering at Northeastern University. His research interests are in scheduling algorithms and bounds for modern processors and compilers.

David R. Kaeli received his B.S. in Electrical Engineering from Rutgers University, his M.S. in Computer Engineering from Syracuse University, and his PhD in Electrical Engineering from Rutgers University. He is currently an Associate Professor on the faculty

of the Department of Electrical and Computer Engineering at Northeastern University. Prior to 1993, he spent 12 years at IBM, the last 7 at IBM T.J. Watson Research in Yorktown Heights, N.Y.. In 1996 he received an NSF CAREER Award. He currently directs the Northeastern University Computer Architecture Research Laboratory (NUCAR). Dr. Kaeli's research interests include computer architecture and organization, compiler optimization, VLSI design, trace-driven simulation and workload characterization. He is a member of the IEEE and ACM. He is presently an Associate Editor for IEEE Transactions on Computer and IEEE Computer Architecture Letters.

Scattering from Objects Buried in Multilayered Random Rough Surfaces Using the Steepest Descent Fast Multipole Method

ABSTRACT

The scattering of electromagnetic waves from a penetrable shallow object buried beneath 2-D multilayered random rough surface is presented. A rigorous electromagnetic model has been developed for scattering from inhomogeneous rough ground surfaces that is based on the classical equivalence theorem and the method of moments (MoM). The model is significantly accelerated by implementing the Steepest Descent Fast Multipole Method (SDFMM). Four homogeneous regions are involved in this application; air, dielectric object, upper dry-soil layer and lower wet-soil layer. Numerical results for normalized radar cross sections (RCS) are presented for a variety of lossy and lossless multilayered ground, incident angles, thickness of upper-layer, and incident wave polarization. The results clearly demonstrate the considerable effect of both the thickness and the dielectric constant of the upper-layer relative to that of the lower-layer on the scattered waves.

I. INTRODUCTION

The electromagnetic sensing of buried objects in the presence of a random rough interface is a crucial step for subsurface detection problems in general. An observation agreed upon by most theoreticians and experimentalists is that surface roughness constitutes a major source of clutter (i.e., noise) in the received electromagnetic signals. As a result, several researchers have thoroughly investigated and published works on electromagnetic scattering from one- (1-D) or

two-dimensional (2-D) rough surfaces (i.e., x - or y -directions), e.g., [1]-[15]. These publications are for rough surface scattering without any buried objects. In addition, works on modeling electromagnetic waves from objects buried under a 1-D rough surface are published; e.g., [16]-[18]. Moreover, modeling and detecting objects buried beneath flat half-space surfaces were presented [19]-[22]. There are few published works for a single object buried beneath a 2-D random rough surface [23]-[26]. In addition, in an effort to simulate a landmine buried near a clutter object (e.g., tree root), results for sensing two penetrable objects buried beneath a 2-D random rough ground are presented in [27], [28].

However, in all work cited above, ground surface is assumed to be single layered and *not* multilayered; this is not the case in the real environment. There are few works published to model scattering from multilayered half space or multilayered rough surfaces *without* buried objects, [29]-[32]; while no work has yet been published on scattering from objects buried beneath multilayered randomly rough ground. Therefore, the objective of this work is to increase the efficacy of the present subsurface sensing methods by accounting for the multilayer nature of the rough ground. However, the computational complexity of the problem dramatically increases upon inserting penetrable objects under the multilayered rough interface. This complex scenario necessitates the use of fast computational algorithms such as the Fast Multipole Method (FMM) [33]-[35], the SDFMM [13],[36]-[38], the Sparse Matrix/Canonical Grid Method (SMCG) [23],[39] and the Spectral Algorithm combined with the Forward-Backward Method (FB/NSA) [40]. Recently, the SDFMM that has $O(N)$ computational complexity where N is the number of surface current unknowns, has been successfully implemented for a variety of subsurface sensing applications [24],[26]-[28],[32],[41]. The rigorous electromagnetic model presented in [27] for analyzing the scattering from two dielectric objects buried under the 2-D random rough ground is

used in this work. The geometry of the current application is shown in Fig. 1 where a dielectric object is buried between the air-ground rough interface and the underground rough interface with burial depth H that is less than one free space wavelength. It is important to mention that the SDFMM was originally developed for analyzing quasi-planar 3-D structures [36], which implies shallow burial depth H compared with the free space wavelength.

II. FORMULATION

The inhomogeneous geometry considered in this work is shown in Fig. 1c and is composed of four different regions; the air, the ground, the first inner scatterer and the second inner scatterer with relative permittivity and permeability as ϵ_1 and μ_1 , ϵ_2 and μ_2 , ϵ_3 and μ_3 , and ϵ_4 and μ_4 , respectively. The rigorous integral equation-based electromagnetic model derived in [27] is employed to calculate the unknown equivalent surface currents on all scatterers shown in Fig. 1. Upon simulating the incident waves as a carefully tapered Gaussian beam [23], [42], the closed scatterers can be approximated by open scatterers where the excited surface currents on the back of the scatterers S_1 and S_3 can be neglected as depicted in Fig. 1b. All scatterers shown in Fig. 1c; the air-ground rough interface, the buried object, and the underground rough interface are discretized into triangular patches [43],[44]. After some algebraic manipulations, the unknown equivalent electric and magnetic surface currents (in Fig. 1c) are \bar{J}_1 and \bar{M}_1 on the air-ground interface, \bar{J}_3 and \bar{M}_3 on the buried object and \bar{J}_5 and \bar{M}_5 on the underground interface as included in the following six integral equations (details are presented in [27]):

$$\bar{E}^{inc}(\bar{r})\big|_{\text{tang.}} = \left[(L_1 + L_2)\bar{J}_1 - (K_1 + K_2)\bar{M}_1 - L_3\bar{J}_3 + K_3\bar{M}_3 - L_4\bar{J}_5 + K_4\bar{M}_5 \right]_{\text{tang.}} \quad (1a)$$

$$\bar{H}^{inc}(\bar{r})\big|_{\text{tang.}} = \left[(K_1 + K_2)\bar{J}_1 + \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{M}_1 - K_3\bar{J}_3 - \frac{L_3}{\eta_2^2} \bar{M}_3 - K_4\bar{J}_5 - \frac{L_4}{\eta_2^2} \bar{M}_5 \right]_{\text{tang.}} \quad (1b)$$

$$0 = [-L_2 \bar{J}_1 + K_2 \bar{M}_1 + (L_3 + L_5) \bar{J}_3 - (K_3 + K_5) \bar{M}_3 + L_4 \bar{J}_5 - K_4 \bar{M}_5]_{\text{tang.}} \quad (1c)$$

$$0 = \left[-K_2 \bar{J}_1 - \frac{L_2}{\eta_2^2} \bar{M}_1 + (K_3 + K_5) \bar{J}_3 + \left(\frac{L_3}{\eta_2^2} + \frac{L_5}{\eta_3^2} \right) \bar{M}_3 + K_4 \bar{J}_5 + \frac{L_4}{\eta_2^2} \bar{M}_5 \right]_{\text{tang.}} \quad (1d)$$

$$0 = [-L_2 \bar{J}_1 + K_2 \bar{M}_1 + L_3 \bar{J}_3 - K_3 \bar{M}_3 + (L_4 + L_6) \bar{J}_5 - (K_4 + K_6) \bar{M}_5]_{\text{tang.}} \quad (1e)$$

$$0 = \left[-K_2 \bar{J}_1 + \frac{L_2}{\eta_2^2} \bar{M}_1 + K_3 \bar{J}_3 + \frac{L_3}{\eta_2^2} \bar{M}_3 + (K_4 + K_6) \bar{J}_5 + \left(\frac{L_4}{\eta_2^2} + \frac{L_6}{\eta_4^2} \right) \bar{M}_5 \right]_{\text{tang.}} \quad (1f)$$

where the intrinsic impedance is $\eta_i = \sqrt{\mu_i / \epsilon_i}$, with $i=1, 2, \dots, 4$ and L_j and K_j , $j=1, 2, \dots, 6$ are the integro-differential operators derived in [27]. The unknown electric and magnetic surface currents in (1) are approximated using the vector basis functions $\bar{j}(\bar{r})$ [43],[44] as:

$$\bar{J}_i(\bar{r}) = \sum_{n=1}^{N_k} I_{in} \bar{j}_{kn}(\bar{r}), \quad \bar{M}_i(\bar{r}) = \eta_1 \sum_{n=1}^{N_k} I_{(i+1)n} \bar{j}_{kn}(\bar{r}), \quad \bar{r} \in S_k, \quad \text{for } i=1, 3 \text{ and } 5 \quad (2)$$

in which $k=1, 2$ and 3 for $i=1, 3$ and 5 , respectively. Substituting (2) in (1), the linear system of equations is obtained [27]

$$\bar{\bar{Z}} \bar{I} = \bar{V} \quad (3a)$$

The total impedance matrix $\bar{\bar{Z}}$ has order of $2(N_1 + N_2 + N_3) \times 2(N_1 + N_2 + N_3)$, where the number of current unknowns on the air/ground interface, the buried object and the underground interface are $2N_1$, $2N_2$ and $2N_3$, respectively. The vector \bar{V} represents the tested tangential incident electric field \bar{E}^{inc} and the normalized magnetic field $\eta_1 \bar{H}^{inc}$ on the air/ground interface.

The matrix $\bar{\bar{Z}}$ is given by

$$\bar{\bar{Z}} = \begin{bmatrix} Z_{11} & Z_{12} & Z_{13} \\ Z_{21} & Z_{22} & Z_{23} \\ Z_{31} & Z_{32} & Z_{33} \end{bmatrix} \quad (3b)$$

in which the submatrices Z_{11} , Z_{22} , and Z_{33} represent the self interactions on the air-ground interface, the buried object and the underground interface, respectively. On the other hand, the submatrices Z_{12} (and Z_{21}) and Z_{13} (and Z_{31}) represent the interactions between the air-ground interface with the buried object and with the underground interface, respectively. The submatrices Z_{32} (and Z_{23}) represent the interactions between the underground interface and the buried object. The SDFMM is implemented to dramatically accelerate solving for the unknown surface current coefficients \bar{I} in (3a) [27].

III. NUMERICAL RESULTS

As discussed in Section II and pictorially described in Fig. 1, the tapered Gaussian beam is used to illuminate the multilayered ground surface [23], [42]. The rough surfaces are characterized with Gaussian statistics for the height and for the autocorrelation function [45]. In this section, the transpose-free quasi-minimal iterative solver (TFQMR) is used to solve (3a) with a tolerance range of 10^{-3} - 10^{-5} [46]. In all the examples presented here, only one rough surface realization is considered.

For the multilayered rough ground with buried object shown in Fig. 1c, it is necessary to validate the SDFMM implemented for this application versus the MoM. The percentage of the relative norm of the error in surface currents is plotted in Fig. 2 where the vector C represents the electric and magnetic currents on surfaces S_1 , S_2 and S_3 shown in Fig. 1b. In Fig. 2a, the norm of the error and the computer memory requirements are plotted versus the SDFMM's finest block size depicted in Fig. 1c. The scale on the left is for the relative error, and on the right is for the computer memory. In this work; flat/flat implies that both the air-ground and the underground interfaces are flat while flat/rough implies the air-ground interface is flat and the underground one is rough, etc. The multilayered ground in this small-scale example consists of a flat/flat with a buried oblate

spheroid. The two flat surfaces have dimensions of $2.96\lambda_0 \times 2.96\lambda_0$, the underground interface is buried at $z = -0.5\lambda_0$ (i.e., $H = 0.5\lambda_0$ in Fig. 1c), and the oblate spheroid's dimensions are $a = 0.3\lambda_0$ and $b = 0.15\lambda_0$ with burial depth measured from its center equal to $z = -0.25\lambda_0$. The total number of the electric and magnetic surface currents unknowns is 16,732 ($2N_1 = 2N_3 = 8066$ and $2N_2 = 600$). The incident angles of the Gaussian beam are $\theta^i = 0$ and $\phi^i = 0$. The relative dielectric constants of the upper layer of the ground, the buried object and the lower layer are $\epsilon_{r2} = 2.5 - j0.18$, $\epsilon_{r3} = 2.9 - j0.0092$ and $\epsilon_{r4} = 6.5 - j0.1$, respectively. The results show the monotonic decrease in the error with increasing the FMM's finest block size. On the other hand, a rapid increase in the computer memory requirements, due to the multilayered nature of the scatterer, is clearly observed in Fig. 2a. In Fig. 2b, the relative norm of the error in $\|C\|$ is plotted versus the height H of the upper layer (see Fig. 1c). The results show the trend of increasing the error with increasing H since the SDFMM is more efficient for quasi-planar structures. For non-quasi-planar structures, the SDFMM multiple interaction model can be used instead of the complete SDFMM model implemented in the current work [47]. In this section, the SDFMM's finest block has dimensions of $0.32\lambda_0 \times 0.32\lambda_0$.

In the second example, the dimensions of the multilayered ground are increased to be $6.48\lambda_0 \times 6.48\lambda_0$ with the same buried spheroid as before. The total number of the electric and magnetic surface current unknowns is 78,684 ($2N_1 = 2N_3 = 39042$ and $2N_2 = 600$). The object is buried at $z = -0.3\lambda_0$ while the underground layer is buried at $z = -0.6\lambda_0$. Both the air-ground and the underground interfaces are random rough surfaces with rms height and correlation length equal to $\sigma_1 = 0.04\lambda_0, l_{c1} = 0.5\lambda_0$ and $\sigma_2 = 0.03\lambda_0, l_{c2} = 0.4\lambda_0$, respectively. The normalized

RCS is defined in this work by $4\pi r^2 |\bar{E}^s|^2 / (2\eta_0 P^i A_z)$, where A_z is the footprint area and P^i is the incident power [31]. All RCS results in this work are presented as RCS/λ_0^2 where λ_0 is the free space wavelength in meters.

In Fig. 3a the three regions are assumed to be lossless with no buried objects with $\epsilon_{r2} = 6.5$ and $\epsilon_{r4} = 2.5$ for Case 1 while $\epsilon_{r2} = 2.5$ and $\epsilon_{r4} = 6.5$ for Case 2. On the other hand, in Fig. 3b there is a spheroid buried at $z = -0.3\lambda_0$ and the three regions are assumed to be lossy with $\epsilon_{r2} = 6.5 - j0.1$ and $\epsilon_{r4} = 2.5 - j0.18$ for Case 1 and $\epsilon_{r2} = 2.5 - j0.18$, and $\epsilon_{r4} = 6.5 - j0.1$ for Case 2. It is assumed that $\epsilon_{r3} = 2.9$ and $\epsilon_{r3} = 2.9 - j0.0092$ for lossless and lossy cases, respectively. In Fig. 3c, the data of Fig. 3b is used but with no spheroid buried in the ground. The results in Figs. 3a-c are for normal incidence while in Fig. 3d they are for $\vartheta^i = 10^\circ$. The results of Fig. 3a show larger magnitudes for the lossless case than those for the lossy cases of Figs. 3b-d. Moreover, in Figs. 3a-c, the results show larger magnitudes for the flat/flat Case 2 than for the flat/flat Case 1. This implies that when $\epsilon_{r4} > \epsilon_{r2}$, the lower interface dominates the scattering mechanism at $H = -0.6\lambda_0$. Similar observation is shown for the lossless case when both interfaces are rough surfaces, however, for the lossy cases in Figs 3b and 3c, slightly larger magnitudes are observed for Case 1 than for Case 2. Moreover, a slight difference is observed between the results of Fig. 3b (no buried spheroid) and 3c (with buried spheroid) due to the small size of the object which agrees with previous work where a single or multiple objects were buried in a single layered ground [24],[26],[27].

The results in Fig. 4 are for a lossless rough/rough multilayered ground with the same buried spheroid, polarization and incident angle as in Case 1 in Fig. 3. In Fig. 4a, the norms $\|C\|$ of the currents on the spheroid surface, the air-ground and the underground interfaces relative to the

norm of all currents $\|C_{\text{total}}\|$ are plotted versus the height H . These quantitative results show that the currents on the underground interface are the largest in this example. Moreover, the currents on the spheroid are changing slightly with increasing height H while the currents on both the air-ground and the underground interfaces show a trend to change only at $H = 0.65\lambda_0$. Even though the results of Fig. 3a showed larger magnitudes for the rough/rough Case 2 than the rough/rough Case 1 when $H = 0.6\lambda_0$, however, the results of Fig. 4b suggest that this observation could be changing with increasing H . The results in this example are for the HH-polarization in the backscatter direction.

In Fig. 5, the ground is assumed to be a lossless rough/rough multilayer with $\epsilon_{r2} = 6.5$, $\epsilon_{r3} = 2.9$ and ϵ_{r4} is real. The relative norm of the electric and magnetic currents $\|C\|/\|C_{\text{total}}\|$ are plotted versus the dielectric constant of the underground layer ϵ_{r4} . The results show that the currents on the spheroid are smaller than those on the upper- and underground interfaces. The currents on the underground interface are decreasing while the currents on the air-ground interface are increasing with increasing ϵ_{r4} as shown in Fig. 5a. Interestingly, when $\epsilon_{r4} = \epsilon_{r2} = 6.5$, i.e., homogeneous ground, the underground surface currents become almost the same as those on the underground interface, which could be due to the lossless nature of the ground and due to the relatively small height ($H = 0.6\lambda_0$). On the other hand, for the lossy case (as will be shown in Fig. 7a), the currents on the underground interface are clearly smaller than those on the air-ground one. In Fig. 5b, the normalized HH-RCS is increasing with ϵ_{r4} where the results are for the backscatter direction at $\vartheta^i = 0$. These results show that for $\epsilon_{r4} < \epsilon_{r2}$ the wave transmission into the lower layer is larger than the waves transmission when $\epsilon_{r4} > \epsilon_{r2}$. This mechanism could explain the observation that the equivalent currents on the underground

interface are larger than those on the air-ground one when $\epsilon_{r4} < \epsilon_{r2}$ and vice-versa when $\epsilon_{r4} > \epsilon_{r2}$ as shown in Fig. 5a.

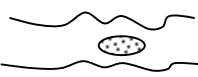

Similar investigations for the lossless case are conducted but versus the dielectric constant of the upper layer as shown in Fig. 6a, where $\|C\|/\|C_{\text{total}}\|$ is plotted versus ϵ_{r2} with $\epsilon_{r3} = 2.9$ and $\epsilon_{r4} = 6.5$. The results quantitatively show, that as ϵ_{r2} increases the currents on the spheroid decreases. In this case, fewer waves are transmitted into the ground causing less excitation to the object. Consistent with the observation of Fig. 5a, the results in Fig. 6a show that when $\epsilon_{r2} < \epsilon_{r4}$, the equivalent currents on the underground interface are smaller than those on the air-ground one and vice versa when $\epsilon_{r2} > \epsilon_{r4}$. Interestingly, the normalized HH-RCS shows initial decrease followed by monotonic increase with increasing ϵ_{r2} as shown in Fig. 6b (the results are in the backscatter at $\vartheta^i = 0$). These results show that the RCS has minimum value when $\epsilon_{r2} \approx 4.2$ which could be due to a destructive multiple interaction mechanism between the air-ground and the underground interfaces.

In Fig. 7, the rough/rough ground is assumed to be lossy with $\epsilon_{r2} = 2.5 - j0.18$, $\epsilon_{r3} = 2.9 - j0.0092$, $\epsilon_{r4} = 6.5 - j0.1$, and the incident waves are assumed to be vertically-polarized. The relative norms $\|C\|/\|C_{\text{total}}\|$ are plotted versus incident angle θ^i where all results are in the backscatter direction ($\theta^i = \theta^s, \phi^i - \phi^s = \pi$). The results in Fig. 7a show that the currents on the spheroid are smaller than those on the air-ground and underground interfaces. Moreover, the currents on the underground interface reflect the lossy nature of the ground in this example compared with the lossless case results in Fig. 6a. In Fig. 7b and 7c, the normalized RCS for the VV- and the HV- polarization are plotted versus the incident angle θ^i , respectively. These results are compared with those of the single layer rough ground and the same buried

spheroid, i.e., $\epsilon_{r2} = \epsilon_{r4} = 2.5 - j0.18$ and $\epsilon_{r3} = 2.9 - j0.0092$. The results in Fig. 7b show the impact of the underground interface on the VV-RCS especially at small elevation angles. However, due to the small ground roughness considered in this work of both the air-ground and the underground interfaces, the HV-RCS is much smaller than the VV- case as shown in Fig. 7b. But the waves scattered from the multilayered rough ground show more depolarization than those scattered from a single layer rough ground as demonstrated in Fig.7c. Similar results are obtained for the HH- and the VH- cases.

The results in Table 1 summarize the computational complexity of three subsurface sensing applications using the SDFMM [24], [27]. These results show the rising computational complexity for the multilayered ground.

Table 1 CPU time and computer memory requirements comparison

Description	Geometry	# Unknowns	CPU time (Hrs)	Memory (MB)
Single object buried beneath single layer rough ground [24].		60,200	2.0	840
Two objects buried beneath single layered rough ground [27].		60,800	3.6	856
Single object buried in multi layered rough ground (current work).		78,684	6.6	1760

IV. CONCLUSIONS

A 3-D analysis of the multilayered rough ground with a buried dielectric object is investigated using a rigorous electromagnetic model significantly accelerated by using the SDFMM. The results show the considerable impact of the multilayered nature of the ground on the scattering process compared with the single layer ground. In both cases, the buried object is clearly the weakest scatterer due to its small size compared with the wavelength. The thickness

and the dielectric constant of the upper-layer of the ground relative to the ground lower-layer significantly contribute to the scattering mechanism in the current application.

Electromagnetic sensing of buried objects in the presence of a random rough interface is a crucial step for subsurface detection problems in general. Most theoreticians and experimentalists agreed that surface roughness constitutes a major source of clutter (i.e., noise) in the received electromagnetic signals. However, due to the complexity of the problem, the ground surface is often assumed to be single layered and *not* multi-layered. This is not the case in the real environment but no work has yet been published on scattering from objects buried beneath multi-layered randomly rough ground. Therefore, the objective of this work is to investigate the scattering of electromagnetic waves from a penetrable shallow object buried in 2-D multi-layered random rough surfaces. It is known that the computational complexity of the scattering problem dramatically increases for the multi-layered rough interface.

A rigorous electromagnetic model has been developed for scattering from inhomogeneous rough ground surfaces. This model is based on the classical equivalence theorem and the method of moments (MoM) that is dramatically accelerated by implementing the Steepest Descent Fast Multipole Method (SDFMM). Four different homogeneous regions are involved in this application; air, dielectric object, upper soil layer and lower soil layer. A tapered Gaussian beam is used to illuminate the multi-layered ground surface. The rough surfaces are characterized with Gaussian statistics for the height and for the autocorrelation function. Since the SDFMM was originally developed for quasi-planar structures where the whole height of the 3-D scatterer should be in the order of one free space wavelength, it is necessary to validate the SDFMM implemented for this application versus the MoM. The relative norm of the error in surface current is presented. The computer memory requirement is plotted versus the SDFMM finest block size for the multi-layered ground with the buried object. It is necessary to mention that the air-ground interface and the underground layer could be flat and/or could be random rough surfaces with different roughness parameters and lossy or lossless soil. Numerical results representing the RCS of the multi-layered ground with the buried object are shown. The effect of the physical characteristics and the surface roughness of the multi-layers are investigated. The thickness of the multi-layer ground is varied to study its influence on the buried object signature.

The results of this work could increase the efficacy of the present subsurface sensing methods by accounting for the multi-layer nature of the rough ground.

Scattering from Non-Shallow Targets Buried Beneath Two-Dimensional Random Rough Surfaces Using the Multiple Interaction Model

magda@uark.edu

The multiple interaction approach is used with the robust Steepest Descent Fast Multipole Method (SDFMM) to compute the signature of non-shallow penetrable scatterers buried beneath 2-D random rough surfaces. The most attractive feature of the proposed model is removing the quasi-planar structure constraint of the Steepest Descent Fast Multipole Method (SDFMM) when used in analyzing non-quasi-planar scatterers. The basic idea of the multiple interaction model is to decompose certain non-quasi-planar structures into two quasi-planar scatterers where the conventional SDFMM can be applied separately to each one. The interactions between the sub-quasi-planar scatterers are calculated directly using the electromagnetic vector potentials near-field expressions. Significant reductions in the CPU time and computer memory are achieved by using the SDFMM in the model. A variety of geometries are used to test the model and their numerical results are validated with the conventional MoM.

The results show that the buried object's signature is largely due to the first interaction mechanism (i.e. ground-object-ground). However, the contribution of each additional interaction is explicitly calculated using the model. Interestingly, the contributions from repeating this mechanism become insignificant especially for lossy background soil. This conclusion depends on the physical properties of the scatterer.

The multiple interaction model successfully demonstrates the exploitation of the SDFMM robustness when applied to the multilayered rough ground where the burial depth of the underground rough layer is on the order of a wavelength.

The scattering of electromagnetic waves from a penetrable shallow target buried beneath 2-D multilayered random rough surfaces will be presented. There are several applications for this work, e.g. detection of anti-personnel mines, anti-tank mines, water and/or gas pipes, location of underground water, etc. In reality, these targets are buried under the Earth's surface, which is a randomly rough interface and also is not simply composed of a single layer, but is a multilayered media. The closer the real environment is incorporated into the electromagnetic model, the more accurate and practical inferences can be gained from the numerical results. Without modeling the multiple ground layers, many targets *cannot be detected*. One unobtrusive way these buried targets can be detected is by bombarding the Earth's surface with electromagnetic waves, and comparing the scattered signature of the ground alone with that of the ground with the buried target.

A rigorous electromagnetic model based on the equivalence theorem and the method of moments (MoM) is developed to analyze this 3-D scattering problem. Three layers are considered in this work; air, dry-soil and wet-soil. The penetrable target is buried between the air/dry-soil interface and the dry/wet-soil interface. The Steepest Descent Fast Multipole Method (SDFMM) is implemented to significantly accelerate the computations of the unknown electric and magnetic surface currents. The effect of the lossy underground rough layer (wet soil) on the target signature will be investigated. Moreover, images based on the scattered electric fields for the buried target will be presented.

A rigorous electromagnetic model has been developed to analyze the scattering mechanism of a target buried near a clutter-object under the two-dimensional random rough ground (3-D scattering problem). In realistic landmine fields, the anti-personnel (AP) nonmetallic mine is often buried nearby a rock, tree root, etc. The presence of a second object buried near the nonmetallic mine can easily obscure the target and/or cause a false alarm during the detection process.

The rigorous model is based on the classical electromagnetic equivalence theorem leading to producing six new integral equations. Using the Method of Moment (MoM), the new integral equations are transformed into a linear system of equations to be solved for the unknown electric and magnetic currents on the surface of three scatterers; rough ground, target and clutter-object. The MoM impedance matrix completely represents every interaction between these three scatterers. The Steepest Descent Fast Multipole Method (SDFMM) is used to tremendously accelerate the computations of the unknown MoM surface currents.

In previous work, we thoroughly investigated the effect of ground roughness on the signature of the target when it is buried alone under the ground. In this work, we will present numerical results for parametric investigations of the objects proximity, orientations, materials, and shapes. The results show that in certain situations, the target can be completely obscured due to the presence of the nearby clutter-object (e.g., tree root). In other cases a false indication of presence of a third buried object is observed. When the sources of clutter (e.g. the rough ground and the clutter object) are removed, by subtracting the return from both the rough ground and the clutter-object, the signature of the target can be clearly observed and analyzed. The numerical results show that the ground roughness along with the separation distance, between the target and the clutter-object, play a significant role on the probability of true or false alarm in the detection process.

ABSTRACT

The modified Mueller matrix elements for electromagnetic scattering from penetrable objects buried under 2-D random rough surfaces are investigated. This matrix relates the incident with the scattered waves and it contains different combinations of the fully polarimetric scattering matrix elements. The statistical average of each Mueller matrix element is computed based on the Monte Carlo simulations with exploiting the speed of the 3-D Steepest Descent Fast Multipole Method (SDFMM). The numerical results clearly show that relying only on the co- and/or the cross-polarized intensities (i.e., vv , hh , vh and hv) is not sufficient for sensing the buried objects. However, examining all the sixteen Mueller matrix elements significantly increases the possibility of detecting these objects. This technique can be used in remote sensing of scatterers buried beneath the rough ground.

Keywords: Subsurface sensing, Mueller matrix elements, multiple buried objects, rough surface scattering, radar cross section.

I. INTRODUCTION

Remote sensing of objects buried under the rough ground has tremendous civil and defense applications, e.g. archeology discovery, mine detection, sensing underground resources, etc. In previous work [1]-[3], the scattered electric near-field was calculated to simulate the ground

penetrating radar (GPR) measurements. A single penetrable and/or perfect electric conductor (PEC) object was buried under the rough ground, where the average of the scattered electric near-fields over the azimuth angle was presented in [1] while the average over the rough surface realizations was presented in [2]. In [3], two dielectric objects were buried under the random rough ground and the electromagnetic near-field interference between the objects was studied. The reported results showed the significant distortion in the near-field signals caused by the presence of the rough air-ground interface. In [1]-[3], the signature of the target was often obtained by removing the background from the received signals (i.e. by subtracting the scattering from the rough ground with no buried objects). In [4], the angular correlation function (ACF) and the radar cross section (RCS) were presented for a PEC sphere buried under the rough ground in which the authors presented the advantage of computing the ACF over the RCS. In [5], the sixteen Mueller matrix elements were analytically obtained for scattering from coated 2-D random rough surface where the configuration represented three-layer geometry (the air and two layered-rough interfaces) with no buried objects. The Mueller matrix elements, which relate the incident with the scattered waves, are defined in terms of the modified Stokes vector [6]-[8]. The results reported in [5] showed a great sensitivity of some Mueller matrix elements (m_{34} and m_{43}) in the backscatter direction to the thickness of the coated layer. In other words, these two elements showed considerable differences due to the underground inhomogeneity, which was not the case for the other Mueller matrix elements (m_{11} , m_{12} , m_{22} , etc.). This finding is the motivation of the current work, however, the configuration here represents two different dielectric objects buried under the 2-D random rough ground as shown in Fig. 1.

It is necessary to differentiate between the results reported in [2] and the current work. In [2], the statistical average of the buried object's signature was computed based on the scattered

electric fields in the near-zone. In the current work, the statistical average of the scattered electric fields from one and/or from two buried objects is calculated in the far-zone and presented in terms of the Mueller matrix elements. More importantly, the subtraction process often used in [1]-[3] is not used in the current work. In other words, the far-fields scattered from the rough ground with the buried objects are directly compared with those scattered from the rough ground with no buried objects.

The formulations of the problem are given in Section II, the numerical results are presented in Section III and the conclusions are stated in Section IV. More details are given in Appendices A and B.

II. FORMULATIONS

The integral equation-based rigorous electromagnetic model was developed in [3] for scattering from multiple objects buried under the rough ground. This technique is employed to calculate the unknown method of moments (MoM) surface currents on the rough ground and on both buried objects (see Fig. 1). The inhomogeneous scatterer is composed of four different regions; the air, the ground, and two different materials for the objects where the relative permittivity and permeability are ϵ_1 and μ_1 for the air, ϵ_2 and μ_2 for the ground, ϵ_3 and μ_3 for the first object, and ϵ_4 and μ_4 for the second object. The unknown equivalent electric and magnetic surface currents are \bar{J}_1 and \bar{M}_1 on the ground, \bar{J}_2 and \bar{M}_2 on the first object and \bar{J}_3 and \bar{M}_3 on the second object. The final set of surface integral equations on the ground (S_1), the first object (S_2) and the second object (S_3) are given by [1], [3],[9]:

$$\bar{E}^{inc}(\bar{r})\Big|_{\text{tang.}} = \left[(L_1 + L_2)\bar{J}_1 - (K_1 + K_2)\bar{M}_1 - L_3\bar{J}_2 + K_3\bar{M}_2 - L_4\bar{J}_3 + K_4\bar{M}_3 \right]_{\text{tang.}}, \bar{r} \in S_1 \quad (1a)$$

$$\bar{H}^{inc}(\bar{r})|_{\text{tang.}} = \left[(K_1 + K_2)\bar{J}_1 + \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{M}_1 - K_3\bar{J}_2 - \frac{L_3}{\eta_2^2} \bar{M}_2 - K_4\bar{J}_3 - \frac{L_4}{\eta_2^2} \bar{M}_3 \right]_{\text{tang.}}, \bar{r} \in S_1 \quad (1b)$$

$$0 = [-L_2\bar{J}_1 + K_2\bar{M}_1 + (L_3 + L_5)\bar{J}_2 - (K_3 + K_5)\bar{M}_2 + L_4\bar{J}_3 - K_4\bar{M}_3]_{\text{tang.}}, \bar{r} \in S_2 \quad (1c)$$

$$0 = \left[-K_2\bar{J}_1 - \frac{L_2}{\eta_2^2} \bar{M}_1 + (K_3 + K_5)\bar{J}_2 + \left(\frac{L_3}{\eta_2^2} + \frac{L_5}{\eta_3^2} \right) \bar{M}_2 + K_4\bar{J}_3 + \frac{L_4}{\eta_2^2} \bar{M}_3 \right]_{\text{tang.}}, \bar{r} \in S_2 \quad (1d)$$

$$0 = [-L_2\bar{J}_1 + K_2\bar{M}_1 + L_3\bar{J}_2 - K_3\bar{M}_2 + (L_4 + L_6)\bar{J}_3 - (K_4 + K_6)\bar{M}_3]_{\text{tang.}}, \bar{r} \in S_3 \quad (1e)$$

$$0 = \left[-K_2\bar{J}_1 + \frac{L_2}{\eta_2^2} \bar{M}_1 + K_3\bar{J}_2 + \frac{L_3}{\eta_2^2} \bar{M}_2 + (K_4 + K_6)\bar{J}_3 + \left(\frac{L_4}{\eta_2^2} + \frac{L_6}{\eta_4^2} \right) \bar{M}_3 \right]_{\text{tang.}}, \bar{r} \in S_3 \quad (1f)$$

in which the intrinsic impedance is $\eta_i = \sqrt{\mu_i / \epsilon_i}$, with $i = 1, 2, \dots, 4$ and L_j and K_j , $j = 1, 2, \dots, 6$ are the integro-differential operators as summarized in Appendix A [1], [3], [9]. The surfaces of the rough ground and the two objects are discretized into triangular patches where the unknown equivalent electric and magnetic currents in (1) are approximated using the Rao, Wilton and Glisson (RWG) vector basis functions $\bar{j}(\bar{r})$ [9], [10] as:

$$\bar{J}_k(\bar{r}) = \sum_{n=1}^{N_k} I_n^{(k)} \bar{j}_n^{(k)}(\bar{r}), \quad \bar{M}_k(\bar{r}) = \eta_1 \sum_{n=1}^{N_k} I_{(n+N_k)}^{(k)} \bar{j}_n^{(k)}(\bar{r}), \quad \bar{r} \in S_k, \text{ for } k = 1, 2, 3 \quad (2)$$

After some algebraic manipulations, the linear system of equations is obtained as $\bar{\bar{Z}} \bar{I} = \bar{V}$ (as summarized in Appendix B) where the total impedance matrix $\bar{\bar{Z}}$ has order $2(N_1 + N_2 + N_3) \times 2(N_1 + N_2 + N_3)$. The number of surface unknowns on the ground, the first object and the second object are $2N_1$, $2N_2$ and $2N_3$, respectively. The vector \bar{V} represents the tested tangential incident electric field \bar{E}^{inc} and normalized magnetic field $\eta_1 \bar{H}^{inc}$ on the exterior surface of the ground. The SDFMM [11] was implemented in [1]-[3] to dramatically

accelerate solving for the unknown surface current coefficients \bar{I} . Once the unknown surface currents are obtained, the scattered electric fields in the far-zone can be computed [12].

For the modified Mueller matrix elements [5]-[8], we are following the notations used in [7] where the normalized modified Stokes vector is given by

$$I = \begin{bmatrix} |E_v|^2 \\ |E_h|^2 \\ 2\text{Re}(E_v E_h^*) \\ 2\text{Im}(E_v E_h^*) \end{bmatrix} / \eta_1 \quad (3a)$$

in which v and h represent the vertical and horizontal polarizations, respectively, thus from [7]

$$I^s = \frac{1}{r^2} M_m I^i \quad (3b)$$

where, the superscripts s and i represent the scattered and incident waves, respectively. The modified Mueller matrix M_m is given by [7]

$$M_m = \begin{bmatrix} |S_{vv}|^2 & |S_{vh}|^2 & \text{Re}(S_{vh}^* S_{vv}) & -\text{Im}(S_{vh}^* S_{vv}) \\ |S_{hv}|^2 & |S_{hh}|^2 & \text{Re}(S_{hv}^* S_{hh}) & -\text{Im}(S_{hv}^* S_{hh}) \\ 2\text{Re}(S_{vv} S_{hv}^*) & 2\text{Re}(S_{vh} S_{hh}^*) & \text{Re}(S_{vv} S_{hh}^* + S_{vh} S_{hv}^*) & -\text{Im}(S_{vv} S_{hh}^* - S_{vh} S_{hv}^*) \\ 2\text{Im}(S_{vv} S_{hv}^*) & 2\text{Im}(S_{vh} S_{hh}^*) & \text{Im}(S_{vv} S_{hh}^* + S_{vh} S_{hv}^*) & \text{Re}(S_{vv} S_{hh}^* - S_{vh} S_{hv}^*) \end{bmatrix} \quad (3c)$$

where S_{pq} is the p -polarized scattered waves due to the q -polarized incident waves ($p, q = v, h$) as described in the fully polarimetric scattering matrix S [7]

$$\begin{bmatrix} E_v^s \\ E_h^s \end{bmatrix} = \frac{e^{jkr}}{r} \begin{bmatrix} S_{vv} & S_{vh} \\ S_{hv} & S_{hh} \end{bmatrix} \begin{bmatrix} E_v^i \\ E_h^i \end{bmatrix} \quad (3d)$$

where $E_{v,h}^i$ and $E_{v,h}^s$ are the vertically and horizontally polarized incident and scattered electric fields in the far-zone, respectively.

III. NUMERICAL RESULTS AND DISCUSSIONS

The random rough surface characterized with Gaussian statistics for simulating the ground is generated 100 times for the configuration shown in Fig. 1. The linear system of equations is solved for each random surface realization for both the vertically- and the horizontally-polarized incident waves. Each set of the Monte Carlo simulations to obtain the average scattered intensity is based on the 100 independent realizations. The sixteen modified Mueller matrix elements in (3c) are calculated for the total scattered waves (i.e. not for the incoherent scattered waves). Using the standard matrix notations in (3c), these elements are $m_{11} = \langle |S_{vv}|^2 \rangle$, $m_{22} = \langle |S_{hh}|^2 \rangle$, $m_{14} = -\text{Im}(\langle S_{vh}^* S_{vv} \rangle)$, etc., where the angular brackets denote the ensemble average. All Mueller matrix elements presented here are normalized by the factor $4\pi/(2\eta_o A_z P^i)$, where A_z , η_o , and P^i are the footprint area on the ground, the intrinsic impedance of the free space and the total incident power. With this normalization, the element m_{11} becomes the normalized vertically co-polarized RCS (vv), the element m_{22} becomes the normalized horizontally co-polarized RCS (hh), the element m_{12} becomes the normalized cross-polarized RCS (vh), and the element m_{21} is the normalized cross-polarized RCS (hv). For the incident tapered Gaussian beam used in this work [5],[13] the total incident power is the sum of the power in each plane wave [14]. Similar to the previous work [1]-[3], the dimensions of the ground are assumed to be $8\lambda_0 \times 8\lambda_0$ with Gaussian half-beam width equal to $1.6\lambda_0$ centered on the ground at $4\lambda_0 \times 4\lambda_0$, where λ_0 is the free space wavelength.

In this work, the first object is modeled as an oblate spheroid ($a = 0.15\lambda_0, b = 0.3\lambda_0$) and the second object is modeled as a circular cylinder ($a = 0.15\lambda_0, h = 0.9\lambda_0$) or a circular disk ($a = 0.3\lambda_0, h = 0.1\lambda_0$) as shown in Figs. 1c-e. The locations of these objects vary in each

example. The rms height and the correlation length of the rough ground are assumed to be $\sigma = 0.1\lambda_0$ and $l_c = 0.5\lambda_0$, respectively. The relative dielectric constants of the ground, the cylinder, the spheroid, and the disk are assumed as $\epsilon_r = 2.5 - j0.18$, $\epsilon_r = 4.0$, $\epsilon_r = 2.9 - j0.072$ and $\epsilon_r = 4.0$, respectively. The total number of surface current unknowns is 61200 for the geometry shown in Fig. 1, where $2N_1 = 60000$ (on the ground surface), $2N_2 = 600$ (on the first object) and $2N_3 = 600$ (on the second object) [3]. These numbers of unknowns are the result of discretizing the ground surface into 10101 nodes and 20000 triangular patches, and discretizing each object into 102 nodes and 200 triangular patches and they are kept the same for all the cases discussed in this Section.

In Example 1, a spheroid and a horizontal cylinder are buried under the ground. The spheroid's center is located at $x = 4.5\lambda_0$, $y = 3.5\lambda_0$ and $z = -0.4\lambda_0$ while the horizontal cylinder is tilted by 30° with the x -axis and is located at $x = 4.01\lambda_0$, $y = 4.375\lambda_0$ and $z = -0.4\lambda_0$ measured from the axis mid-point (see Fig. 1c). For $\theta^i = 0^\circ$, $\phi^i = 0^\circ$, the ensemble average for each modified Mueller matrix element is plotted versus the scatter angle as presented in Fig. 2. As expected, the results show that all the diagonal elements of the Mueller matrix have maximum values approximately in the specular direction ($\theta^i = 0^\circ$). Interestingly, the elements m_{14} , m_{24} , m_{41} and m_{42} show distinguished signature for the rough ground with the two buried objects different from the rough ground alone (i.e. with no buried objects). Moreover, the elements m_{12} , m_{21} , m_{32} , m_{13} , m_{34} and m_{43} show slight differences between these two cases. However, the diagonal elements m_{11} , m_{22} , m_{33} , and m_{44} show almost no differences between the two cases.

It is important to investigate whether the significant differences shown in Fig. 2 are due to the interference between the objects or due to other causes. Therefore, additional results for the cylinder and the spheroid, each is buried alone under the same rough ground, are presented in Figs. 3 and 4, respectively. Each object is buried in its original location under the random rough ground as discussed in the data of Fig. 2. The results in Fig. 3 show the same observation of Fig. 2, i.e., the elements m_{14} , m_{24} , m_{41} , and m_{42} clearly show an indication to the presence of the cylinder under the ground while the elements m_{11} and m_{22} show no such indication.

The results in Fig. 4, for the buried spheroid alone, show that only elements m_{42} and m_{14} indicate to the presence of the spheroid. In other words, the results in Figs. 3 and 4 clearly show the significant sensitivity of some of the Mueller matrix elements to the presence of buried objects. The sensitivity level of these elements clearly depends on the object's orientation, material and size as presented in Figs. 2-4. It is interesting to notice that the expressions of m_{14} , m_{24} , m_{41} , and m_{42} as given in (3c) are the imaginary parts of the product of the co- and cross-polarized scattering elements. This implies that these elements contain some phase information, which is not the case for the other elements, e.g., m_{11} and m_{22} . The results in Figs. 2-4 clearly indicate that if one relies only on the co- and/or the cross-polarized intensities (i.e., m_{11} , m_{22} , m_{12} and m_{21}); it might not be possible to detect the buried objects. However, investigating all the sixteen Mueller matrix elements significantly increases the possibility of detecting these objects.

In Example 2, the cylinder's orientation effect is investigated with keeping the rest of the data of Fig. 2. Therefore, the cylinder is tilted with the x -axis by 90° and is buried alone under the rough interface. The axis's mid-point is located at $x = 3.6\lambda_0$, $y = 4.0\lambda_0$ and $z = -0.4\lambda_0$ (see Fig. 1d). As shown in Fig. 5, almost twelve elements out of the sixteen ones, show considerable differences due to the presence of the cylinder. Comparing the results of Fig. 3 and Fig. 5, where

the same size and material of the horizontal cylinder are used, shows that the cylinder's orientation plays an effective role in the sensitivity level of these elements. The depolarization level of the scattered waves from the rough ground with the buried cylinder vary with the orientation of the cylinder leading to observed variation in some of the Mueller matrix elements.

In Example 3, the cylinder is replaced with a circular disk tilted with the z -axis by 20° and of the same material (i.e., $\epsilon_r = 4.0$). The center of its top circle is located $x = 3.3\lambda_0$, $y = 4.9\lambda_0$, $z = -0.35\lambda_0$ and is buried alone under the rough ground (see Fig. 1e). Again, the results plotted in Fig. 6 show that some of the Mueller matrix elements show the indication to the presence of the disk. In particular, the elements m_{14} , m_{24} , m_{41} , m_{42} , m_{12} and m_{21} show considerable differences between the rough ground only and the rough ground with the buried disk. Consistent with the previous examples, the vv or hh intensities (i.e. m_{11} and m_{22}) show almost no differences between the two cases.

In Example 4, the Mueller elements for the spheroid and the horizontal cylinder, both buried under the ground (same data of Fig. 2), are computed at different incident angles $\theta^i = 30^\circ$, $\phi^i = 120^\circ$ as shown in Fig. 7. None of the elements in the current case show indication to the presence of the buried objects except for the elements m_{34} and m_{43} . In addition, all the elements in this case are significantly different from those presented in Fig. 2, which shows their dependency on the incident angles. In this Example, the far-fields are computed in the same plane of incidence, i.e., at $0^\circ \leq \theta^s \leq 90^\circ$ for $\phi^s = 120^\circ$ and for $\phi^s = 300^\circ$.

As mentioned earlier, in Examples 1-4, all the Mueller matrix elements represent the average values based on the Monte Carlo simulations of 100 rough surface realizations. This indicates that the observed sensitivity of some of these elements is consistent for all rough surface realizations since it survived the averaging process. To investigate this point, as an example, the

elements m_{42} and m_{14} are plotted for the scattered waves from only one rough surface realization as shown in Fig. 8. The numerical results show that these elements for the rough ground alone are different from all the other buried scatterers. This observation indicates that investigating all the Mueller matrix elements can be very useful in detecting the buried objects under the realistic rough ground represented here by one rough surface realization.

The above results support the observation reported in [5] in which the underground inhomogeneity was caused by the presence of the coated irregular layer above the rough ground while here the inhomogeneity is due to the presence of dielectric objects buried beneath the ground. As mentioned in [7], the modified Mueller matrix, in general, is not symmetric which is demonstrated in all figures. However, in all results it is observed that $m_{34} \approx -m_{43}$ which can be attributed to the slight cross-polarization caused by the small roughness parameters considered in this work. For the same reason it is observed that $m_{33} \approx m_{44}$ in all figures. However, in Figs. 2-6, it is observed, as expected, that $m_{11} \approx m_{22}$ (normal incidence case) while in Fig. 7 $m_{22} > m_{11}$ (oblique incidence case). In the later case, the incident electric field for the h -polarization is parallel to the axis of the buried cylinder while for the v -polarization, it is perpendicular to cylinder axis, see Fig. 1-b.

Notice that the elements $m_{12} \neq m_{21}$ because all the Mueller matrix elements presented here are for the bistatic case and not for the backscatter. Even though, it is more practical for remote sensing applications to consider the backscatter case, however, the bistatic results showed the considerable sensitivity of some Mueller matrix elements to the presence of buried objects. In addition, calculating the average of these elements in the backscatter direction will be computationally more expensive.

Examining the Mueller matrix expression in (3c), it is clear that several elements are functions of the amount of wave depolarization. This could be one of the factors that the Mueller elements for the tilted cylinder are the most distinguished ones as shown in the numerical results. The materials, locations of the buried scatterers and their contrast with the surrounding underground medium have impact on these elements as well. More work need to be conducted to investigate how the ground roughness will affect these elements since in this work we assumed small roughness parameters.

IV. CONCLUSIONS

The fast 3-D SDFMM computer code is used to calculate the average of each modified Mueller matrix element for the scattering from dielectric objects buried under the random rough ground. The statistical average for each element is computed using the Monte Carlo simulation. These simulations are obtained by running the 3-D SDFMM computer code hundreds of times, which shows the great advantage of using the Fast Multipole Method (FMM). The numerical results clearly show that if one relies only on the co- and/or the cross-polarized intensities; it is very difficult to sense the buried objects. However, investigating all the sixteen Mueller matrix elements significantly help in detecting these objects.

Appendix A

With representing the surface electric and magnetic currents \bar{J} and \bar{M} on S_1 , S_2 and S_3 by the vector \bar{X} , the integro-differential operators L_j and K_j , $j=1, 2, \dots, 6$, are [1], [3], [9]:

$$L_{1,2}\bar{X} = \int_{S_1} \left\{ i\omega\mu_{1,2}\Phi_{1,2}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{1,2}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{1,2} \right\} ds', \quad K_{1,2}\bar{X} = \int_{S_1} \bar{X}(\bar{r}') \times \nabla\Phi_{1,2} ds' \quad (\text{A1})$$

$$L_{3,5}\bar{X} = \int_{S_2} \left\{ i\omega\mu_{2,3}\Phi_{2,3}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{2,3}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{2,3} \right\} ds', \quad K_{3,5}\bar{X} = \int_{S_2} \bar{X}(\bar{r}') \times \nabla\Phi_{2,3} ds' \quad (\text{A2})$$

$$L_{4,6}\bar{X} = \int_{S_3} \left\{ i\omega\mu_{2,4}\Phi_{2,4}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{2,4}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{2,4} \right\} ds', \quad K_{4,6}\bar{X} = \int_{S_3} \bar{X}(\bar{r}') \times \nabla\Phi_{2,4} ds' \quad (\text{A3})$$

Appendix B

The linear system of equations, $\bar{\bar{Z}}\bar{I} = \bar{V}$, is given by [1], [3], [9]

$$\begin{pmatrix} \bar{Z}_{11} & \bar{Z}_{12} & \bar{Z}_{13} \\ \bar{Z}_{21} & \bar{Z}_{22} & \bar{Z}_{23} \\ \bar{Z}_{31} & \bar{Z}_{32} & \bar{Z}_{33} \end{pmatrix} \begin{pmatrix} I^1 \\ I^2 \\ I^3 \end{pmatrix} = \begin{pmatrix} \bar{V}_1 \\ 0 \\ 0 \end{pmatrix} \quad (\text{B1})$$

where the submatrix \bar{Z}_{11} is

$$\bar{Z}_{11} = \begin{pmatrix} \langle \bar{j}_1, (L_1 + L_2)\bar{j}_1 \rangle_{S_1} & \langle \bar{j}_1, -\eta_1(K_1 + K_2)\bar{j}_1 \rangle_{S_1} \\ \langle \bar{j}_1, \eta_1(K_1 + K_2)\bar{j}_1 \rangle_{S_1} & \left\langle \bar{j}_1, \eta_1^2 \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{j}_1 \right\rangle_{S_1} \end{pmatrix} \quad (\text{B2})$$

in which $\langle \bar{A}, \bar{B} \rangle_S$ denotes the complex inner product between vector functions \bar{A} and \bar{B} on a

surface S . The submatrices \bar{Z}_{12} , \bar{Z}_{13} , and \bar{Z}_{23} are given by

$$\bar{Z}_{12} = \begin{pmatrix} \langle \bar{j}_1, -L_3 \bar{j}_2 \rangle_{S_1} & \langle \bar{j}_1, \eta_1 K_3 \bar{j}_2 \rangle_{S_1} \\ \langle \bar{j}_1, -\eta_1 K_3 \bar{j}_2 \rangle_{S_1} & \left\langle \bar{j}_1, -\eta_1^2 \left(\frac{L_3}{\eta_2^2} \right) \bar{j}_2 \right\rangle_{S_1} \end{pmatrix}, \bar{Z}_{13} = \begin{pmatrix} \langle \bar{j}_1, -L_4 \bar{j}_3 \rangle_{S_1} & \langle \bar{j}_1, \eta_1 K_4 \bar{j}_3 \rangle_{S_1} \\ \langle \bar{j}_1, -\eta_1 K_4 \bar{j}_3 \rangle_{S_1} & \left\langle \bar{j}_1, -\eta_1^2 \left(\frac{L_4}{\eta_2^2} \right) \bar{j}_3 \right\rangle_{S_1} \end{pmatrix} \quad (B3)$$

$$\bar{Z}_{23} = \begin{pmatrix} \langle \bar{j}_2, L_4 \bar{j}_3 \rangle_{S_2} & \langle \bar{j}_2, -\eta_1 K_4 \bar{j}_3 \rangle_{S_2} \\ \langle \bar{j}_2, \eta_1 K_4 \bar{j}_3 \rangle_{S_2} & \left\langle \bar{j}_2, \eta_1^2 \frac{L_4}{\eta_2^2} \bar{j}_3 \right\rangle_{S_2} \end{pmatrix} \quad (B4)$$

Similar expressions can be obtained for all the other submatrices in B1.

Abstract

A rigorous electromagnetic model has been developed to analyze the scattering from two dielectric shallow objects buried under the 2-D random rough ground as a means of predicting false alarms due to a clutter object near a target object. The Method of Moments (MoM) accelerated by the Steepest Descent Fast Multipole Method (SDFMM) is used to compute the unknown electric and magnetic surface currents on both the rough ground surface and the two buried objects. The roughness parameters strongly influence the scattered interference of the two objects, especially when their separation distance is several correlation lengths. This could increase the probability of false alarms.

I. INTRODUCTION

In realistic minefields, buried anti-personnel (AP) nonmetallic mines are often closely accompanied by underground clutter-objects. The presence of this object considerably obscures the targets causing a false alarm during the detection process. The separation distance between the AP-mine and the clutter-object plays a primary role on the probability of false alarms. A rigorous electromagnetic model has been developed to analyze the scattering mechanism of two dielectric objects buried beneath a rough ground surface as reported in [1]. Using the $O(N)$ fast algorithm, the Steepest Descent Fast Multipole Method (SDFMM) [2-3] tremendously accelerates the computations of the N unknown surface currents [1,4]. When the two objects were located close to one another under flat ground, the strong scattering interference generates a false response appearing to be a third buried object [1]. The dependency of the observed scattering interference on the ground roughness parameters is investigated in this work.

II. FORMULATION

The rigorous electromagnetic model derived in [1] is employed in this work where six integral equations are used to obtain the equivalent surface currents on dielectric scatterers shown in Fig. 1 (3-D scattering problem). Four different regions are involved in this scattering problem; air, soil, first object and second object. The unknown electric and magnetic currents on the ground surface, on the target surface, and on the clutter object surface are approximated using the well-known RWG vector basis functions [5]. After some algebraic manipulations, the linear system of equations is obtained as: $\bar{\bar{Z}} \bar{I} = \bar{V}$, where the total impedance matrix $\bar{\bar{Z}}$ has order of $2(N_1 + N_2 + N_3) \times 2(N_1 + N_2 + N_3)$. The number of electric and magnetic current unknowns (edges) on the ground, on the target and on the second object are $2N_1$, $2N_2$ and $2N_3$, respectively. The tested tangential incident electric field \bar{E}^{inc} and the tested normalized magnetic field $\eta_1 \bar{H}^{inc}$ on the exterior of the ground surface are expressed in \bar{V} . The SDFMM is implemented to significantly accelerate solving the linear system of equations for the unknown current coefficients [1-4].

II. NUMERICAL RESULTS

In this Section, we investigate the scattering interference between the two buried objects as a function of their separation distances and the ground roughness. Several values for the root mean square height σ and the correlation length l_c are considered with emphasis on small roughness parameters for the AP-mine detection application. The incident wave is assumed to be a Gaussian beam at normal incidence that is carefully tapered to minimize edge effects [6]. The two objects are oblate spheroids with dimensions $a = 0.3\lambda_0$, $b = 0.15\lambda_0$ and at depth $z = -0.4\lambda_0$ measured from the center. The relative dielectric constant of the ground soil is assumed to be $\epsilon_r = 2.5 - j0.18$ and for both objects is assumed to be $\epsilon_r = 2.9 - j0.072$. The $8\lambda_0 \times 8\lambda_0$ ground surface is discretized into 60,000 electric and magnetic surface current unknowns. Each object is discretized into 600 electric and magnetic surface current unknowns. In order to analyze the object signatures, the electric fields scattered from each rough ground are removed by subtraction similar to our work in [4].

In Fig. 2, the object signatures are plotted across the diagonal as shown in Fig.1. When the two objects are separated by $S = 1.4\lambda_0$, the results show three peaks of almost equal magnitudes; the first peak is above the first object, the second peak is above the second object and the third peak is at mid-point between them. This third peak is due to the strong constructive interference between the two objects. This phenomenon could easily cause a false alarm during the detection process. However, when the separation distance increases, the mid-point peak is dissolved into several secondary peaks as observed when $S = 2.1\lambda_0$ and $2.8\lambda_0$. These secondary peaks become insignificant when S is increased to $4.2\lambda_0$. As noticed in this figure, the asymmetry around the mid-point ($x = 4.0\lambda_0$) is clearly caused by the random roughness of the ground. Moreover, the magnitudes of all peaks decrease with increasing separation distance because the objects are further from the beam footprint center (ground center in this work). In Figs. 3 and 4, the separation distance is $S = 1.4\lambda_0$, the range for σ is $0.04\lambda_0$ - $0.1\lambda_0$ and the range for l_c is $0.4\lambda_0$ - $1.0\lambda_0$. The results clearly show the influence of the roughness parameters, however, the observed strong interference (mid-point peak) is slightly affected by the ground roughness in this case. This study is repeated for $S = 2.1\lambda_0$ as shown in Figs. 5 and 6, and for $S = 2.8\lambda_0$ as shown in Figs. 7 and 8. It is interesting to notice that when the separation distance becomes several correlation lengths, as shown in Figs. 6 and 8, stronger scattered interference is observed. This is demonstrated by the increase in the number of secondary peaks from three in the flat ground case to four and five in the rough ground case as shown in Figs. 6 and 8, respectively. This mechanism could increase the possibility of false alarms.

III. CONCLUSIONS

False alarms could easily occur because of the interference mechanism between the target and a second nearby object buried under the ground. The roughness parameters strongly influence the scattering interference mechanism between the two objects, which could increase the probability of false alarms.

Abstract

In realistic landmine fields, the anti-personnel plastic mine is often buried nearby a clutter-object under the ground. The presence of a second object buried near the mine under a two-dimensional (2-D) rough ground can easily obscure the target and/or cause a false alarm. The separation distance between the AP mine and clutter-object plays a significant role on the probability of true or false alarm in this situation. A rigorous electromagnetic model has been developed to analyze the scattering mechanism between the target and the clutter-object, between the target and the rough ground, between the clutter-object and the rough ground and the multiple scattering between different spots on the rough ground itself. The new rigorous model is based on the classical electromagnetic equivalence theorem leading to producing six new integral equations. Using the Method of Moment (MoM), the new integral equations are transformed into a linear system of equations to be solved for the unknown electric and magnetic currents on the surface of three scatterers; (1) rough ground, (2) target and (3) clutter-object. The MoM impedance matrix completely represents every interaction between these three scatterers. The superior Steepest Descent Fast Multipole Method (SDFMM) is used to tremendously speed up the computations of the unknown MoM surface currents.

I. INTRODUCTION

In realistic minefields, buried anti-personnel (AP) nonmetallic mines are often closely accompanied by underground clutter-objects. The presence of this object considerably obscures the targets causing a false alarm during the detection process. The separation distance between the AP-mine and the clutter-object plays a primary role on the probability of false alarms. A rigorous electromagnetic model has been developed to analyze the scattering mechanism of two dielectric objects buried beneath a rough ground surface as reported in [1]. Using the $O(N)$ fast algorithm, the Steepest Descent Fast Multipole Method (SDFMM) [2-3] tremendously accelerates the computations of the N unknown surface currents [1,4]. When the two objects were located close to one another under flat ground, the strong scattering interference generates a false response appearing to be a third buried object [1]. The dependency of the observed scattering interference on the ground roughness parameters is investigated in this work.

II. FORMULATION

The rigorous electromagnetic model derived in [1] is employed in this work where six integral equations are used to obtain the equivalent surface currents on dielectric scatterers shown in Fig. 1 (3-D scattering problem). Four different regions are involved in this scattering problem; air, soil, first object

and second object. The unknown electric and magnetic currents on the ground surface, on the target surface, and on the clutter object surface are approximated using the well-known RWG vector basis functions [5]. After some algebraic manipulations, the linear system of equations is obtained as: $\bar{\bar{Z}} \bar{I} = \bar{V}$, where the total impedance matrix $\bar{\bar{Z}}$ has order of $2(N_1 + N_2 + N_3) \times 2(N_1 + N_2 + N_3)$. The number of electric and magnetic current unknowns (edges) on the ground, on the target and on the second object are $2N_1$, $2N_2$ and $2N_3$, respectively. The tested tangential incident electric field \bar{E}^{inc} and the tested normalized magnetic field $\eta_1 \bar{H}^{inc}$ on the exterior of the ground surface are expressed in \bar{V} . The SDFMM is implemented to significantly accelerate solving the linear system of equations for the unknown current coefficients [1-4].

III. NUMERICAL RESULTS

In this Section, we investigate the scattering interference between the two buried objects as a function of their separation distances and the ground roughness. Several values for the root mean square height σ and the correlation length l_c are considered with emphasis on small roughness parameters for the AP-mine detection application. The incident wave is assumed to be a Gaussian beam at normal incidence that is carefully tapered to minimize edge effects [6]. The two objects are oblate spheroids with dimensions $a = 0.3\lambda_0$, $b = 0.15\lambda_0$ and at depth $z = -0.4\lambda_0$ measured from the center. The relative dielectric constant of the ground soil is assumed to be $\epsilon_r = 2.5 - j0.18$ and for both objects is assumed to be $\epsilon_r = 2.9 - j0.072$. The $8\lambda_0 \times 8\lambda_0$ ground surface is discretized into 60,000 electric and magnetic surface current unknowns. Each object is discretized into 600 electric and magnetic surface current unknowns. In order to analyze the object signatures, the electric fields scattered from each rough ground are removed by subtraction similar to our work in [4].

In Fig. 2, the object signatures are plotted across the diagonal as shown in Fig.1. When the two objects are separated by $S = 1.4\lambda_0$, the results show three peaks of almost equal magnitudes; the first peak is above the first object, the second peak is above the second object and the third peak is at mid-point between them. This third peak is due to the strong constructive interference between the two objects. This phenomenon could easily cause a false alarm during the detection process. ABSTRACT

This paper analyzes various ground-contact microwave antenna designs for land mine detection. Designs include monopole probes with differing tip lengths, and small loop probes. Factors affecting the performance of the antenna include position of the antenna in the soil, angle of insertion into the ground, type of soil (loam, sand, etc.), and the moisture of the soil. It is important to find an antenna whose frequency response varies minimally with depth. Using a metal rod and a deactivated plastic mine as targets, a soil tank, and a network analyzer to observe the coupling of the antenna to the soil and to the target, we experimentally show that for the best antenna tested — a 2 cm tip monopole probe — both targets could be unambiguously detected and discriminated.

INTRODUCTION

Although there are many technologically advanced means of detecting mines in the field, the problem is far from being solved. It is important to consider detector cost, practicality, and adaptability to currently used systems. While a scientifically sophisticated sensor might be able to perfectly image a buried mine shape anomaly or detect the presence of high explosive, these systems often require laboratory-like background conditions, lengthy acquisition times, or a large truck full of support equipment. To address the current high-priority need for improving the effectiveness of current mine detection equipment, this study examines a relatively simple adaptation of the confirmatory probe.

The vast majority of handheld mine detection is performed by first alarming at the presence of buried metal with a electromagnetic induction sensor, and then poking the ground in the vicinity of the suspected target with a narrow nonmetallic probe. This is tedious, dangerous, and often frustrating work, with the most likely outcome being finding nothing: no mine, no metal, not even a rock. Speeding up this probing process by lowering the false alarm rate, and reducing the danger by providing advanced warning would be of great advantage to the person sweeping the field.

The mine detection problem is even more difficult when the target is nonmetallic. Although an EMI metal detector can often detect the small metal mass in firing pins and striker plates and cups in plastic mines, its sensitivity must be increased so much that any scrap bit of metal would register an alarm. In addition, plastic mines share similar dielectric characteristics to soil, thus making it harder to locate with ground penetrating radar [1, 2].

With rough ground surfaces, the random clutter intensity caused by the ground reflection is often greater than the scattering by the nonmetallic target [3, 4]. One advantage of a probe-mounted ground penetrating antenna is that the interrogating signal starts under the ground surface. The clutter from the random rough ground surface still has a measurable effect, but since the reflection is from below the surface, it is much less than for conventional ground penetrating radar.

When designing antennas for this purpose, many factors need to be taken into consideration. The antenna radiation pattern in soil is important. If the antenna generates a symmetrical field pattern, it can be inserted into the ground at any orientation relative to the target. The best frequency range that is both relatively independent of antenna depth in soil and most sensitive to foreign objects must be determined. And it goes without saying that the antenna should be able to pierce the soil with minimal probability of disturbing the land mine.

This experimental study considered two types of antennas which could be easily incorporated into a soil probe: a monopole, constructed by simply removing the outer conductor of a semi-rigid coaxial cable; and a small loop, constructed by bending the extended coaxial center conductor into a loop and joining it with the outer conductor.

Figure 1: Monopole and loop antennas suitable for ground penetrating probes

By analyzing the reflected signal (S_{11}) from these antennas with a network analyzer it is possible to determine some of the characteristics of the surrounding medium. Measurements were made in the frequency range of 0.5 GHz to 8 GHz to observe any wideband resonance effects and ensure that there was adequate sensitivity to short distances from the probe to the target.

LOOP ANTENNA DESIGN

Constructing a 5 mm loop antenna requires stripping approximately 1.5 cm of the copped outer conductor from a semi-rigid cable, and bending the inner wire around into a loop and soldering it to the remaining outer copper conductor. This exposed loop can be modeled as a small magnetic dipole, couple microwave power primarily though the magnetic field passing through the loop.

Figure 2: Measured S_{11} as a function of loop antenna depth.

Our results showed that the loop coupled well with the soil, especially from 6.5 GHz to 8 GHz. Its depth independence within this frequency range is excellent, as shown in Figure 2, with almost no variation in S_{11} for 1.5 to 3 inch loop burial depth. However, the sensitivity of the loop to other objects in the soil was poor, as indicated in Fig. 3. It is difficult to distinguish the differences caused by nearby targets.

Figure 3: Measured S_{11} of loop antenna near buried targets.

MONOPOLE PROBE ANTENNA DESIGN

The nearfield pattern created by the simple monopole probe of Figure 1 is as uniform as possible, which is advantageous since it allows the observer to place the antenna at almost any orientation in the ground and expect similar results. The only design consideration with this type of probe antenna is the amount of outer copper conductor stripped off. The plastic coating on the inner wire was kept to increase durability for our testing. Probes with different tip lengths were tested (1 cm to 3 cm).

The various length monopole probe antenna were tested for its frequency dependent electromagnetic coupling to the surrounding soil medium, and its dependence with depth of insertion and the extent of perturbation in the presence of nearby buried plastic and metal targets. An ideal antenna will transmit the all power supplied to it across a range of frequencies no matter the depth of the soil in which it is buried. The 2 cm tip probe gave the best results. Figures 4 and 5 show its depth-independent coupling in moist clay soil.

Figure 4: Measured S_{11} of 2 cm tip monopole antenna at 60 degrees insertion angle for a variety of burial depths

Figure 5: Detail of Figure 4.

Measurements were conducted for both the normal inserted probe, and the more realistic case of 60° insertion angle. We found better results for the latter, with best discrimination of targets in the 7.5 GHz to 8 GHz a range. The 2 cm tip monopole could differentiate between no target, a thin metal rod, and a plastic antipersonnel mine in close proximity for both 2.0 cm (Figure 5) and 2.5 cm (Figure 6). insertion depths in both moist soil and dry sand (Figure 7).

Figure 5: Measured S_{11} of 2 cm tip monopole antenna at 60 degrees insertion angle at 2.0 cm below surface near mine targets in moist clay soil

Figure 6: Measured S_{11} of 2 cm tip monopole antenna at 60 degrees insertion angle at 2.5 cm below surface near mine targets in moist clay soil

Figure 7: Measured S_{11} of 2 cm tip monopole antenna at 60 degrees insertion angle at 2.0 cm below surface near mine targets in dry sand

CONCLUSIONS

Depth independent soil coupling across a wide frequency range with a simple symmetric field pattern are important characteristics of a good probe-based ground penetrating antenna. We examined several types of small antennas that could be readily incorporated into existing mine confirmation probes, and found that the simple monopole antenna satisfied these requirements. The 2 cm monopole probe was best able to couple to common soils yet detect impedance differences of small buried nearby plastic and metal objects. Using a monopole antenna to sense the impedance variations in soil has the potential of aiding the mine detection process by alarming before actually contacting the object.

Modeling Radar Detection of Floating Sea Mines

Carey Rappaport
Northeastern University
Boston, MA 02115
rappaport@neu.edu

Abstract

To detect and classify mines floating in seawater using radar, it is essential to understand and quantify the electromagnetic scattering by the target immersed in its realistic cluttered background. While the metallic surface of the mine presents a strong scattering target, the water surrounding it will strongly scatter incident waves as well. In addition, seawater is electromagnetically lossy, readily absorbing incident waves. While deeply submerged mines are undetectable, a floating mine might be partially exposed, scattering waves that could be distinguished from those scattered by the background. The degree to which the target scattered waves can be discriminated from the waves scattered by the random water surface height variations determines whether the mine can be detected in realistic situations.

Computational modeling shows that even when a mine is mostly submerged, the scattered fields are still quite characteristic of a large metallic scatterer. Close inspection shows that the scattered waves are scattered most strongly in the vertical direction. This study shows that only a small amount of the target need be exposed to generate significant scattered field that is distinguishable from a very rough water surface.

Introduction

To determine the expected scattering features of the mine in its actual environment, a full phenomenological study of the target in a variety of backgrounds must be conducted. While it might be possible to experimentally measure a portion of the fields scattered by a scale model mine in a test tank, it would be extremely challenging to capture the entire wave behavior throughout all space near the target without perturbing the field one is measuring with measurement antennas. In addition, controlling the state of the water surface is problematic. Thus, the only practical way to capture the scattered field is to model it numerically.

Current electromagnetic computational capabilities allow for sophisticated modeling of wave scattering on desktop computers. The most applicable modeling method for this problem for standard radar sources is the finite difference frequency domain (FDFD) method. For impulse radars, the time domain version, FDTD is best. Both the FDFD and FDTD methods discretize all space in the vicinity of the target, and approximate the differential form of Maxwell's equations with second-order finite differences of nearest neighbors. Both methods are flexible, with easy specification of rough surfaces, corners, and fins, and both can model metal, conductive dielectrics, and frequency-dependent material.

One important detail, which must be carefully addressed for exterior, unbounded geometries, is simulating the wave's radiation to infinity. Although the computational domain terminates at the end of the array lattice, the wave must act as if it were continuing outward. In other words, the wave must not reflect off the artificial boundary. The boundary must absorb all incident waves; hence it is referred to as an Absorbing Boundary Condition (ABC). In principle, no numerical condition can absorb waves from every incident angle, but there have been several ABC's proposed which absorb those near normal incidence making use lossy matched layers and pseudo-differential annihilation operators.

The FDFD method requires the solution of the set of simultaneous equations that self-consistently describe the electric and/or magnetic fields everywhere in space for a given frequency [1, 2]. As such, the resulting matrix equation involves a very large, very sparse square matrix. Depending on the ABC, as few as a dozen entries in any given row of a 2-D or 3-D FDFD matrix are non-zero. The ABC used in this analysis is the perfectly matched layer (PML) of Berenger [3-6]

Prototypical Problem Geometry

As an example of the 2-D modeled fields near a typical spherical sea mine in rough seas is shown in Fig. 1. This geometry considers a mine floating substantially out of the water. The water surface varies with Gaussian height and correlation length statistics, which might be typical of ocean waves. The various identified regions represent those perturbations to a nominal air/water half-space that give rise to the non-ideal scattered waves. The nominal plane wave scattering from a smooth, target-free problem geometry is determined analytically, and can be added to the perturbation-scattered field to give the total field.

Figure 1 Problem geometry, showing various modeled regions: air (top, orange), nominal water (bottom, green), water peaks (middle right, yellow), water troughs (middle left, salmon), mine below nominal water level (bottom middle, blue), mine above nominal water level (center, red).

Computed Results

The total field for 300 MHz normally incident plane wave excitation (as generated by an airborne radar pointing straight down) for the target geometry of Fig. 1, is shown in Fig. 2. Note the recognizable outline of the circular metallic target, the almost complete exclusion of field from the water, and the change in standing wave structure around the mine. Also note the left/right asymmetry of field due to the differences of the surface heights on the left and right sides of the problem space.

Figure 2 Total electric field at 300 MHz, for horizontally polarized E-field (into plane of figure), for geometry of Figure 1.

Figure 3 shows the scattered field only; e.g., fields of Fig. 2 less the analytic plane wave scattering of the planar water half-space. From a radar detection perspective, it is the field of Fig. 3 that would be measured once the nominal signal is removed. The waves scattered by the mine are significantly greater than those of the rough water surface. It appears clear that this target could be picked out of the background clutter with radar.

Figure 3 Electric field at 300 MHz due to just the mine and the surface roughness, for horizontally polarized E-field (into plane of figure), for geometry of Figure 1.

Figures 4 and 5 show the total and scattered fields for the same problem geometry at the higher frequency of 500 MHz. Clearly the wave structure is more complicated, with additional nodal structure in the horizontal direction. While the target resolving capability of the radar increases with frequency, the clutter effects increase as well. Choosing the best frequency, or set of frequencies to detect a particular mine target in the presence of a given water surface roughness is an important part of this study.

Figure 4 Total electric field at 500 MHz, for horizontally polarized E-field (into plane of figure), for geometry of Figure 1.

Figure 5 Electric field at 500 MHz due to just the mine and the surface roughness, for horizontally polarized E-field (into plane of figure), for geometry of Figure 1.

To consider a slightly different geometry, we test a deeper mine target, as shown in Figure 6. The water surface is chosen to be the same for comparison purposes. The total and scattered fields for this deeper geometry are shown in Figures 7 and 8. Although this mine is mostly submerged, the scattered fields are still quite characteristic of the large metallic scatterer. Close inspection shows that the scattered waves are scattered most strongly in the vertical direction, as opposed to the more widely scattered waves of the greatly protruding mine of Fig 5. This example shows that even at the higher frequency, only a small amount of the target need be exposed to generate significant scattered field that is distinguishable from a very rough water surface. Using multiple frequencies greatly enhances the potential for target discrimination [7].

Figure 8 Electric field at 500 MHz due to just the mine and the surface roughness, for horizontally polarized E-field (into plane of figure), for geometry of Figure 6.

Conclusions

Although seawater is relatively impenetrable to RF waves, and causes strong reflections from its random rough surface, computational modeling has shown that it is still possible to detect the stronger and more organized scattering from the top of a floating sea mine. By considering additional information of multiple views of the same metal target with a moving water surface, it is possible to distinguish the target from the background. The scattered wave features of the circular metal target appear to be relatively independent of depth, and thus provide a detectable invariant in the highly cluttered background. There appears to be great potential in the use of radar to find floating sea mines.

Abstract

A rigorous electromagnetic model has been developed to analyze the scattering from two dielectric shallow objects buried under the 2-D random rough ground as a means of predicting false alarms due to a clutter object near a target object. The Method of Moments (MoM) accelerated by the Steepest Descent Fast Multipole Method (SDFMM) is used to compute the unknown electric and magnetic surface currents on both the rough ground surface and the two buried objects. The roughness parameters strongly influence the scattered interference of the two objects, especially when their separation distance is several correlation lengths. This could increase the probability of false alarms.

I. INTRODUCTION

In realistic minefields, buried anti-personnel (AP) nonmetallic mines are often closely accompanied by underground clutter-objects. The presence of this object considerably obscures the targets causing a false alarm during the detection process. The separation distance between the AP-mine and the clutter-object plays a primary role on the probability of false alarms. A rigorous electromagnetic model has been developed to analyze the scattering mechanism of two dielectric objects buried beneath a rough ground surface as reported in [1]. Using the $O(N)$ fast

algorithm, the Steepest Descent Fast Multipole Method (SDFMM) [2-3] tremendously accelerates the computations of the N unknown surface currents [1,4]. When the two objects were located close to one another under flat ground, the strong scattering interference generates a false response appearing to be a third buried object [1]. The dependency of the observed scattering interference on the ground roughness parameters is investigated in this work.

II. FORMULATION

The rigorous electromagnetic model derived in [1] is employed in this work where six integral equations are used to obtain the equivalent surface currents on dielectric scatterers shown in Fig. 1 (3-D scattering problem). Four different regions are involved in this scattering problem; air, soil, first object and second object. The unknown electric and magnetic currents on the ground surface, on the target surface, and on the clutter object surface are approximated using the well-known RWG vector basis functions [5]. After some algebraic manipulations, the linear system of equations is obtained as: $\bar{\bar{Z}} \bar{I} = \bar{V}$, where the total impedance matrix $\bar{\bar{Z}}$ has order $2(N_1 + N_2 + N_3) \times 2(N_1 + N_2 + N_3)$. The number of electric and magnetic current unknowns (edges) on the ground, on the target and on the second object are $2N_1$, $2N_2$ and $2N_3$, respectively. The tested tangential incident electric field \bar{E}^{inc} and the tested normalized magnetic field $\mathbf{h}_1 \bar{H}^{inc}$ on the exterior of the ground surface are expressed in \bar{V} . The SDFMM is implemented to significantly accelerate solving the linear system of equations for the unknown current coefficients [1-4].

II. NUMERICAL RESULTS

In this Section, we investigate the scattering interference between the two buried objects as a function of their separation distances and the ground roughness. Several values for the root mean square height σ and the correlation length l_c are considered with emphasis on small roughness

parameters for the AP-mine detection application. The incident wave is assumed to be a Gaussian beam at normal incidence that is carefully tapered to minimize edge effects [6]. The two objects are oblate spheroids with dimensions $a = 0.3\lambda_0$, $b = 0.15\lambda_0$ and at depth $z = -0.4I_o$ measured from their centers. The relative dielectric constant of the ground soil is assumed to be $\epsilon_r = 2.5 - j0.18$ and for both objects is assumed to be $\epsilon_r = 2.9 - j0.072$. The $8I_o \times 8I_o$ ground surface is discretized into 60,000 electric and magnetic surface current unknowns. Each object is discretized into 600 electric and magnetic surface current unknowns. In order to analyze the object signatures, the electric fields scattered from each rough ground are removed by subtraction similar to our work in [4].

In Fig. 2, the object signatures are plotted across the diagonal as shown in Fig.1. When the two objects are separated by $S = 1.4\lambda_0$, the results show three peaks of almost equal magnitudes; the first peak is above the first object, the second peak is above the second object and the third peak is at mid-point between them. This third peak is due to the strong constructive interference between the two objects. This phenomenon could easily cause a false alarm during the detection process. However, when the separation distance increases, the mid-point peak is dissolved into several secondary peaks as observed when $S = 2.1\lambda_0$ and $2.8\lambda_0$. These secondary peaks become insignificant when S is increased to $4.2\lambda_0$. As noticed in this figure, the asymmetry around the mid-point ($x = 4.0\lambda_0$) is clearly caused by the random roughness of the ground. Moreover, the magnitudes of all peaks decrease with increasing separation distance because the objects are further from the beam footprint center (ground center in this work). In Fig. 3, the separation distance is $S = 1.4\lambda_0$, σ is $0.1\lambda_0$ and the range for l_c is $0.4\lambda_0 - 1.0\lambda_0$. The results clearly show the influence of the roughness parameters, however, the observed strong interference (mid-point peak) is slightly affected by the ground roughness in this case. Similar results were obtained

upon varying σ from $0.04\lambda_0$ to $0.1\lambda_0$ with $l_c=0.5\lambda_0$. This study is repeated for $S = 2.1\lambda_0$ as shown in Fig. 4 and for $S = 2.8\lambda_0$ as shown in Figs. 5 and 6. It is interesting to notice that when the separation distance becomes several correlation lengths, as shown in Figs. 4 and 6, stronger scattered interference is observed. This is demonstrated by the increase in the number of secondary peaks from three in the flat ground case to four and five in the rough ground case as shown in Figs. 4 and 6, respectively. This mechanism could increase the possibility of false alarms.

III. CONCLUSIONS

False alarms could easily occur because of the interference mechanism between the target and a second nearby object buried under the ground. The roughness parameters strongly influence the scattering interference mechanism of the two objects, which could increase the probability of false alarms.

Statistical Method to Detect Subsurface Objects Using Array Ground Penetrating Radar Data

Xiaoyin Xu, Eric L. Miller, Carey M. Rappaport and Gary D. Sower

Abstract

We introduce a combination of high-dimensional analysis of variance (HANOVA) and sequential probability ratio test (SPRT) to detect buried objects from an array ground penetrating radar (GPR) surveying a region of interest in a progressive manner. Using HANOVA, we exploit the transient characteristic of GPR signals in the time domain to extract information about buried objects at fixed positions of the array. Based on the output of the HANOVA, the SPRT is employed to make detection decisions recursively as the array moves downtrack. The method is on-line implementable and of low computational complexity. Our approach is validated using field-data from a landmine detection application.

I. INTRODUCTION

Ground penetrating radar (GPR) is widely used in detecting subsurface objects such as buried landmines, unexploded ordnance, and utility lines [1]. Compared with other subsurface sensing technologies, GPR has a few advantages. First, it is sensitive to changes in all three electromagnetic characteristics of a media, electric permittivity, electric conductivity, and magnetic permeability. Thus GPR is capable of detecting both metallic and non-metallic

X. Xu, E. L. Miller, and C. M. Rappaport are with the Center for Subsurface Sensing and Imaging Systems, Department of Electrical and Computer Engineering, Northeastern University, Boston, MA 02115, USA. G. D. Sower is with the EG&G MSI Inc., 2450 Alamo Ave. S.E., Albuquerque, NM 87106. This work was supported by an ARO MURI on Demining under Grant DAAG55-97-1-0013

objects. Second, unlike sensors that can only survey an area directly beneath them, GPR can survey an area in front of it [2, 3]. Therefore a GPR system can be used to detect dangerous objects before the system moves over and past them. This can be important for operations such as buried landmine detection and unexploded ordnance remediation.

A typical GPR transmitter/receiver configuration is shown in Fig. 1(a). The system consists of one transmitter and one receiver. The transmitter emits a short pulse of electromagnetic energy and the receiver collects the echo for a certain time period. The exact type of the transmitter and receiver, shape of the electromagnetic pulse, and system setup depend on the specific application of the GPR [1, 4–6]. To improve performance and efficiency, a GPR array is usually employed to sweep a large area in a relatively short time. Fig. 1(b) shows a typical GPR array moving in the x -direction. At every stop of the array, the GPR array operates in the following sequence: 1) the first transmitter radiates a pulse into the ground and then turns off, 2) the first receiver turns on to collect reflected signal, 3) the first receiver turns off after a short time, usually 10 to 20 ns. The above process repeats from every pair of transmitters and receivers and then the GPR array moves to next position. Based on the echoes, the processing objective is to determine if an object is present in the GPR's field of view.

The inherent near-field nature of the GPR detection problem coupled with the fact that the objects of interest are embedded in an inhomogeneous halfspace with a typically rough interface present some significant challenges in the area of GPR signal processing. Indeed assuming one has detailed knowledge of the air-earth interface as well as the electrical properties of the subsurface, just modeling the received signal using, for example, a three dimensional finite difference time domain code, is a daunting task [4, 7]. The use of such a forward model in any form of on-line processing routine where one might need to account

Fig. 1. Setup, a) a single GPR system, b) a GPR array (plane view).

for e.g. unknown ground structure is clearly infeasible at the current time.

Thus, here we consider detection methods which are less computationally demanding with an eye toward approaches that could be used in real-world scenarios. Our interests are in techniques possessing three important characteristics. First, to reflect the manner in which GPR data are acquired and the nature of the GPR mission, the algorithms should be causal in that they need only the data at the current and previous sensor position to determine whether an object is present in the field of view of the sensor. Second, they should be of low complexity. Preferably the number of calculations would grow linearly with the size of the data set. Finally, the processing schemes should be robust to uncertainties in the GPR environment and hence the particular detailed structure of the received signals.

Current signal processing methods with some or all of these characteristics fall into one of three categories. First, pattern matching methods [8] employ techniques such as fuzzy set theory and neural networks. Such methods can be fast but also require extensive training to function well. Second, image-then-detect techniques [9] employ a beamforming or backpropagation approach to build an image of the subsurface which is then post-processed to detect objects. These approaches generally require the data from the full GPR scan to

form an image and are thus not well suited to on-line computations in which information is processed sequentially as the array proceeds down-track. Finally, there has been much work done in statistical signal processing, where one can employ statistical tools to detect objects and examine quantities such as probability of detection and probability of false-alarm [10].

Here we consider a statistical, transient detection approach. By “transient” we mean that the signals of interest are manifest in the GPR data for a small number of sensor positions and for relatively few samples in any received waveform. For example, in Fig. 2 we plot raw observations obtained by one T/R pair from an EG&G GPR system [11], over an M20 metal mine. Each column of this image is a time-series of observations for a given stop of the array. It is seen that the received GPR signal is transient in two ways. First, for each time-series (i.e. for each column of the image) containing an object signal, the signal appears only in a brief window, roughly from samples 300 to 700. The reason is that the object signal always comes after the signal arising from the bounce off of the air-ground interface and attenuates quickly in lossy media. Second, the object signal shows up only at a few down-track positions of the GPR array, specifically locations 15 through 25. In both cases, the appearance of object signal changes the mean value of the data. Our method for object detection then is based on detecting change in this mean first in the cross-track direction and then in the down-track direction.

More specifically our approach consists of two parts. First, at each down-track position of the array, we process the data among all T/R pairs to generate one test statistic. We use high-dimensional analysis of variance (HANOVA) to test whether the data consists of reflected signal from a buried object. The HANOVA is a generalized version of standard analysis of variance (ANOVA), which is a method for testing hypothesis about means of random vectors [12, 13]. Second, a sequential probability ratio test (SPRT) is applied to

Fig. 2. Observation from one T/R pair, for a metal mine M20 buried at about position 20. Unit in down-track position is about 7.6 cm. Unit in time axes is 0.02 ns.

process the statistic of the HANOVA as the array moves down-track. The SPRT is a recursive statistical hypothesis testing technique that provides early indication of the onset of changes in a time series. The output of the SPRT is compared with a threshold. If it exceeds the threshold, a detection is declared, otherwise, the GPR array moves one more step down-track and new data are collected and processed in the above manner [14].

As explained in greater detail below, our approach does in fact satisfy the three requirements we discussed previously. It is causal and has computational complexity that grows linearly with the size of the data. Moreover, we show through real-data examples that it is robust, requiring little in the way of training and able to successfully address the object detection problem for a number of GPR systems operating in a wide range of environments. We do stress here that the algorithm in this paper is intended *only* to find anomalies beneath the GPR array and *not* to solve the far more challenging classification problem. Thus, from a practical perspective our approach will serve well as an efficient “pre-screener” in a larger automatic target detection algorithm suite. Finally, our method is motivated by landmine detection using GPR, however it can also be used in other detection application, such as laser-induced acoustic subsurface objects detection [15].

The paper is organized as follows. Section II discusses the problem formulation and our

method. Section III gives some examples of using the method in different situations. Field data from different radar configurations and test sites are used to show how the algorithm works. Conclusion and direction of future work are given in Section IV.

II. PROBLEM FORMULATION AND ALGORITHM

To begin, we consider a single GPR T/R pairs as shown in Fig. 1(a). After each transmission, the receiver collects an echo for a certain amount of time. Depending on the presence of an object, there are either two or three components in the echo. One is measurement noise, assumed to be white and Gaussian. Another is background, i.e., “nominal” signal observed in object-free regions. The third component is object signal, reflection from a buried object.

For the GPR array shown in Fig. 1(b), assume we have M GPR Transmitter/Receiver (T/R) pairs surveying an area in N steps, the task is to use present and previous array measurement to detect buried mines as the array moves down-track. At each down-track position, we model the array detection problem in a typical hypotheses testing framework [14],

$$H_0 : \quad \text{there is no object,}$$

$$H_1 : \quad \text{there is an object.}$$

The null hypothesis H_0 means that there is no buried object in the field of view of the GPR array, so the total received signal is comprised of nominal background and measurement noise. By nominal background, we mean any portion of the received waveform not sensor noise and not arising from the interaction of the transmitted pulse with the object. Reflection from the air-ground interface is the dominant component of this part of the signal. The alternative hypothesis H_1 indicates that there is buried object so that the received signal consists of nominal background, measurement noise, and an object signal.

In this paper we assume that the nominal background signal has been removed via a

preprocessing stage. The most used background removal methods include casual methods, such as subtraction of a moving average from the observation [16], and non-causal methods, such as subtraction of an ensemble average from the observation [17, 18]. Causal methods use data from previous and present collection, non-causal methods use data from previous and future collection. In this paper, a moving average (MA) filter is used to eliminate the nominal background.

In practice, the receiver collects time-samples of the reflection and stores it as a vector. For convenience, we use vector notation in our discussion, i.e., $\mathbf{y}(m, n)$ is a column vector representing observation of the m th T/R pair at the n th down-track position. The length of $\mathbf{y}(m, n)$ is K , the number of samples in time. Fig. 3 shows the received signal after the nominal background removal.¹ We then have the hypothesis test

$$\begin{aligned} H_0 : \quad \mathbf{y}(m, n) &= \mathbf{v} \\ H_1 : \quad \mathbf{y}(m, n) &= \mathbf{s}(m, n) + \mathbf{v} \end{aligned} \tag{1}$$

where $m = 1, \dots, M$, $n = 1, \dots, N$ are positions of GPR, $\mathbf{s}(m, n)$ is the assumed signal due to presence of buried object, \mathbf{v} is assumed to be a white Gaussian noise with a zero mean, and covariance matrix $\sigma_v^2 \mathbf{I}$, where \mathbf{I} is the identity matrix of size K and independent of (m, n) .

The statistical assumptions about \mathbf{v} are not strictly accurate in describing the noise in a GPR signal. For example the background removal process will not be perfect leaving a component of correlated “clutter” in the data which may or may not possess Gaussian statistics. Despite the mismatch, the use of the additive white Gaussian noise model is useful for a number of reasons. This model allows us to develop an algorithm for object

¹ For the purpose of illustration, in this section we use field data from a buried metal mine to illustrate clearly the concept under consideration. Examples which demonstrate better the utility of our approach on more challenging problems, including buried plastic mines, are given in Section III.

Fig. 3. Signals from four T/R pairs, after background removal, a) pair 1, b) pair 2, c) pair 3, d) pair 4. Unit in time axes is 0.02 ns.

detection which is firmly rooted in Gaussian-based statistical decision theory and which can be generalized in the future for more complex noise processes. Moreover, the complexity of such algorithms is quite low making them well suited for real-world implementation. Finally, test results in Section III from real field data demonstrate that the method is quite effective in detecting objects. Thus, the Gaussian noise model is shown to work in practice. While it may be interesting to explore other, more accurate models for the sensor noise to determine for example what can be gained in terms of performance and what would be lost in terms of computational complexity, such an effort is beyond the scope of the work in this paper.

Based on the previous discussion, after background removal the hypothesis test in (1) may be written as

$$\begin{aligned} H_0 : \quad & \mathbf{y}(m, n) \sim N(\mathbf{0}, \sigma_v^2 \mathbf{I}) \\ H_1 : \quad & \mathbf{y}(m, n) \sim N(\mathbf{s}(m, n), \sigma_v^2 \mathbf{I}), \quad m = 1, \dots, M, \quad n = 1, \dots, N \end{aligned} \quad (2)$$

where the notation $\mathbf{y} \sim N(\bar{\mathbf{x}}, \mathbf{R})$ indicates that \mathbf{y} is distributed as a Gaussian random vector with mean $\bar{\mathbf{x}}$ and covariance matrix \mathbf{R} .

As stated in the Introduction, we take a two-step approach to the processing of $\mathbf{y}(m, n)$. First for each n we use the HANOVA procedure to generate a single test statistic, $Y(n)$, from the data from all T/R pairs. Second, a recursive, sequential detection scheme is employed to process $Y(n)$ as we proceed down track in order to determine where objects are present.

A. Cross-track Processing

We begin by discussing the use of HANOVA to process data in the cross-track direction. HANOVA is a generalized version of analysis of variance (ANOVA). ANOVA is a body of methods to analyze the data with a view to test hypotheses about the effects of one or more factors [19]. To review the basics of ANOVA, we follow the notation established above for the GPR problem and for simplicity assume we have one data vector of size $K \times 1$ from a single T/R pair, $\mathbf{y} \sim N(\mathbf{s}, \sigma^2 \mathbf{I})$ and we wish to test $H_0 : \mathbf{s} = \mathbf{0}$ (i.e., no object) vs. $H_1 : \mathbf{s} \neq \mathbf{0}$ (i.e., an object present)². Standard ANOVA is essentially an “energy detection” scheme [12] where we estimate \mathbf{s} by \mathbf{y} , generate the test statistic $Y = \|\mathbf{y}\|^2$, and compare Y to a threshold, γ . If Y exceeds the threshold, H_1 is chosen, else H_0 is selected. The probability of detection of the standard ANOVA is

$$P_d(H_1|H_1) = Q\left(\frac{\gamma - \frac{\|\mathbf{s}\|^2}{\sigma^2 \sqrt{2K}}}{\sqrt{1 + \frac{2\|\mathbf{s}\|^2}{\sigma^2 K}}}\right) \quad (3)$$

² For notational simplicity, we drop the explicit dependence of all quantities on m and n in this discussion

where γ is the test threshold decided by setting an acceptable probability of false-alarm under H_0 and Q is the complementary cumulative distribution function and is strictly decreasing [20]

$$Q(Y) = \int_{\gamma}^{\infty} P_1(Y) dY. \quad (4)$$

Recently, Fan [12] and Fan and Lin [13], have noted that the performance of ANOVA suffers for problems when the signal of interest is limited to a window of the observation vector. The reason is that a full dimensional test loses its power due to accumulation of stochastic noise. To see why, suppose \mathbf{s} is different from $\mathbf{0}$ only for say the first k_0 samples of the full observation vector. Then on average as $K > k_0$ goes large, $\sum_{k=1}^K [\mathbf{s}]_k^2 / \sigma^2 \sqrt{2K}$ decreases due to the accumulation of zero mean noise samples and the term within the parenthesis of (3) increases, thus reducing P_d . Therefore, for higher probability of detection, we would like to confine the test on a window mostly containing the signal of the observation vector. The window we choose is a box window \mathbf{w} , defined as

$$[\mathbf{w}]_k = \begin{cases} 1, & k = k_1, \dots, k_2 \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

where $1 \leq k_1 < k_2 \leq K$. The k_1 and k_2 are chosen in a preset manner, as discussed later in this section. Multiplying each element in \mathbf{y} by the corresponding element of \mathbf{w} gives the windowed \mathbf{y}_w

$$[\mathbf{y}_w]_k = [\mathbf{y}]_k \times [\mathbf{w}]_k, \quad k = 1, \dots, K. \quad (6)$$

To demonstrate the utility of HANOVA, we test the time-series shown in Fig. 4(a). We choose to test the vector at its full dimension k_1 in (5) is 1 and $k_2 = 1000$, and two windowed sub-dimensions (each containing fewer and fewer noise components) $k_1 = 100$ and $k_2 = 900$,

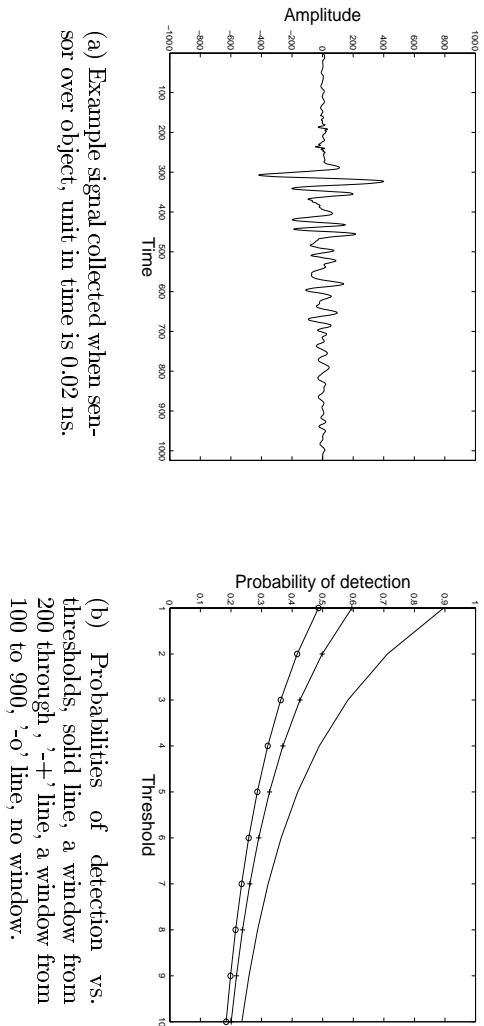

Fig. 4. Motivating example for use of HANOVA rather than ANOVA. (a) displays sample data collected by a GPR when over an object. The transient nature of the relevant portion of the signal is clear. Using this signal, in (b) we display the decreasing detection rates associated with including increasing numbers of “noise” samples in the processing.

and $k_1 = 200$ and $k_2 = 800$. From Fig. 4(b), it is seen that by setting the window properly, higher probability of detection is gained at different levels of detection thresholds, γ in (3). It demonstrates that when signal is not “full-dimensional”, looking for a window of signal-rich sub-dimensions to test will increase the probability of detection.

When the observation is a sequence of high-dimensional vectors whose components are mostly noise, as is the case for our GPR problem, it is desirable to adaptively choose the window to maximize the probability of detection. This kind of method of reducing a full dimensional test to a windowed version is called HANOVA [13]. Fan’s original work was limited to problems in which the first k_0 dimensions are believed to be signal-rich and used in HANOVA, with k_0 found from the data. Here we consider a generalization of Fan’s work to take into account the fact that for the GPR problem the transient signal is significant over a window not generally starting with the first dimension but in the middle of the observation vector. Moreover, this window will vary with (m, n) .

To choose this window we note that (3) indicates that the probability of detection achieves its maximum value when the term inside the parenthesis is minimized. Equally, one wants to maximize the quantity

$$\arg \max_{k_1, k_2} \frac{\sum_{k=k_1}^{k_2} [\mathbf{s}(m, n)]_k^2}{\sigma_v^2 \sqrt{k_2 - k_1 + 1}} - \sqrt{k_2 - k_1 + 1} \quad (7)$$

where $k_1 < k_2$ and $k_1, k_2 \in 1, \dots, K$. The difficulty for us is that in general, the precise structure of \mathbf{s} is not known. Hence, we use the data to form an estimate of \mathbf{s} as follows. Assume we are at the n th stop, then we estimate \mathbf{s} by the mean value of the previous l vectors

$$\hat{\mathbf{y}}(m, n) = \begin{cases} \frac{\sum_{j=1}^n \mathbf{y}(m, j)}{j}, & n = 1, \dots, l \\ \frac{\sum_{j=n-l}^n \mathbf{y}(m, j)}{l}, & n > l \end{cases} \quad (8)$$

where $m = 1, \dots, M$ and the corresponding window $\mathbf{w}(m, n)$ is decided based on $\hat{\mathbf{y}}(m, n)$ as k_1, k_2 are defined by (7). More will be said about choosing a proper l in Appendix A.

Rather than looking for the optimal window by searching over all k_1 - k_2 pairs, we pursue a suboptimal, but more efficient two-stage approach. First, we fix k_1 as 1, incrementally increase k_2 , and stop when (7) is maximized. Thus we determine the end point of the window k_2 . Starting from k_2 , working backward toward the first point, we similarly determine the starting point of the window, k_1 . Both searching steps can be computed in linear complexity, it takes $o(K)$ steps to find the k_2 and $o(k_2)$ steps to find the k_1 ³. In summary the steps for looking for windows at the n th stop of the GPR array are given in Fig. 5.

Having determined the window at the position (m, n) , the next stage of processing is to generate a single detection statistic at stop n . Here we generalize HANOVA to multiple vector observations, via

$$Y(n) = \frac{1}{\sigma_v^2} \sum_{m=1}^M \|\mathbf{y}_w(m, n)\|^2. \quad (10)$$

³ The notation $o(K)$ means that the computational complexity grows slower than or equally fast as K increases.

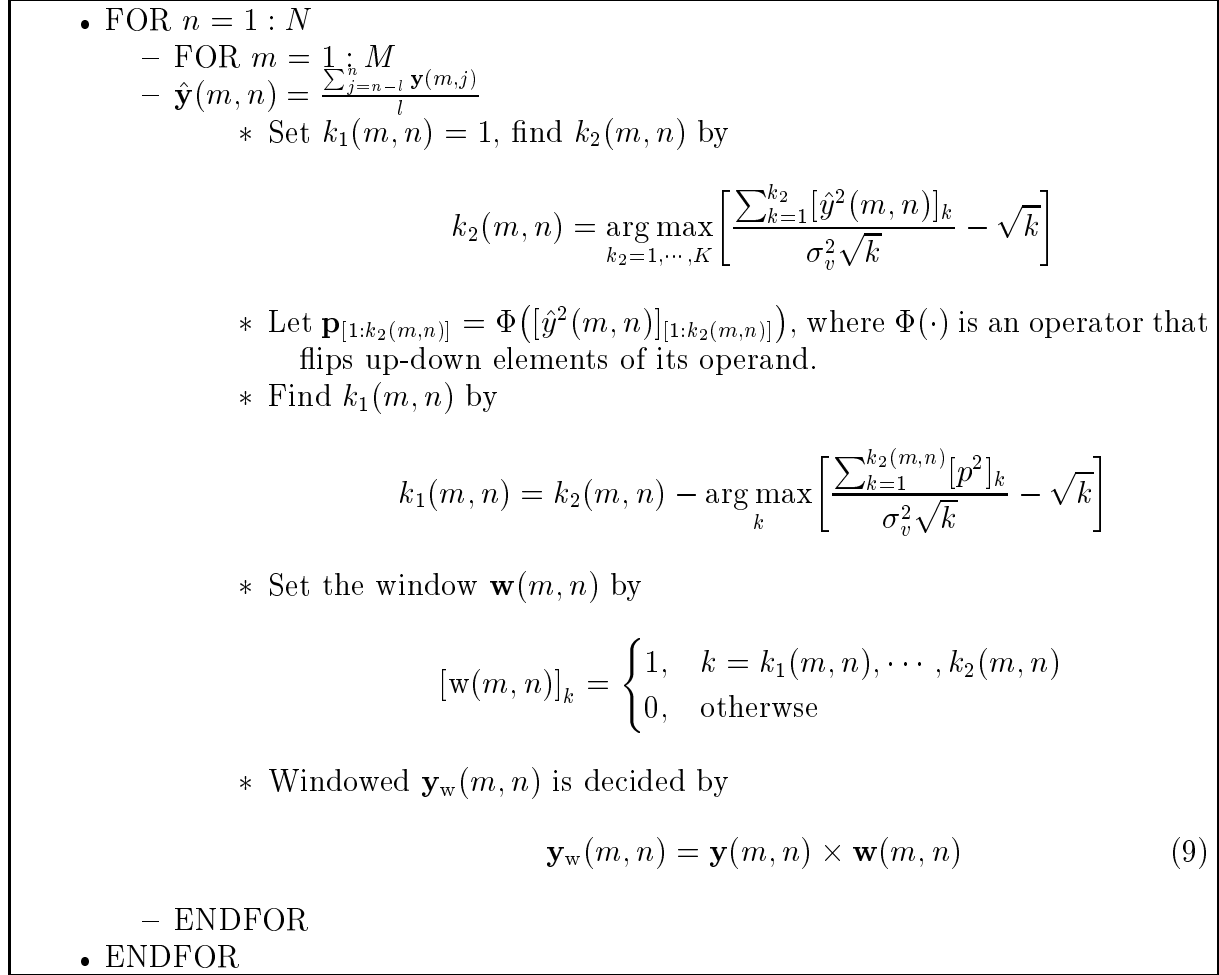

Fig. 5. Steps of deciding window $\mathbf{w}(m, n)$ and $\mathbf{y}_w(m, n)$.

Note $\mathbf{y}_w(m, n)$ can be of different length because of different window applied. Fig. 6(a) shows the result of applying HANOVA to the data in Figure 3. Where the HANOVA output is high, so too is the likelihood of an object being present. Thus in Fig. 6(a), the object is clearly detectable. More examples involving different types of objects will be given in Section III.

B. Down-track Processing

While HANOVA detects statistical significance at one stop of the array, it does not capture the object signal structure seen as the array moves down-track. To improve detection performance, we employ a sequential detection scheme to process $Y(n)$ recursively as n

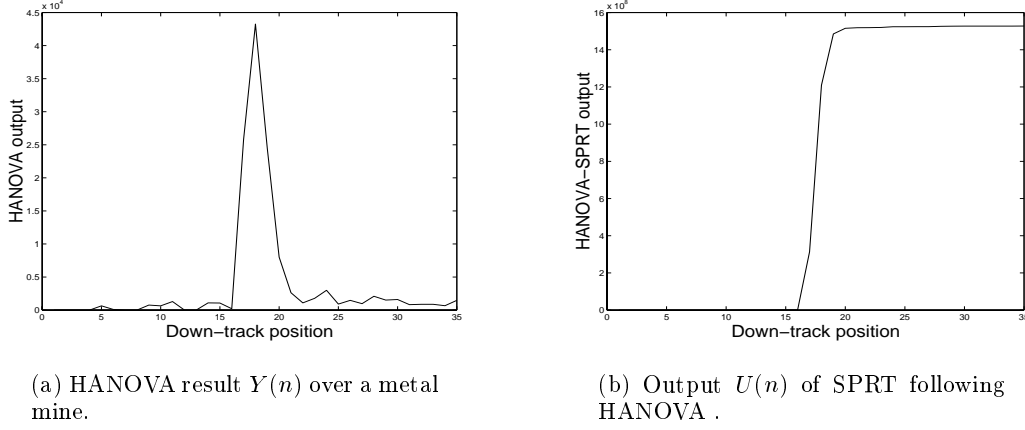

Fig. 6. HANOVA and SPRT processing results for metal mine data shown in Fig. 3

increases in order to identify the transient signal arising from the mine [14,21]. Specification of this sequential probability ratio test (SPRT) begins by noting that under our models $Y(n)$ takes on a χ^2 distribution under both H_0 and H_1 . Standard statistical analysis [12] yields

$$\begin{aligned}
 H_0 : \quad Y(n) &\sim \chi^2_{\sum_{m=1}^M \Delta k(m,n)}(0) \\
 H_1 : \quad Y(n) &\sim \chi^2_{\sum_{m=1}^M \Delta k(m,n)}(\delta^2(n))
 \end{aligned} \tag{11}$$

for $n = 1, \dots, N$ where the notation $x \sim \chi_p^2(\delta^2)$ indicates that the random variable x is distributed according to a χ^2 law of order p and non-centrality parameter δ^2 [20] and $\Delta k(m, n) = k_2(m, n) - k_1(m, n)$ is the length of the (n, m) th window. For the GPR problem it is easy to show that

$$\delta^2(n) = \frac{1}{\sigma_v^2} \sum_{m=1}^M \|\mathbf{s}(m, n) \times \mathbf{w}(m, n)\|^2. \tag{12}$$

For our problem, the length of each window, $\Delta k(m, n)$, is large (on the order of hundreds) and the central limit theorem permits us to approximate the χ^2 distribution using a Gaussian

distribution [20]. We then have

$$\begin{aligned} H_0 : Y(n) &\sim N(\mu_0, \sigma_0^2) \equiv N\left(\sum_{m=1}^M \Delta k(m, n), 2 \sum_{m=1}^M \Delta k(m, n)\right) \\ H_1 : Y(n) &\sim N(\mu_1(n), \sigma_1^2(n)) \equiv N\left(\sum_{m=1}^M \Delta k(m, n) + \delta^2(n), 2 \sum_{m=1}^M \Delta k(m, n) + 4\delta^2(n)\right). \end{aligned} \quad (13)$$

At stop n , the log likelihood ratio for the hypothesis testing problem in (13) is

$$u(n) = \ln \frac{p_n(Y(n))}{p_0(Y(n))}, \quad n = 1, \dots, N \quad (14)$$

where $p_n(Y(n))$ is the PDF of $Y(n)$ evaluated at the n th stop under H_1 and $p_0(Y(n))$ is the PDF of $Y(n)$ evaluated under H_0 . Under H_0 , μ_0 and σ_0^2 are estimated using data from an object-free area. Therefore, for this algorithm, the GPR array must start by collecting data in a calibration region to initialize these variables. Under H_1 , one difficulty with generating $u(n)$ is that $\mu_1(n)$ and $\sigma_1^2(n)$ are typically not known *a priori* since the underlying $\mathbf{s}(m, n)$ are not assumed known. It turns out that we only need to estimate $\mu_1(n)$, and $\sigma_1^2(n)$ can be found from the following relation

$$\begin{aligned} \sigma_1^2(n) &= 2 \sum_{m=1}^M \Delta k(m, n) + 4\delta^2(n) \\ &= 2 \sum_{m=1}^M \Delta k(m, n) + 4 \left[\mu_1(n) - \sum_{m=1}^M \Delta k(m, n) \right] \\ &= 4\mu_1(n) - 2 \sum_{m=1}^M \Delta k(m, n). \end{aligned} \quad (15)$$

At the n th stop, we estimate the mean of $Y(n)$ by its maximum likelihood estimator $\mu_1(n) = Y(n)$.

The *sequential probability ratio test* statistic $U(n)$ is a cumulative sum, changing with the acquisition of each new $u(n)$

$$U(n) = \max(0, U(n-1) + u(n)). \quad (16)$$

- $U(1) = 0$
- FOR $n = 2, \dots, N$
 - $\mu_1(n) = Y(n)$
 - Form $\sigma_1^2(n)$ according to (15)
 - Form $u(n)$ according to (14)
 - $U(n) = \max(0, U(n-1) + u(n))$
 - IF $U(n) > \alpha$, declare object, set $U(n) = 0$, ENDIF
- ENDFOR

Fig. 7. Sequential processing.

Because subsurface object detection is a binary hypothesis testing problem, e.g., we are only interested in knowing whether there is a buried object, the SPRT statistic is bounded from lower bound, zero. When $U(n-1) + u(n)$ is negative, $U(n)$ is reset to zero. For a preset threshold α , the SPRT will make one of two decisions at each n

$$U(n) \geq \alpha \Rightarrow \text{choose } H_1$$

$$U(n) < \alpha \Rightarrow \text{take another observation.}$$

The sequential detection is then essentially a repeated SPRT [22] and summarized in Fig. 7. Fig. 6(b) shows the sequential test statistic when the SPRT is applied to the data in Fig. 6(a). Because the SPRT in (16) has the form of a modified “integrator,” a typical time series for the SPRT statistic takes a step-like form. The larger and sharper the step, the more likely it is that a target is present. At the position where there is an object, the sequential test statistics has a clear upward change again indicating the existence of an object at about position 16.

III. EXAMPLES

In this section we use field data as examples to illustrate the performance of our method. The field data are collected by both single GPR and GPR arrays at different test sites. For each data set, we compare the results from using standard ANOVA, HANOVA, ANOVA

followed by SPRT, and HANOVA followed by SPRT. Comparison indicates that generally HANOVA performs better than ANOVA, and with SPRT, both ANOVA and HANOVA make fewer false-alarms. In other words, HANOVA with SPRT gives the best receiver-operating characteristics, as we shall see later in this section.

At first, we apply our method on data collected by single GPR at different test sites. Some data are taken under relatively favorable condition, while most are from more hostile test sites which involve rough ground surface and other clutter. Fig. 8 compares results of ANOVA and HANOVA on a buried steel object at position 50. For comparison, the outputs of ANOVA and HANOVA are normalized to one. It is observable that while both methods detect the object easily, the HANOVA is better in suppressing noise output where there is no object, e.g., at position 1 through 40 and 60 through 100, Fig. 8(c) and (d). Fig. 9 shows the results from detecting a plastic mine, M19, at position 50. Again, the HANOVA performs better in suppressing noise. At positions 20 through 40, the HANOVA creates a much lower noise level than the ANOVA does. Similarly, the HANOVA produces a cleaner output at the end of the run.

Fig. 10 shows the results of ANOVA and HANOVA in detecting an anti-tank mine, TM62, from a very “noisy” data set. The mine is buried at position 60. Outputs of both HANOVA and ANOVA consist of the correct detection and some false alarms. The HANOVA maintains a better performance than the ANOVA in the sense that, for a given detection threshold, the HANOVA would generally have a smaller number of false-alarms. For the HANOVA, no false alarms will be declared for a threshold greater than 0.5, while for the ANOVA, the threshold must be set above 0.8 to avoid making a wrong decision. Between threshold 0.5 and 0.8, the ANOVA will make two false-alarms while the HANOVA has zero false-alarm.

Fig. 8. Results of a single GPR measurement above a steel object around position 50, a) raw observation, b) observation after nominal background removal, c) ANOVA output, d) HANOVA output. In a) and b), each unit in time axes is 0.02 ns.

Next, by comparing the outputs of the SPRT in the above three examples, we see that sequential processing generally smoothes the output and generates fewer false-alarms than by using ANOVA (or HANOVA) only, Fig. 11. In all three examples, SPRT following HANOVA performs better than SPRT following ANOVA, in the sense that the output is more leveled off at object-free area and the jump at the position of the buried object is sharper.

To study the receiver operating characteristic (ROC) of the method, we test our method on multiple runs of different type of targets. Fig. 12(a) shows the ROC curves of ANOVA and HANOVA to detect metallic objects. The objects include metallic mines such as TM15,

Fig. 9. Comparison between the ANOVA and HANOVA, a) raw data over an M19, anti-tank mine, buried at position 50, b) demeaned data, c) result of the ANOVA over the M19, d) result of the HANOVA.

TM46, and PMN. Fig. 12(b) shows the ROC of ANOVA-SPRT and HANOVA-SPRT. Compared with Fig. 12(a), SPRT improves the performance of both ANOVA and HANOVA. In generating these curves a correct identification of any of the objects was taken to be a “detection” whether or not the object itself was a mine. Indeed, as noted in the Introduction, the algorithm in this paper is intended *only* to detect the presence of objects below the array and not to solve the classification problem. Still, given the “real-world” conditions under which the data were taken, the low false alarm rates here point to the robustness of our approach.

Next, we compare the performance of ANOVA, HANOVA, ANOVA-SPRT, and HANOVA-
April 29, 2001—3 : 44 pm DRAFT

Fig. 10. More comparison between the ANOVA and HANOVA, a) raw data over a TM62, anti-tank mine, buried to the side of the track at position 58, b) demeaned data, c) result of the ANOVA, d) result of the HANOVA.

SPRT in detecting plastic mines. The mines are M19, VS-1.6, T72, and C4A1. Fig. 13 shows the ROC curves of the above four methods. It is seen that both the ANOVA-SPRT and HANOVA-SPRT perform better than the ANOVA and HANOVA, respectively.

As another example, we test our method on a different array radar system at another test site. The setup of the GPR array is shown in Fig. 14. There is one transmitter in this system. In front of the transmitter, four receivers are positioned in a 2×2 pattern. Above the transmitter and the receivers there is a hyperbolic reflection plate, it is set so that the transmitter is at the focal point of the reflection plate. The array moves on a linear track

to collect data. At each step, the transmitter sends a spherical wave to the reflection plate and after reflection, the sphere wave becomes plane wave. The four receivers then collect reflection of this plane wave from the ground. The system has the advantage of generating plane wave and points it forward to reduce ground reflection. Fig. 15 displays collected data from the two front receivers at the Dedham test site of Northeastern University and the corresponding signal after background removal. In an area of 58 m², there are 12 buried landmines of different types, such as M19, PMN, VS-2.2, and so on. Using our method we are able to detect all 12 mines with a few false-alarms, Fig. 16. The results are similar to those obtained by a single GPR. For a detection rate above 90%, the HANOVA has a significantly smaller number of false-alarm.

IV. SUMMARY

In this paper, we have proposed a sequential, high-dimensional ANOVA to process GPR returns. The method is tested on real data and has a relaxed requirement on the physical model used in the processing routine. The method is on-line implementable and has a linear computational load. The method works in two stages: first it looks for statistically significant difference from array observations, second, it applies a sequential detection as new data are obtained. HANOVA is powerful in the sense of maximizing probability of detecting statistically significant difference among sub-dimensions of a full vector of observations. Sequential detection recursively processes the result of the HANOVA and enables real-time processing as new data are collected. We have demonstrated the performance of this technique on samples of field data.

Future research will focus on classification and localization. Classification consists of two steps. First, a feature extraction scheme is applied on reflected signals to generate intermediate result, second, the output from feature extraction is fed into a Bayesian classifier

to make the classification. Localization is based on optimized frequency-wavenumber (F-K) migration. F-K migration is an inversion method that back-propagates wavefield from the ground surface to subsurface and construct an image of subsurface reflectivity. Regular F-K migration is well modeled for seismic signal processing. Though GPR signal is different from seismic signal, F-K migration can still work very well in processing GPR signals. Nonetheless, improvement in terms of resolution and accuracy can be achieved by considering optimization in F-K migration. In our future work, an optimization method will be used to improve the F-K migration.

APPENDIX

I. WINDOW SELECTION IN HANOVA

Ideally, we want to find a window that is sensitive to the presence of a signal and provides little response in the test statistic when there is noise only. But these two requirements are often in conflict with each other. From (8), we can change the order l of the MA process to control the window we use. The smaller is l , the more sensitive the window is to the presence of signal and strong noise. On the other hand, the larger is l , the more robust will the statistic be to noise, which translates into a smaller probability of false-alarm. But a large l reduces sensitivity of the HANOVA to signal. Fig. 17 shows the effect of l on window selection and the corresponding HANOVA results. Three different l are used, i.e., $l = 1, 4, 9$. In the data, there are three mine objects, two metal mines at the position 110 and 170. A weak mine object is at position 25. For comparison, we normalize the HANOVA outputs in each case by its maximum value, which corresponds to the strong metal mine buried at position 110. Fig. 17(a) and (b) show the window chosen by a MA of order 1 and the resulting HANOVA output. The two strong objects can be detected at a threshold of 0.7, the weak object can only be found at a threshold of 0.2. Fig. 17(c) shows the window

chosen by a MA of order 4. The window oscillates much less than the window in Fig. 17(a). From the HANOVA result, Fig. 17(d), we can find all the three objects at a threshold of 0.3. Increasing the order of MA process can make the results worse, Fig. 17(e) and (f). A large window reduces the sensitivity of the HANOVA to signal and actually makes detection more difficult. Now the weak object at position 25 can not be detected at a threshold greater than 0.3. As a guideline, we find that MA processes of order between 3 and 10 yield good windows both in sensitivity to signal and robustness to noise. This selection is affected by the step-size of the array. An array moving at small step-size will allow an MA process of large l in selecting windows, and vice versa.

Fig. 11. Results of the SPRT, a buried steel object, a) output of ANOVA-SPRT, b) output of HANOVA-SPRT; a buried M19, c) output of ANOVA-SPRT, d) output of HANOVA-SPRT; a buried TM62, e) output of ANOVA-SPRT, f) output of HANOVA-SPRT.

Fig. 12. Rate of detection and rate of false-alarms in detecting metallic objects, solid line is the result of HANOVA, dashed line is the result of ANOVA, a) ANOVA vs. HANOVA, b) ANOVA-SPRT vs. HANOVA-SPRT.

Fig. 13. Rate of detection and rate of false-alarms in detecting plastic mines, solid line is the result of HANOVA, dashed line is the result of ANOVA, a) ANOVA vs. HANOVA, b) ANOVA-SPRT vs. HANOVA-SPRT.

Fig. 14. GPR array used at Dedham test site of Northeastern University, a) plane view, b) side view.

Fig. 15. GPR data from the Dedham test site, (a) from the left front receiver, (b) from the right front receiver, (c) signal (a) after background removal, (d) signal of (b) after background removal. Unit in time axes is 120 ps.

Fig. 16. ROCs of the Dedham test, solid line, HANOVA-SPRT, dash line, ANOVA-SPRT.

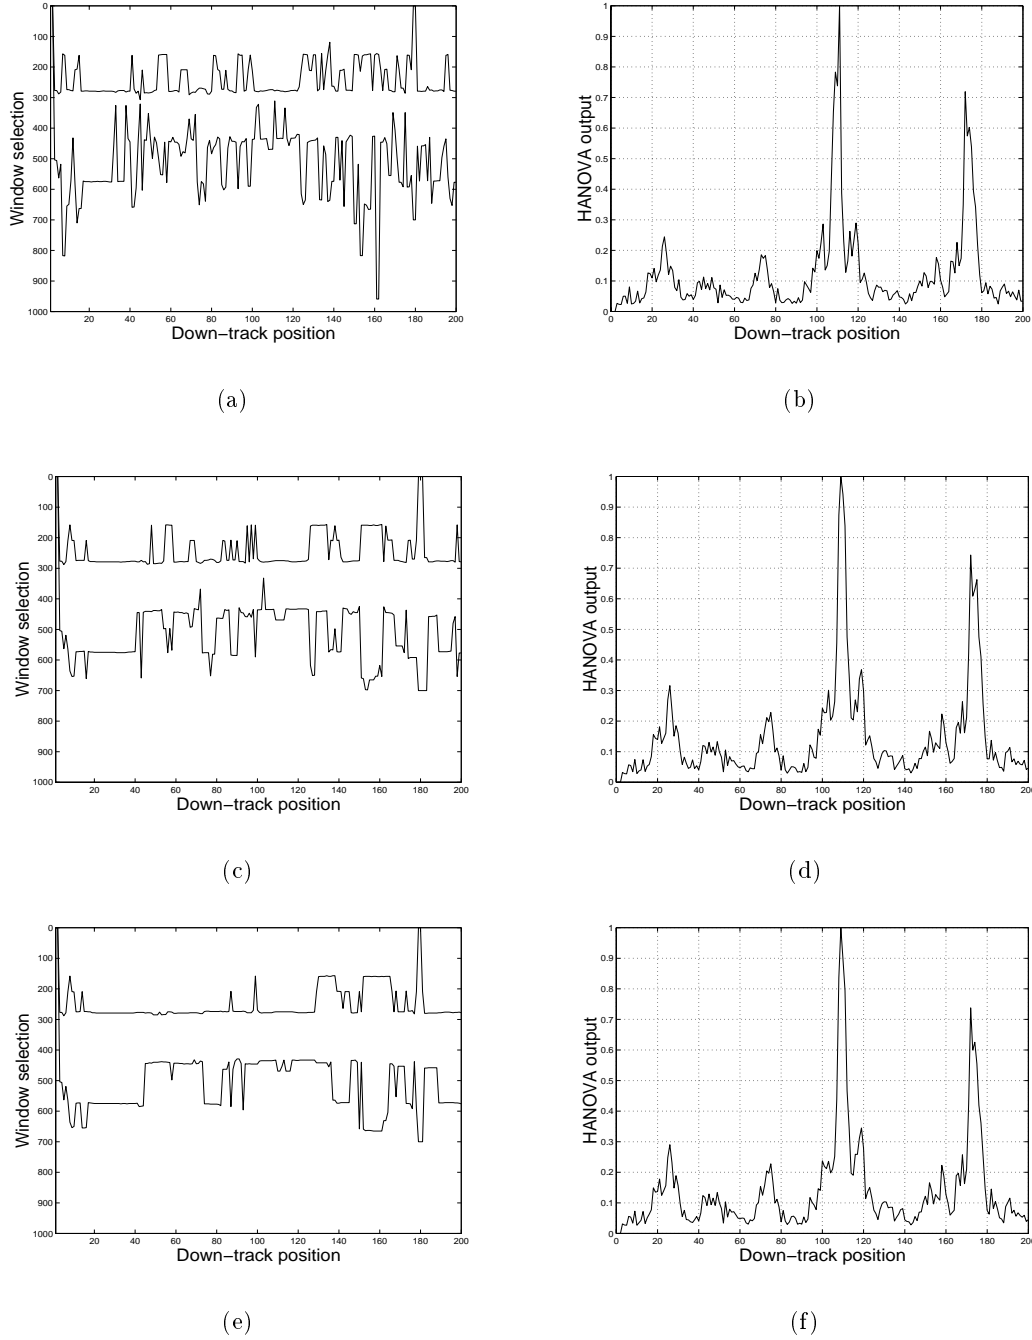

Fig. 17. Choices of window and effect on HANOVA, lower line is $k_1(m, n)$, upper line is $k_2(m, n)$, a) window selected by an order 1 MA process, b) HANOVA result from the window to the left, c) window selected by an order 4 MA process, d) HANOVA result from the window to the left, e) window selected by an order 10 MA process, f) HANOVA test result from the window to the left.
